Although neurohumoral processes define a few immediate effects of ventilation on the heart, these neurohumoral processes probably play a primary role in all the long-term effects of ventilation on the cardiovascular system. Most of the immediate effects of ventilation of the heart are secondary to changes in autonomic tone. The lungs are richly enervated with somatic and autonomic fibers that originate, traverse through, and end in the thorax. These networks mediate multiple homeostatic processes through the autonomic nervous system altering instantaneous cardiovascular function. The most commonly known of these are the vagally mediated heart rate changes during ventilation.[4,5] Inflation of the lung to normal tidal volumes (<10 mL/kg) induces vagal-tone withdrawal, accelerating heart rate. This phenomenon is known as respiratory sinus arrhythmia[6] and can be used to document normal autonomic control,[7] especially in patients with diabetes who are at risk for peripheral neuropathy.[8] Inflation to larger tidal volumes (>15 mL/kg), however, decreases heart rate by a combination of both increased vagal tone[9] and sympathetic withdrawal. Sympathetic withdrawal also creates arterial vasodilation.[4,10–14] This inflation–vasodilation response can reduce LV contractility in healthy volunteers[15] and in ventilator-dependent patients with the initiation of high-frequency ventilation[4] or hyperinflation.[12] This inflation–vasodilation response is presumed to be the cause of the initial hypotension seen when infants are placed on mechanical ventilation. It appears to be mediated at least partially by afferent vagal fibers, because it is abolished by selective vagotomy. Hexamethonium, guanethidine, and bretylium, however, also block this reflex.[16,17] These data suggest that lung inflation mediates its reflex cardiovascular effects by modulating central autonomic tone. Interestingly, the almost total lack of measurable hemodynamic effects of unilateral hyperinflation in subjects with normal lungs receiving split-lung ventilation[18] suggests that these autonomic cardiovascular effects require a general increase in lung volume to be realized. This is not a minor point because selective hyperinflation within lung units commonly occurs in patients with acute lung injury (ALI) and chronic obstructive pulmonary disease (COPD). If localized hyperinflation were able to induce cardiovascular impairment, these subjects would be profoundly compromised.

Humoral factors, including compounds blocked by cyclooxygenase inhibition,[19] released from pulmonary endothelial cells during lung inflation may also induce this depressor response[20–22] within a short (15 seconds) time frame. These interactions, however, do not appear to grossly alter cardiovascular status.[23] Ventilation also alters the more chronic control of intravascular fluid balance via hormonal release. The right atrium functions as the body's effective circulating blood-volume

sensor. Circulating levels of a family of natriuretic peptides increase in heart failure states secondary to right-atrial stretch.[24] These hormones promote sodium and water diuresis. The levels of these hormones vary directly with the degree of heart failure. Both positive-pressure ventilation and sustained hyperinflation decrease right-atrial stretch mimicking hypovolemia. During positive-pressure ventilation, plasma norepinephrine and renin increase,[25,26] whereas atrial natriuretic peptide decreases.[27] This humoral response is the primary reason why ventilator-dependent patients gain weight early in the course of respiratory failure, because protein catabolism is also usually seen. Interestingly, when patients with congestive heart failure (CHF) are given nasal continuous positive airway pressure (CPAP), plasma atrial natriuretic peptide activity decreases in parallel with improvements in blood flow.[28,29] This finding suggests that some of the observed benefit of CPAP therapy in heart failure is mediated in part through humoral mechanisms, owing to the mechanical effects of CPAP on cardiac function.

PULMONARY VASCULAR RESISTANCE

Changing lung volume alters pulmonary vascular resistance.[3] Marked increases in pulmonary vascular resistance, as may occur with hyperinflation, can induce acute cor pulmonale and cardiovascular collapse. The reasons for these changes are multifactorial. They can reflect conflicting cardiovascular processes and almost always reflect both humoral and mechanical interactions.

Lung volume can only increase if its distending pressure increases. Lung-distending pressure, called the *transpulmonary pressure*, equals the pressure difference between alveolar pressure (Palv) and ITP. If lung volume does not change, then transpulmonary pressure does not change. Thus, occluded inspiratory efforts (Mueller maneuver) and expiratory efforts (Valsalva maneuver) cause ITP to vary by an amount equal to Palv, but do not change pulmonary vascular resistance. Although obstructive inspiratory efforts, as occur during obstructive sleep apnea, are usually associated with increased RV afterload, the increased afterload is caused primarily by either increased vasomotor tone (hypoxic pulmonary vasoconstriction) or backward LV failure.[30,31]

RV afterload is maximal RV systolic wall stress.[32,33] By law of Laplace, wall stress equals the product of the radius of curvature of a structure and its transmural pressure. Systolic RV pressure equals transmural pulmonary artery pressure. Increases in transmural pulmonary artery pressure increases RV afterload, impeding RV ejection,[34] decreasing RV stroke volume,[35] inducing RV dilation, and passively causing venous return to decrease.[19,21] If such acute increases in transmural pulmonary artery pressure are not reduced, or if RV contractility is not increased by artificial means, then acute cor pulmonale rapidly develops.[36] If RV dilation and RV pressure overload persist, RV free-wall ischemia and infarction can develop.[37] These concepts are of profound clinical relevance because rapid fluid challenges in the setting of acute cor pulmonale can precipitate profound cardiovascular collapse secondary to excessive RV dilation, RV ischemia, and compromised LV filling. Ventilation can alter pulmonary vascular resistance by either altering pulmonary vasomotor tone, via a process known as *hypoxic pulmonary vasoconstriction*, or mechanically altering vessel cross-sectional area, by changing transpulmonary pressure.

Hypoxic Pulmonary Vasoconstriction. Unlike systemic vessels that dilate under hypoxic conditions, the pulmonary vasculature constricts. Once alveolar partial pressure of oxygen decreases below 60 mm Hg, or acidemia develops, pulmonary vasomotor tone increases.[38] Hypoxic pulmonary vasoconstriction is mediated, in part, by variations in the synthesis and release of nitric oxide by endothelial nitric oxide synthase localized on pulmonary vascular endothelial cells, and in part by changes in intracellular calcium fluxes in the pulmonary vascular smooth muscle cells. The pulmonary endothelium normally synthesizes a low basal amount of nitric oxide, keeping the pulmonary vasculature actively vasodilated. Loss of nitric oxide allows the smooth muscle to return to its normal resting vasomotor tone. Nitric oxide synthesis is dependent on adequate amounts of O_2 and is inhibited by both hypoxia and acidosis. Presumably, hypoxic pulmonary vasoconstriction developed to minimize ventilation–perfusion mismatches caused by local alveolar hypoventilation. Generalized alveolar hypoxia, however, increases global pulmonary vasomotor tone, impeding RV ejection.[32] At low lung volumes, terminal bronchioles collapse, trapping gas in the terminal alveoli. With continued blood flow, these alveoli lose their O_2 and also may collapse. Patients with acute hypoxemic respiratory failure have small lung volumes and are prone to both alveolar hypoxia and spontaneous alveolar collapse.[39,40] This is one of the main reasons why pulmonary vascular resistance is increased in patients with acute hypoxemic respiratory failure.

Based on the above considerations, mechanical ventilation may reduce pulmonary vasomotor tone by a variety of mechanisms. First, hypoxic pulmonary vasoconstriction can be inhibited if the patient is ventilated with gas enriched with O_2 increasing alveolar partial pressure of oxygen.[41–44] Second, mechanical breaths and positive end-expiratory pressure (PEEP) can refresh hypoventilated lung units and recruit collapsed alveolar units, causing local increases in alveolar partial pressure of oxygen,[3,45–47] especially if small lung volumes are returned to resting functional residual capacity (FRC) from an initial smaller lung volume.[48] Third, mechanical ventilation often reverses respiratory acidosis by increasing alveolar ventilation.[44] Fourth, decreasing central sympathetic output, by sedation or decreased stress of breathing against high-input impedance during mechanical ventilation, also reduces vasomotor tone.[49,50] Importantly, these effects do not require endotracheal intubation to occur; they occur with mere reexpansion of collapsed alveoli.[51,52] Thus, PEEP, CPAP, recruitment maneuvers, and noninvasive ventilation may all reverse hypoxic pulmonary vasoconstriction and may all improve cardiovascular function.

Volume-Dependent Changes in Pulmonary Vascular Resistance. Changes in lung volume directly alter pulmonary vasomotor tone by compressing the alveolar vessels.[39,46,47] The actual mechanisms by which this occurs have not been completely resolved, but appear to reflect vascular compression induced by a differential extraluminal pressure gradient. The pulmonary circulation lives in two environments, separated from each other by the pressure that surrounds them.[46] The small pulmonary arterioles, venules, and alveolar capillaries sense Palv as their surrounding pressure, and are called *alveolar vessels*. The large pulmonary arteries and veins, as well as the heart and intrathoracic great vessels of the systemic circulation, sense interstitial pressure or ITP as their surrounding pressure, and are called *extraalveolar vessels*. Because the pressure difference between Palv and ITP is transpulmonary pressure, increasing lung volume increases this extraluminal pressure gradient. Increases in lung volume progressively increase alveolar vessel resistance by increasing this pressure difference once lung volumes increase much above FRC (Fig. 36-1).[42,53] Similarly, increasing lung volume, by stretching and distending the alveolar septa, may also compress alveolar capillaries, although this mechanism is less well substantiated. Hyperinflation can create significant pulmonary hypertension and may precipitate acute RV failure (acute cor pulmonale)[54] and RV ischemia.[37] Thus, PEEP may increase pulmonary vascular resistance if it induces overdistension of the lung above its normal FRC.[55]

Extraalveolar vessels are also influenced by changes in transpulmonary pressure. Normally, radial interstitial forces of the lung, which keep the airways patent, only make the large vessels more distended as lung volume increases,[45,56,57] just as increasing lung volume increases airway diameter. These radial forces also act upon the extraalveolar vessels, causing them to remain dilated, increasing their capacitance.[58] This tethering is reversed with lung deflation, thereby increasing extraalveolar vascular resistance.[42,45] Thus, pulmonary vascular resistance is increased at small lung volumes owing to the combined effect of hypoxic pulmonary vasoconstriction and extraalveolar vessel collapse, and at high lung volumes by alveolar compression.

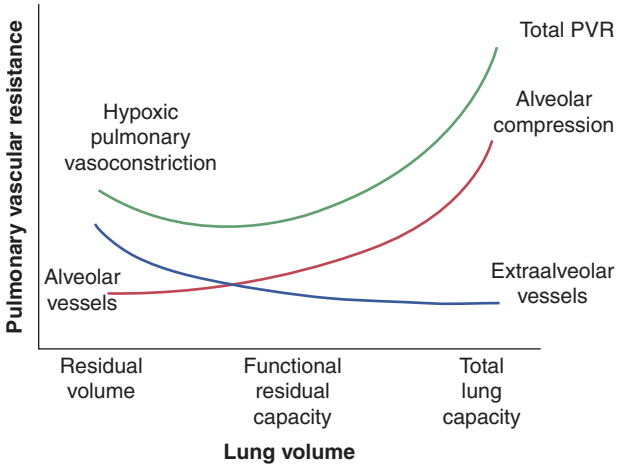

FIGURE 36-1 Schematic of the relationship between changes in lung volume and pulmonary vascular resistance (*PVR*), where the extraalveolar and alveolar vascular components are separated. Pulmonary vascular resistance is minimal at resting lung volume or functional residual capacity. As lung volume increases toward total lung capacity or decreases toward residual volume, pulmonary vascular resistance also increases. The increase in resistance with hyperinflation is caused by increased alveolar vascular resistance, whereas the increase in resistance with lung collapse is caused by increased extraalveolar vessel tone.

Right-Ventricular Afterload. The right ventricle, as opposed to the left ventricle, ejects blood into a low-pressure, high-compliance system: the pulmonary circulation. The pulmonary circulation is capable of accommodating high volumes of blood without generating high pressure, which is beneficial for the right ventricle. Despite being compliant, this circuit does pose resistance to the ejecting right ventricle as quantified by pulmonary artery pressure, which is the pressure limit the right ventricle has to overcome to open the pulmonary valve. RV afterload is conceptually similar to LV afterload and is determined by the wall tension of the right ventricle. RV afterload is highly dependent on the distribution of blood flow in the lung, namely, the proportion of West zones 1 and 2, as compared to zone 3, as originally described by Permutt et al.[59] Zones 1 and 2 exist whenever the intraluminal pressure of juxtaalveolar capillaries is lower than the Palv during the respiratory cycle, thus collapsing vessels and increasing pulmonary vascular resistance. In contrast, zone 3 occurs when intraluminal capillary pressure is higher than Palv, decreasing pulmonary resistance. Importantly, intraluminal pressure of alveolar capillaries tracks changes in ITP,[60] and thus decreases less than Palv during spontaneous inspiration, and increases less than Palv during positive-pressure inspiration. Consequently, both spontaneous and positive-pressure inspiration above FRC increase the afterload to the right ventricle as opposed to the LV afterload, which is reduced by increased ITP.

VENTRICULAR INTERDEPENDENCE

Because right ventricle output is linked to left ventricle output serially, if right ventricle output decreases, left ventricle output must eventually decrease. The two ventricles, however, are also linked in parallel through their common septum, circumferential fibers, and pericardium, which limits total cardiac volume. For this reason, the diastolic filling of the RV has a direct influence on the shape and compliance of the LV, and vice versa. This phenomenon is known as *ventricular diastolic interdependence*.[61] The most common manifestation of ventricular interdependence is *pulsus paradoxus*. Changes in RV end-diastolic volume inversely alter LV diastolic compliance.[62] Because venous return can and often does vary by as much as 200% between inspiration and expiration, owing to associated changes in the pressure gradient for venous return (infra vide, see the section "Systemic Venous Return"), right ventricle filling also changes in

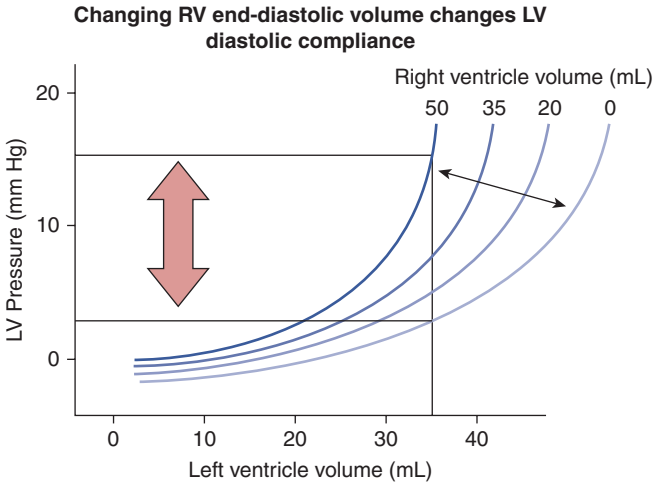

FIGURE 36-2 Schematic of the effect of increasing right-ventricular (RV) volumes on the relationship between left-ventricular (LV) diastolic pressure and left ventricle volume (filling). Increases in right ventricle volumes decrease LV diastolic compliance, such that a higher filling pressure is required to generate a constant end-diastolic volume. (Adapted, with permission, from Taylor RR, Covell JW, Sonnenblick EH, Ross J Jr. Dependence of ventricular distensibility on filling the opposite ventricle. *Am J Physiol*. 1967;213:711–718.)

parallel. Increasing RV end-diastolic volume, as occurs during spontaneous inspiration and spontaneous inspiratory efforts, will reduce LV diastolic compliance, immediately decreasing LV end-diastolic volume. Positive-pressure ventilation may decrease venous return causing RV volumes to decrease, increasing LV diastolic compliance. Except in acute cor pulmonale or biventricular overloaded states, however, the impact of positive-pressure ventilation on LV end-diastolic volume is minimal.

Ventricular interdependence functions through two separate processes. First, increasing RV end-diastolic volume induces an intraventricular septal shift into the LV, thereby decreasing LV diastolic compliance (Fig. 36-2).[63] Because left ventricle wall stress is unaltered, any change in LV output does not reflect a change in LV preload. Because spontaneous inspiration increases venous return, causing right ventricle dilation, LV end-diastolic compliance decreases during spontaneous inspiration. Whereas right ventricle volumes usually do not increase during positive-pressure inspiration, ventricular interdependence usually has less impact over the patient's hemodynamic status. Second, if pericardial restraint or absolute cardiac fossal volume restraint limits absolute biventricular filling, then right ventricle dilation will increase pericardial pressure, with minimal to no septal shift because the pressure outside of both ventricles will increase similarly.[64,65]

Positive-pressure ventilation, however, can still display right ventricle dilation-associated ventricular interdependence. If positive-pressure inspiration overdistends alveoli, as for example during lung recruitment maneuvers, pulmonary vascular resistance will increase. Despite the fact that hemodynamic changes elicited by recruitment maneuvers do not cause persistent cardiovascular insufficiency, transient right ventricle dilation and left ventricle collapse can occur during recruitment maneuvers.[66] This is an important concept when treating patients with borderline RV failure. Thus, recruitment maneuvers should be used with caution and be restricted to 10 seconds or less of an end-inspiratory hold to avoid significant hemodynamic derangements.

The presence of ventricular interdependence can be assessed in mechanically ventilated patients based on heart–lung interactions. Using echocardiographic techniques, Mitchell et al[67] and Jardin et al[68] showed that positive-pressure breaths decrease RV dimensions, whereas both LV dimensions and LV flows increase. Still, the changes in RV output generated by positive-pressure inspiration are much less than the changes in LV output.[69] If ventricular interdependence was the primary process driving hemodynamic interactions during a positive-pressure breath, then a phasic increase in LV stroke volume would occur during inspiration. If the primary process was a phasic decrease in venous return, however, a phasic decrease in LV stroke volume would be observed two to three beats later, usually during the expiratory phase, suggesting the right ventricle is preload responsive. These points underscore the use of LV stroke volume variation during positive-pressure ventilation to identify volume responsiveness.

MECHANICAL HEART–LUNG INTERACTIONS BECAUSE OF LUNG VOLUME

With inspiration, the expanding lungs compress the heart in the cardiac fossa,[70] increasing juxtacardiac ITP. Because the chest wall and diaphragm can move away from the expanding lungs, whereas the heart is trapped within this cardiac fossa, juxtacardiac ITP usually increases more than these external ITPs.[71,72] This effect is a result of increasing lung volume. It is not affected by the means whereby lung volume is increased. Both spontaneous[73] and positive-pressure-induced hyperinflation[56,57] induce similar compressive effects on cardiac filling. If one measured only intraluminal LV pressure, then it would appear as if LV diastolic compliance was reduced, because the associated increase in pericardial pressure and ITP would not be seen.[74–76] When LV function, however, is assessed as the relationship between end-diastolic volume and output, no evidence for impaired LV contractile function is seen[77,74] despite the continued application of PEEP.[78] These compressive effects can be considered as analogous to cardiac tamponade[79–81] and are discussed further in the "The Effect of Intrathoracic Pressure."

Effect of Intrathoracic Pressure

The heart lives within the thorax, a pressure chamber inside a pressure chamber. Thus, changes in ITP affect the pressure gradients for both systemic venous return to the right ventricle and systemic outflow from the left ventricle, independent

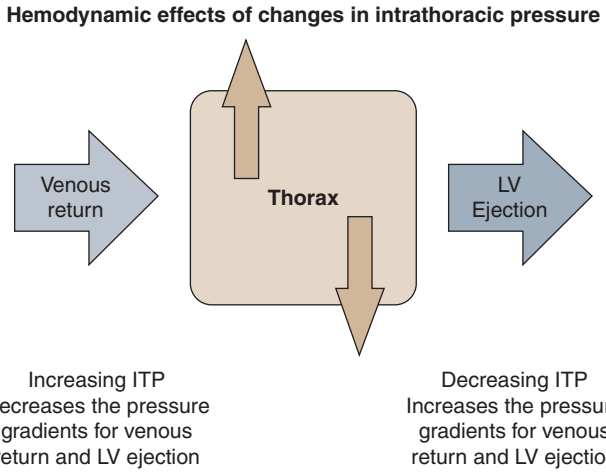

FIGURE 36-3 Schematic of the effect of increasing or decreasing intrathoracic pressure on the left-ventricular (LV) filling (venous return) and ejection pressure.

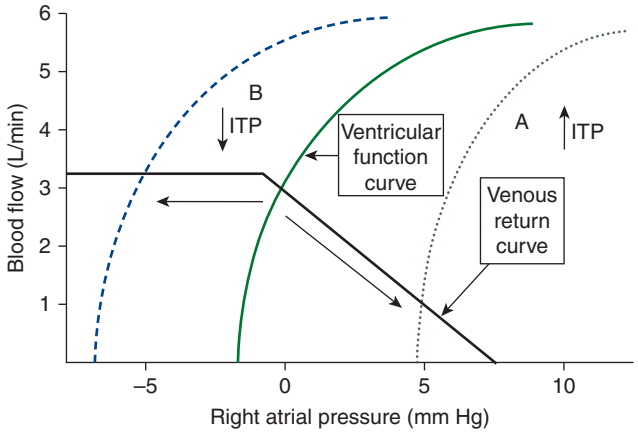

FIGURE 36-4 A venous return curve, describing the relationship between the determinants of right-ventricular preload. Right atrial pressure inversely changes the magnitude of venous return and is influenced by changes in intrathoracic pressure (ITP). Positive-pressure ventilation shifts the ventricular function curve to the right (*A*), increasing right-atrial pressure but decreasing blood flow. Spontaneous inspiration decreases ITP and shifts the ventricular function curve to the left (*B*), decreasing right-atrial pressure but increasing blood flow. As right-atrial pressure becomes negative, as may occur during forced inspiratory efforts against resistance or impedance, a maximal blood flow is reached; further decreases in right-atrial pressure no longer augment venous return.

of the heart itself (Fig. 36-3). Increases in ITP, by increasing right-atrial pressure (Pra) and decreasing transmural LV systolic pressure, will reduce the pressure gradients for venous return and LV ejection decreasing intrathoracic blood volume. Using the same argument, decreases in ITP will augment venous return and impede LV ejection, increasing intrathoracic blood volume. The increases in ITP during positive-pressure ventilation show marked regional differences; juxtacardiac ITP increases more than lateral chest wall ITP as inspiratory flow rate and tidal volume increase.[71] Interestingly, lung compliance plays a minimal role in defining the positive-pressure-induced increase in ITP. For the same increase in tidal volume, ITP usually increases similarly if tidal volume is kept constant.[82,83] If, however, chest wall compliance decreases, then ITP will increase for a fixed tidal volume.[84,85]

SYSTEMIC VENOUS RETURN

Guyton et al described the determinants of venous return more than 50 years ago.[86,87] Blood flows back from the systemic venous reservoirs into the right atrium through low-pressure, low-resistance venous conduits. Pra is the backpressure, or downstream pressure, for venous return. Pressure in the upstream venous reservoirs is called *mean systemic pressure*, and, itself, is a function of blood volume, peripheral vasomotor tone, and the distribution of blood within the vasculature.[88] Ventilation alters both Pra and mean systemic pressure. Many of the observed ventilation-induced changes in cardiac performance can be explained by these changes. Mean systemic pressure does not change rapidly during positive-pressure ventilation, whereas Pra does, owing to parallel changes in ITP (Fig. 36-4).[89,90] Positive-pressure inspiration increases both ITP and Pra, decreasing venous blood flow,[35] RV filling, and consequently, RV stroke volume.[35,89–99] During normal spontaneous inspiration, the opposite effects occur. Spontaneous inspiration decreases ITP and Pra, accelerating venous blood flow, and increasing RV filling and RV stroke volume.[35,36,64,93,96,100–102]

If changes in Pra were the only process that altered venous return, then positive-pressure ventilation would induce profound hemodynamic insufficiency in most patients. The decrease in venous return during positive-pressure ventilation, however, is often lower than one might expect based on the increase in Pra.

The reasons for this preload-sparing effect seen during positive-pressure ventilation are twofold. First, when cardiac output does decrease, increased sympathetic tone decreases venous capacitance, increasing mean systemic pressure, which tends to restore the pressure gradient for venous return, even in the face of an elevated Pra. Increases in sympathetic tone, however, would increase steady-state cardiac output and would not alter the phasic changes in venous return seen during positive-pressure ventilation. The decreased phasic reductions in venous return are caused by associated increases in mean systemic pressure during inspiration. Diaphragmatic descent and abdominal-muscle contraction increase intraabdominal pressure, decreasing intraabdominal vascular capacitance.[103,104] Because a large proportion of venous blood is in the abdomen, the net effect of both inspiration and PEEP is to increase mean systemic pressure and Pra in a parallel but unequal fashion.[105–107] Accordingly, the pressure gradient for venous return may not be reduced as much as predicted as predicted from a pure increase in Pra. This is an important adaptive response by the body to positive-pressure ventilation and PEEP, both of which produce this effect secondary to the associated increase in lung volume, which promotes diaphragmatic descent. This

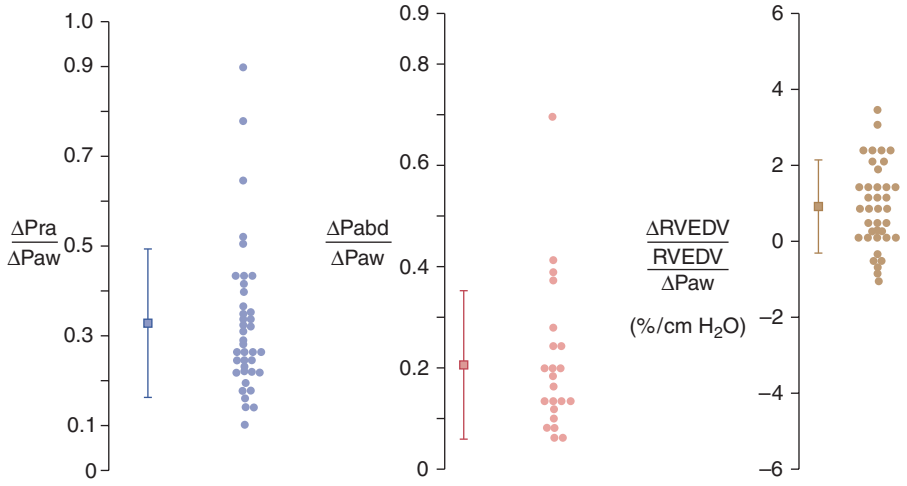

FIGURE 36-5 Effect of increasing levels of continuous positive airway pressure (CPAP) on the relations between increasing airway pressure (*Paw*) and right-atrial pressure (*Pra*) (*left graph*), *Paw* and intraabdominal pressure (*Pabd*) (*center graph*), and *Paw* and changes in right-ventricular end-diastolic volume (*RVEDV*) (*right graph*) in forty-three postoperative fluid-resuscitated cardiac surgery patients. (Data derived, with permission, from data in Van den Berg P, Jansen JRC, Pinsky MR. The effect of positive-pressure inspiration on venous return in volume loaded post-operative cardiac surgical patients. *J Appl Physiol.* 2002;92:1223–1231.)

preload-sparing effect is especially well demonstrated in patients with hypervolemia. In fact, both the translocation of blood from the pulmonary to the systemic capacitance vessels,[108] as well as abdominal pressurization secondary to diaphragmatic descent, may be the major mechanisms by which the decrease in venous return is minimized during positive-pressure ventilation.[109–113] In fact, van den Berg et al[114] documented that up to 20 cm H_2O CPAP did not significantly decrease cardiac output, as measured 30 seconds into an inspiratory-hold maneuver, in fluid-resuscitated, post-operative cardiac surgery patients. Although CPAP induced an increase in Pra, intraabdominal pressure also increased, preventing a significant change in RV volumes (Fig. 36-5). Interest in inverse-ratio ventilation has raised questions as to its hemodynamic effect, because its application includes a large component of hyperinflation.

Current data clearly show that detrimental effects of increased ITP and PEEP on venous return are far more complex than an effect on the pressure gradient between mean systemic pressure and Pra, and that geometric deformation of the venous vasculature and its flow distribution, which alter the resistance to flow, may be a better explanation.[115] Animal data suggest that compression and deformation of capacitance vessels at the entrance of the thorax[103] and compression of the portal circulation by diaphragmatic descent[115] may account for these increments in venous resistance and thus decreased venous return.

Relevance of Intrathoracic Pressure on Venous Return. It is axiomatic that the heart can only pump out that amount of blood that it receives and no more. Thus, venous return is the primary determinant of cardiac output and the two must be the same.[88] Because Pra is the backpressure to venous return and because Pra is normally close to zero relative to atmospheric pressure, venous return is maintained near maximal levels at rest,[12,87,94,98,99] because right ventricle filling occurs with minimal changes in filling pressure.[81] Spontaneous inspiratory efforts usually increase venous return because of the combined decrease in Pra[64,94–96,116] and increase in intraabdominal pressure.[103,104] For Pra to remain very low, however, RV diastolic compliance must be high and RV output must equal venous return. Otherwise, sustained increases in venous blood flow would distend the RV and increase Pra. During normal spontaneous inspiration, although venous return increases, ITP decreases at the same time, minimizing any potential increase in Pra, which might otherwise occur if ITP were not to decrease.[89] Aiding in this process of minimizing RV workload, the pulmonary arterial inflow circuit is highly compliant and can accept large increases in RV stroke volume without changing pressure.[35,117] Thus, increases in venous return proportionally increase pulmonary arterial inflow without significant changes in RV filling or ejection pressures. Accordingly, this compensatory system fails if RV diastolic compliance decreases or if Pra increases independent of changes in RV end-diastolic volume. Figure 36-6 illustrates these differential effects of negative (spontaneous inspiration) and positive (positive-pressure inspiration) swings in ITP on dynamic RV and LV performance. In RV failure states, spontaneous inspiration does not decrease Pra and Pra actually increases. This results in the physical sign of increased jugular venous distension during spontaneous inspiration.

Note further in Figure 36-6 that not only does RV stroke volume increase with spontaneous inspiration and decrease with positive-pressure inspiration, but also that LV stroke volume decreases only during spontaneous inspiration (ventricular interdependence); during positive-pressure inspiration, however, any change in LV stroke volume occurs late, as the decrease in RV output finally reaches the left ventricle. RV

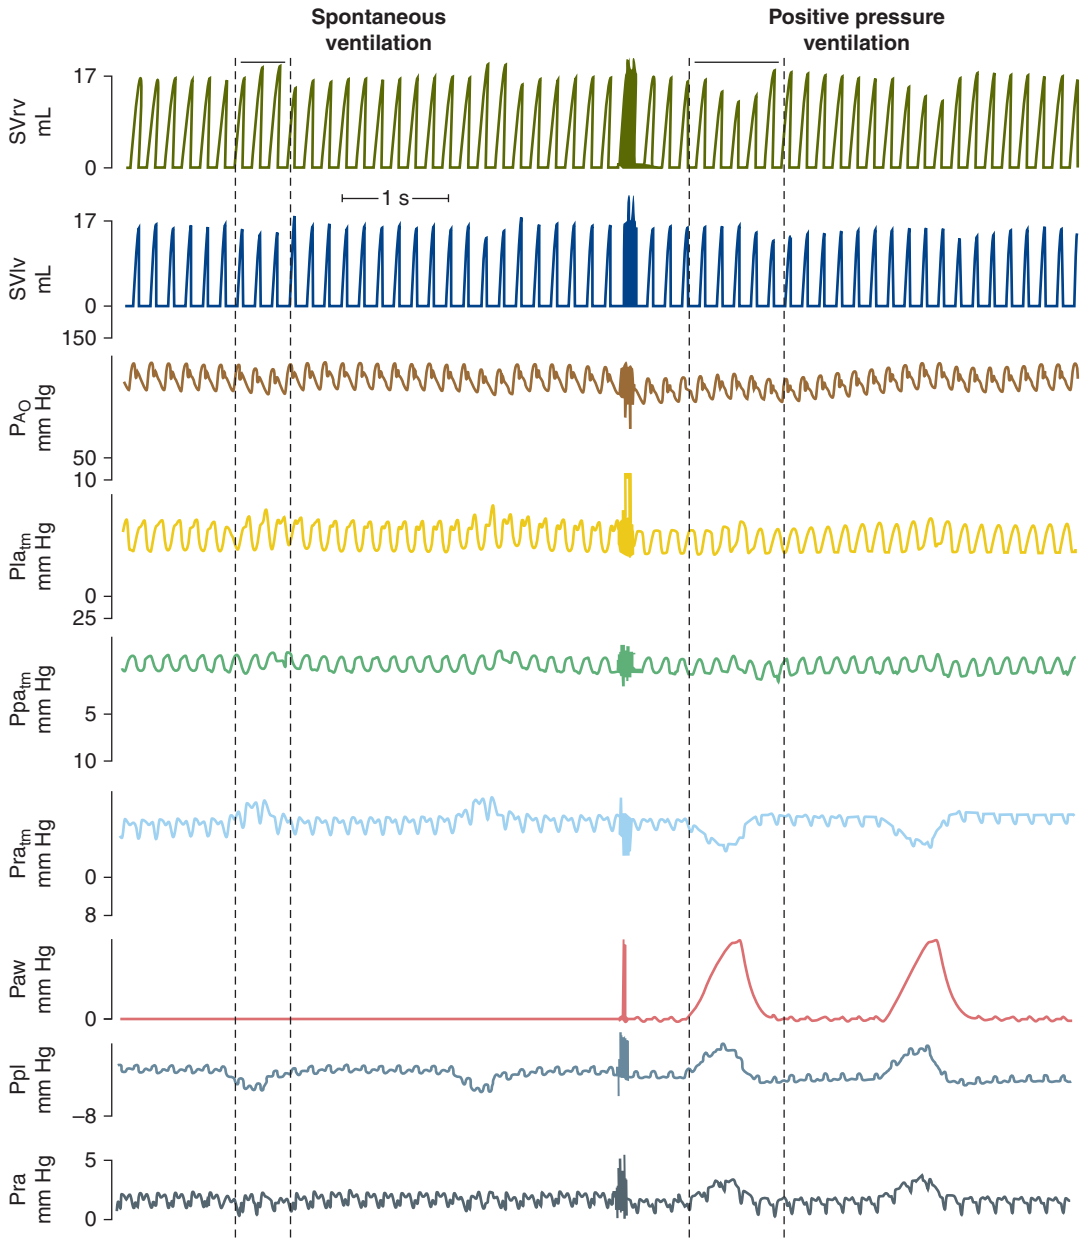

FIGURE 36-6 Strip chart recording of right and left-ventricular stroke volumes (*SVrv* and *SVlv*, respectively), aortic pressure (PA_O), left-atrial, pulmonary arterial, and right-atrial transmural pressures (Pla_{tm}, Ppa_{tm}, and Pra_{tm}, respectively), airway pressure (*Paw*), pleural pressure (*Ppl*), and right-atrial pressure (*Pra*) during spontaneous ventilation (*left*) and similar tidal volume positive-pressure ventilation (*right*) in an anesthetized, intact canine model. (Used, with permission, from Pinsky MR, Matuschak GM, Klain M. Determinants of cardiac augmentation by elevations in intrathoracic pressure. *J Appl Physiol.* 1985;58:1189–1198.)

diastolic compliance can acutely decrease in the setting of acute RV dilation or cor pulmonale (pulmonary embolism, hyperinflation, and RV infarction). Importantly, acute RV dilation and acute cor pulmonale can not only induce rapid cardiovascular collapse, but they are singularly not responsive to fluid resuscitation. Because spontaneous inspiration and inspiratory efforts cause both ITP and Pra to decrease, RV dilation may occur in patients with occult heart failure. Accordingly, some patients who were previously stable and ventilator-dependent can develop acute RV failure during weaning trials.

Finally, with exaggerated negative swings in ITP, as occur with obstructed inspiratory efforts, venous return behaves as if abdominal pressure is additive to mean systemic pressure in augmenting venous blood flow.[118–121] These findings have some investigators to suggest that obstructive breathing may be a therapeutic strategy in sustaining cardiac output in patients in hemorrhagic shock.[122] Interestingly, negative pressure ventilation, by augmenting venous return, increases cardiac output by 39% in children following repair of tetralogy of Fallot.[123] In this condition, impaired RV filling secondary to

RV hypertrophy and reduced RV chamber size are the primary factors limiting cardiac output. This augmentation of venous return by spontaneous inspiration, however, is limited,[119,120] because as ITP decreases below atmospheric pressure, venous return becomes flow-limited because the large systemic veins collapse as they enter the thorax.[87] This vascular flow limitation is a safety valve for the heart, because ITP can decrease greatly with obstructive inspiratory efforts,[13] and if not flow-limited, the RV could become overdistended and fail.[124] Finally, having subjects breathe through an airway that selectively impedes inspiration will result in exaggerated negative swings in both ITP and Pra, and associated greater increases in intraabdominal pressure secondary to recruitment of accessory muscles of respiration (to sustain a normal tidal volume).[122]

Positive-pressure ventilation tends to create the opposite effect: increase in ITP increases Pra, thus decreasing venous return, RV volumes, and ultimately LV output. The detrimental effect of positive-pressure ventilation on cardiac output can be minimized by either fluid resuscitation, to increase mean systemic pressure,[91,100,114,115,118] or by keeping both mean ITP and swings in lung volume as low as possible. Accordingly, prolonging expiratory time, decreasing tidal volume, and avoiding PEEP all minimize this decrease in systemic venous return to the right ventricle.[1,89,93–97,125,126] Increases in lung volume during positive-pressure ventilation primarily compress the two ventricles into each other, decreasing biventricular volumes.[127] The decrease in cardiac output commonly seen during PEEP is caused by a decrease in LV end-diastolic volume, because both LV end-diastolic volume and cardiac output are restored by fluid resuscitation[128,129] without any measurable change in LV diastolic compliance.[74]

A common respiratory maneuver, called a Valsalva maneuver, which is forced expiration against an occluded airway, such as one may do while straining at stool, displays most of the hemodynamic effects commonly seen in various disease states and with different types of positive-pressure ventilation.

During a Valsalva maneuver, airway pressure (Paw) and ITP increase equally, and pulmonary vascular resistance remains constant. During the first phase of the Valsalva maneuver, right ventricle filling decreases because venous return decreases with no change in left ventricle filling, LV stroke volume, or arterial pulse pressure. Although LV stroke volume does not change, LV peak ejection pressure increases equal to the amount of the increase in ITP.[30] As the strain is sustained, both LV filling and cardiac output both decrease owing to the decrease in venous return,[70,131] which results in the second phase. During this second phase of the Valsalva maneuver, both RV and LV output are decreased; arterial pulse pressure is reduced, but peak systolic pressure sustained at an elevated level owing to the sustained increase in ITP. This phase delay in LV output decrease compared to RV output decrease is also seen during positive-pressure ventilation; it is exaggerated if tidal volumes increase or if the pressure gradient for venous return was already low, as is the case in hypovolemia.[1,74–76,98,125,132–138] With release of the strain in phase three of the Valsalva maneuver, arterial pressure abruptly declines as the low LV stroke volume cannot sustain an adequate ejection pressure on its own. Furthermore, with the release of the increased ITP, venous return increases, increasing RV volume, and, through the process of ventricular interdependence, decreases LV diastolic compliance, making LV end-diastolic volume even less. Conceptually, then ventricular interdependence usually becomes apparent with sudden increases in RV volume from apneic baseline, as would occur during spontaneous inspiration, but less so when RV volumes decrease below these volumes. As described above, because RV volumes are usually decreased during positive-pressure ventilation, ventricular interdependence is not a prominent feature of this form of breathing (see Fig. 36-6).[62,136–139] Although PEEP results in some degree of right-to-left intraventricular septal shift, echocardiographic studies demonstrate that the shift is small.[77,132] It follows that positive-pressure ventilation decreases intrathoracic blood volume[94] and PEEP decreases it even more[140,141] without altering LV diastolic or contractile function.[142] During spontaneous inspiration, however, RV volumes increase transiently shifting the intraventricular septum into the LV,[63] decreasing LV diastolic compliance and LV end-diastolic volume.[48,61,139] This transient RV dilation-induced septal shift is the primary cause of inspiration-associated decreases in arterial pulse pressure, which, if greater than 10 mm Hg or 10% of the mean pulse pressure, is referred to as *pulsus paradoxus* (see Fig. 36-6).[64,143]

Left-Ventricular Preload and Ventricular Interdependence. Ventricular interdependence does not induce steady-state changes in left ventricle performance, only phasic ones. Thus, the associated rapid changes in right ventricle filling induced by phasic changes in ITP cause marked changes in LV output, which are a hallmark of ventilation-induced hemodynamic changes as described above (see Figure 36-6 Spontaneous ventilation).

LEFT-VENTRICULAR AFTERLOAD

LV afterload is defined as the maximal LV systolic wall tension, which equals the maximal product of LV volume and transmural LV pressure. Under normal conditions, maximal LV wall tension occurs at the end of isometric contraction, with the opening of the aortic valve. During LV ejection, as LV volumes rapidly decrease, LV afterload also decreases despite an associated increase in ejection pressure. Importantly, when LV dilation exists, as in CHF, maximal LV wall stress occurs during LV ejection because the maximal product of pressure and volume occurs at that time. LV ejection pressure is the transmural LV systolic pressure. This is the main reason why subjects with dilated cardiomyopathies are very sensitive to changes in ejection pressure, whereas patients with primarily diastolic dysfunction are not. Normal baroreceptor mechanisms, located in the extrathoracic carotid body, function to maintain arterial pressure constant with respect to atmosphere. Accordingly, if arterial pressure were to remain constant as ITP increased, then transmural LV pressure would decrease. Similarly, if transmural arterial pressure were to remain constant as ITP increased,

then LV wall tension would decrease.[144] Thus, increases in ITP decrease LV afterload, and decreases in ITP increase LV afterload.[130,145] These two opposing effects of changes in ITP on LV afterload have important clinical implications.

The concept that increases in ITP decrease both LV preload and LV afterload can be clearly illustrated with the use of high-frequency jet ventilation, which can increase ITP but does not result in large swings in lung volume.[135] When high-frequency jet ventilation is delivered in synchrony with the cardiac cycle, such that heart rate and ventilatory frequency are identical, one can dissect out the effects of ITP on preload and afterload. Under hypovolemic and normovolemic conditions with intact cardiovascular reserve, positive-pressure ventilation usually decreases steady-state cardiac output by decreasing the pressure gradient for venous return. When one compares the hemodynamic effects of high-frequency jet ventilation synchronized to occur during diastole (when ventricular filling occurs), cardiac output decreases to levels seen during end-inspiration for normal-to-large tidal-volume (10 mL/kg) ventilation. In the same subject, however, if the increases in ITP occur during systole, the detrimental effects of the same mean Paw, mean ITP, and tidal volume do not impede venous return (Fig. 36-7).[146,147] Furthermore, in heart failure states, positive-pressure ventilation does not impede cardiac output because the same decreases in venous return do not alter LV preload. If these increases in ITP, however, reduce LV afterload, then cardiac output will also increase. These points are illustrated in Figure 36-8, wherein synchronous high-frequency jet ventilation is delivered either during preejection systole (presystolic) or ejection (systolic). The only difference between the two ventilatory states is that arterial pulse pressure does not change despite increases in LV stroke volume with presystolic increases in Paw, consistent with a decreased LV afterload, whereas with systolic increases in Paw, arterial pulse pressure increases, and peak arterial pressure increases by an amount equal to the increase in ITP, consistent with mechanically augmented LV ejection.

Relevance of Intrathoracic Pressure on Myocardial Oxygen Consumption. Decreases in ITP increase both LV afterload and myocardial O_2 consumption. Accordingly, spontaneous ventilation not only increases global O_2 demand by its exercise component,[80,126,148] but also increases myocardial O_2 consumption. Profound decreases in ITP commonly occur during spontaneous inspiratory efforts with bronchospasm, obstructive breathing, and acute hypoxemic respiratory failure. Under these conditions, the cardiovascular burden can be great and may induce acute heart failure and pulmonary edema.[30] Because weaning from positive-pressure ventilation to spontaneous ventilation may reflect dramatic changes in ITP swings, from positive to negative, independent of the energy requirements of the respiratory muscles, weaning is a selective LV stress test.[144,148–150] Similarly, improved LV systolic function is observed in patients with severe LV failure placed on mechanical ventilation.[150] Very negative swings in ITP, as seen with vigorous inspiratory efforts in the setting of airway obstruction (asthma, upper airway obstruction, or vocal cord paralysis) or stiff lungs (interstitial lung disease, pulmonary edema, or ALI), selectively increase LV afterload, and may be the cause of LV failure and pulmonary edema,[13,30,31,151] especially if LV systolic function is already compromised.[152,153]

Pulsus paradoxus seen during spontaneous inspiration under conditions of marked pericardial restraint reflects primarily ventricular interdependence.[154–158] The negative swings in ITP, however, also increase LV ejection pressure, increasing LV end-systolic volume.[130] Other systemic factors may influence LV systolic function during loaded inspiratory efforts. These associated factors also contribute to a greater or lesser degree to the inhibition of normal LV systolic function, including increased in aortic input impedance,[159] altered synchrony of contraction of the global LV myocardium,[160] and hypoxemia-induced decreased global myocardial contractility.[161] Hypoxia also directly reduces LV diastolic compliance.[162] Experimental repetitive periodic airway obstructions induce pulmonary edema in normal animals.[30,31] Furthermore, removing the negative swings in ITP by applying nasal CPAP results in improved global LV performance in patients with combined obstructive sleep apnea and CHF.[130]

Relevance of Intrathoracic Pressure on Left-Ventricular Afterload. If arterial pressure remains constant, then increases in ITP decrease transmural LV ejection pressure, decreasing LV afterload. These points are easily demonstrated in a subject with an indwelling arterial pressure catheter during cough or Valsalva maneuvers. During a cough, ITP increases rapidly without changes in intrathoracic blood volume. Arterial pressure also increases by a similar amount, as described above for phase 1 of the Valsalva maneuver. Thus, transmural LV pressure (LV pressure relative to ITP)[130,163,164] and aortic blood flow[70] would remain constant. Sustained increases in ITP, however, must eventually decrease aortic blood flow and arterial pressure secondary to the associated decrease in venous return.[130] If ITP increased arterial pressure without changing transmural arterial pressure, then baroreceptor-mediated vasodilation would induce arterial vasodilation to maintain extrathoracic arterial pressure-flow relations constant.[134] Because coronary perfusion pressure reflects the ITP gradient for blood flow and is not increased by ITP-induced increases in arterial pressure, such sustained increases in ITP can cause decreased coronary perfusion pressure-induced myocardial ischemia.[165–167]

SPONTANEOUS BREATHING VERSUS MECHANICAL POSITIVE-PRESSURE VENTILATION

Both spontaneous and mechanical ventilation increase lung volume above resting end-expiratory lung volume or FRC. During both spontaneous and positive-pressure ventilation, end-expiratory lung volume can be artificially increased by the addition of PEEP. Thus, the primary hemodynamic

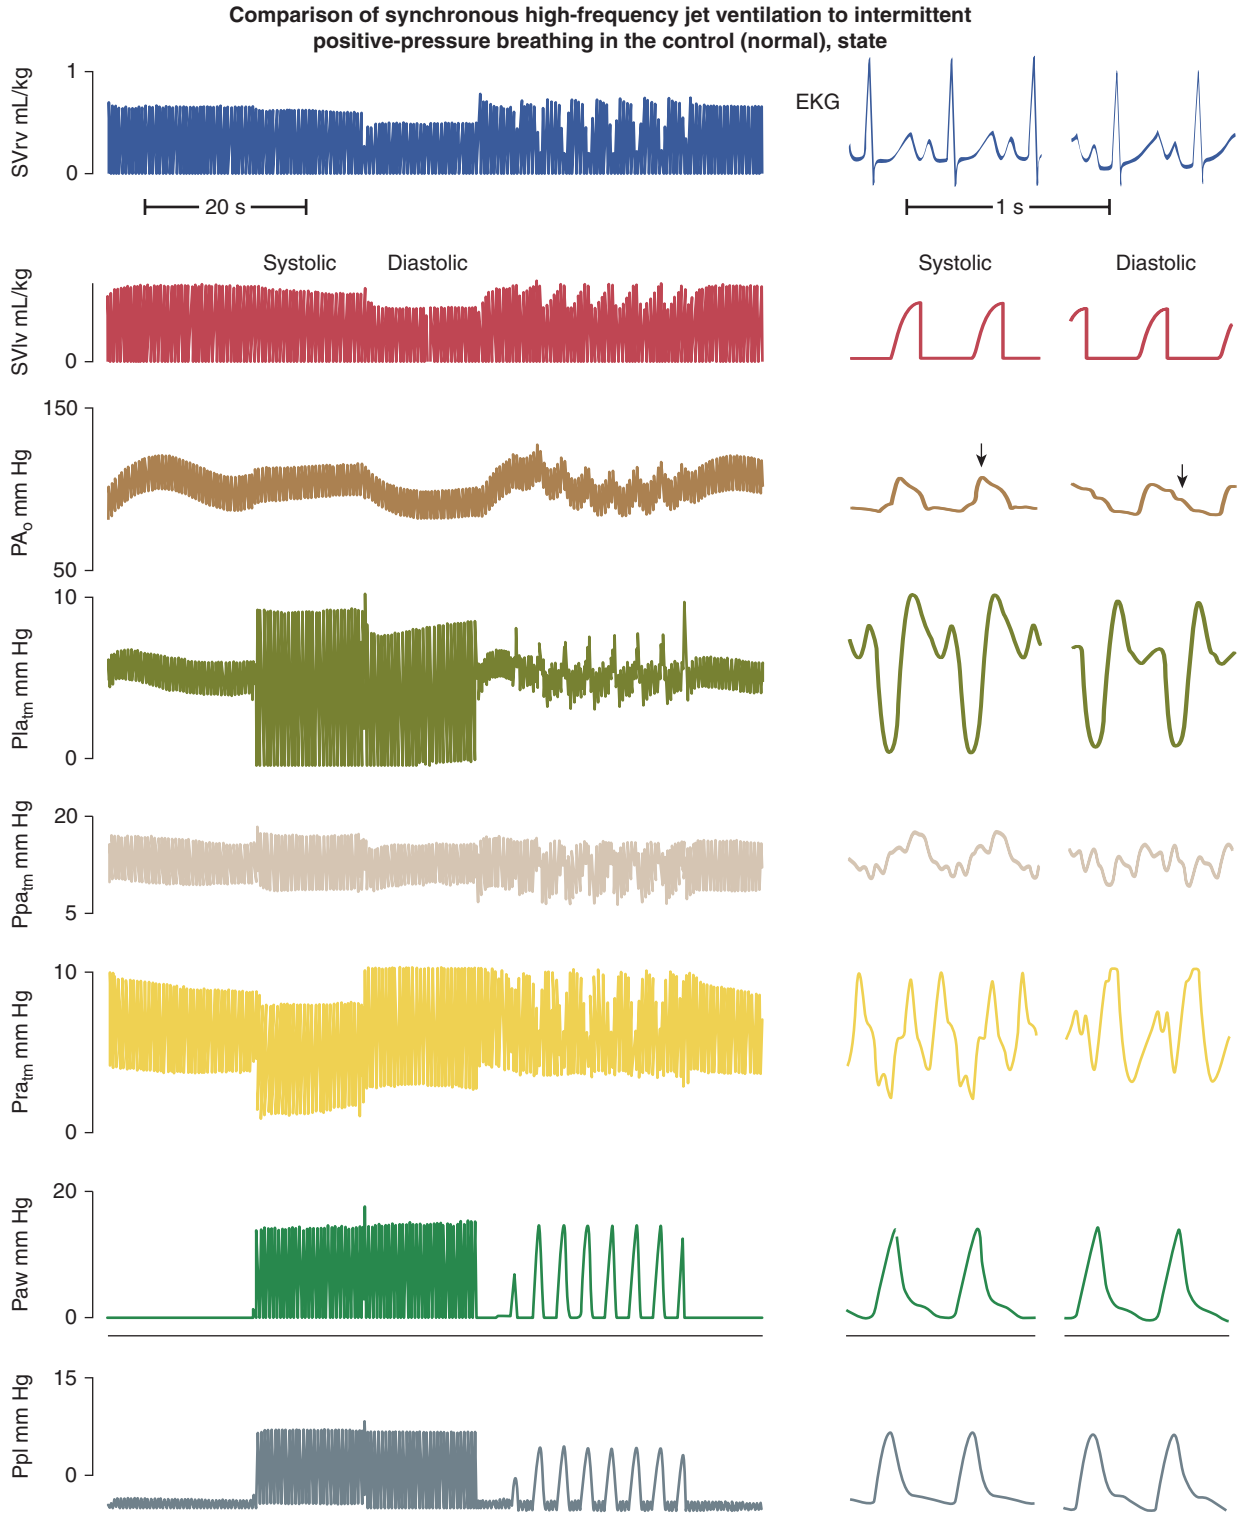

FIGURE 36-7 Strip chart recording of right- and left-ventricular stroke volumes (*SVrv* and *SVlv*, respectively), aortic pressure (PA_O), left atrial, pulmonary arterial, and right atrial transmural pressures (Pla_{tm}, Ppa_{tm}, and Pra_{tm}, respectively), airway pressure (*Paw*), and pleural pressure (*Ppl*) during apnea (*left*), and both systolic (*systole*) and diastolic (*diastole*) high-frequency jet ventilation (HFJV) (*middle*), and intermittent positive-pressure ventilation with similar mean Paw (*right*) in an anesthetized, intact canine model with normal cardiovascular function. Note that the cardiac cycle-specific increases in Paw created by systole HFJV minimally impede cardiac output, whereas diastole HFJV markedly decreases venous return (SVrv decreases first, then SVlv decreases). The rapid strip chart speed shown on the left is to illustrate the exact timing of synchronous HFJV. (Used, with permission, from Pinsky MR, Matuschak GM, Bernardi L, Klain M. Hemodynamic effects of cardiac cycle-specific increases in intrathoracic pressure. *J Appl Physiol.* 1986;60:604–612.)

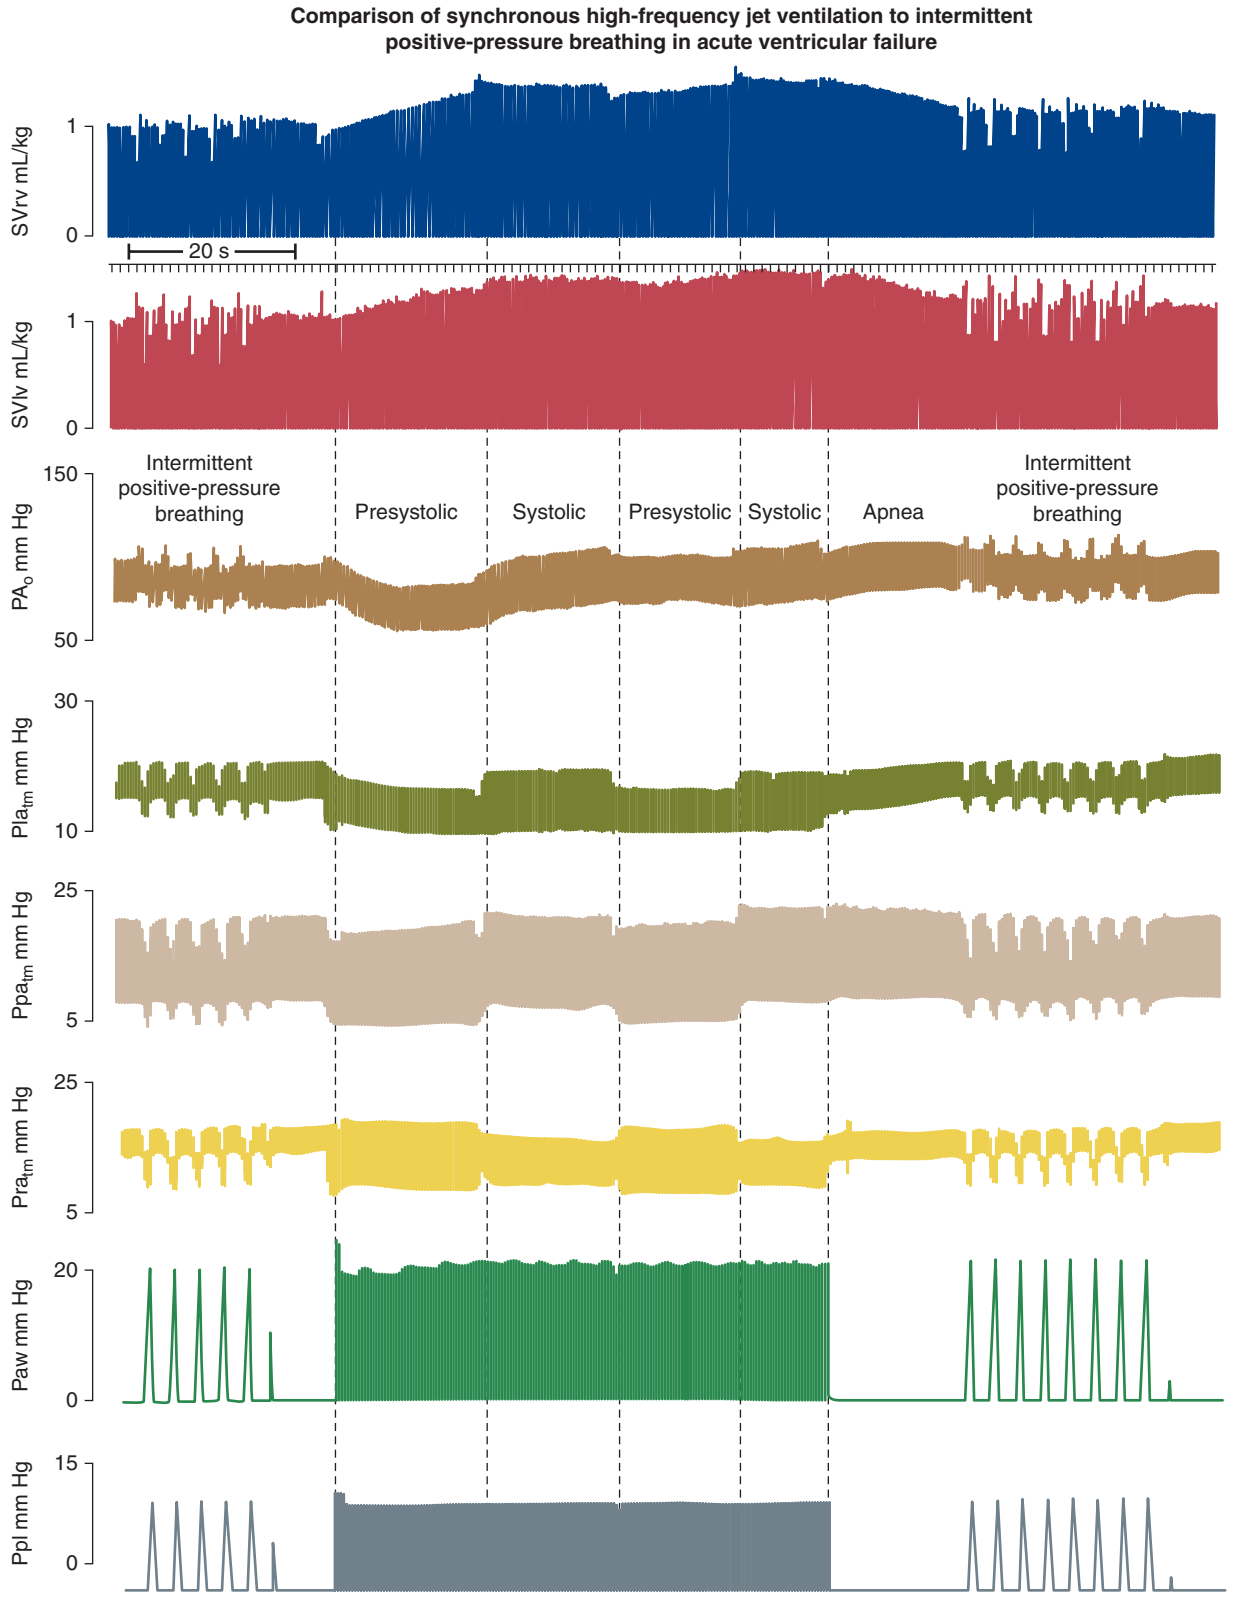

FIGURE 36-8 Continuous strip chart recording of right- and left-ventricular stroke volumes (*SVrv* and *SVlv*, respectively), aortic pressure (PA_O), left atrial, pulmonary arterial, and right-atrial transmural pressures (Pla_{tm}, Ppa_{tm}, and Pra_{tm}, respectively), airway pressure (*Paw*), pleural pressure (*Ppl*), and right-atrial pressure (*Pra*) during intermittent positive-pressure ventilation (tidal volume [V_T] 10 mL/kg), apnea (*left*), and then both preejection systole (presystolic) and LV ejection (systolic) synchronous high-frequency jet ventilation (HFJV) (*middle*), and then intermittent positive-pressure ventilation again (*right*) in an anesthetized, intact canine model with fluid-resuscitated acute ventricular failure. Note that the cardiac cycle–specific increases in Paw created by both presystolic and systolic HFJV increase steady-state SVrv and SVlv (i.e., cardiac output), but affect PA_O differently. Presystolic HFJV does not change PA_O pulse pressure despite an increase in SVlv (reduced afterload), whereas systolic HFJV increases PA_O pulse pressure for a similar increase in SVlv. (Used, with permission, from Pinsky MR, Matuschak GM, Bernardi L, Klain M. Hemodynamic effects of cardiac cycle-specific increases in intrathoracic pressure. *J Appl Physiol.* 1986;60:604–612.)

differences between spontaneous ventilation and positive-pressure ventilation are caused by the changes in ITP and the muscular contraction needed to create these changes. Importantly, even if a patient is receiving ventilator support, spontaneous respiratory efforts can persist and may result in marked increases in metabolic load, and contribute to sustained respiratory muscle fatigue.[168] Still, a primary reason for instituting mechanical ventilation is to decrease the work of breathing. Normal spontaneous ventilation augments venous return and vigorous inspiratory efforts account for most of the increased blood flow seen in exercise. Conversely, positive-pressure ventilation may impair ventricular filling and induce hypovolemic cardiac dysfunction in normal or hypovolemic subjects while augmenting LV function in patients with heart failure. Finally, heart failure, whether primary or induced by ventilation, may induce acute respiratory muscle fatigue causing respiratory failure or failure to wean from mechanical ventilation, and overtax the ability of the circulation to deliver O_2 to the rest of the body.

Fundamental to this concept is the realization that spontaneous ventilation is exercise. Spontaneous ventilatory efforts are induced by contraction of the respiratory muscles, mainly the diaphragm and intercostal muscles.[148] Although ventilation normally requires less than 5% of total O_2 delivery to meet its demand[148] (and is difficult to measure at the bedside even when using calibrated metabolic measuring devices), in lung disease states in which work of breathing is increased, the metabolic demand for O_2 can increase to 30% of total O_2 delivery.[80,125,148,169] With marked hyperpnea, muscles of the abdominal wall and shoulder girdle function as accessory muscles. Blood flow to these muscles is derived from several arterial circuits, whose absolute flow exceeds the highest metabolic demand of maximally exercising skeletal muscle under normal conditions.[148,170,171] Thus, blood flow is usually not the limiting factor determining maximal ventilatory effort. In severe heart failure states, however, blood flow constraints may limit ventilation because blood flow to other organs and to the respiratory muscles may be compromised, inducing both tissue hypoperfusion and lactic acidosis.[170–172] Aubier et al demonstrated that if cardiac output is severely limited by the artificial induction of tamponade in a canine model that respiratory muscle failure develops despite high central neuronal drive.[171] The animals die a respiratory death before cardiovascular standstill. The institution of mechanical ventilation for ventilatory and hypoxemic respiratory failure may reduce metabolic demand on the stressed cardiovascular system increasing mixed venous oxygen saturation ($S\bar{V}O_2$) for a constant cardiac output and arterial oxygen content (CaO_2).[172] Intubation and mechanical ventilation, when adjusted to the metabolic demands of the patient, may dramatically decrease the work of breathing, resulting in increased O_2 delivery to other vital organs and decreased serum lactic acid levels. Under conditions in which fixed right-to-left shunts exist, the obligatory increase in $S\bar{V}O_2$ will result in an increase in the partial pressure of arterial oxygen (Pa_{O_2}), despite no change in the ratio of shunt blood flow to cardiac output.

DETECTION AND MONITORING

Weaning Failure

Ventilator-dependent patients who fail to wean often have impaired baseline cardiovascular performance that is readily apparent,[153] but commonly patients develop overt signs of heart failure during weaning, such as pulmonary edema,[153,174] myocardial ischemia,[175–178] tachycardia, and gut ischemia.[179] Pulmonary artery occlusion pressure may rise rapidly to nonphysiologic levels within 5 minutes of instituting weaning.[153] Although all patients increase their cardiac outputs in response to a weaning trial, those that subsequently fail to wean demonstrate a reduction in mixed venous O_2 saturation, consistent with a failing cardiovascular response to an increased metabolic demand.[180] Weaning from mechanical ventilation can be considered a cardiovascular stress test. Again, investigators have documented weaning-associated electrocardiogram and thallium cardiac blood flow scan-related signs of ischemia in both patients with known coronary artery disease[175] and in otherwise normal patients.[177,178] Using this same logic, placing patients with severe heart failure and/or ischemia on ventilator support, by either intubation and ventilation[181] or noninvasive CPAP[182] can reverse myocardial ischemia. Importantly, the increased work of breathing may come from the endotracheal tube flow resistance.[183] Thus, some patients who fail a spontaneous breathing trial may actually be able to breathe on their own if extubated. There is, however, no known method of identifying this subgroup.

Using Ventilation to Define Cardiovascular Performance

Because the cardiovascular response to positive-pressure breathing is determined by the baseline cardiovascular state, these responses can be used to define such cardiovascular states. Sustained increases in airway pressure will reduce venous return, allowing one to assess LV ejection over a range of end-diastolic volumes. If echocardiographic measures of LV volumes are simultaneously made, then one can use an inspiratory-hold maneuver to measure cardiac contractility, as defined by the end-systolic pressure-volume relationship,[184] which is similar to those created by transient inferior vena-caval occlusion.[185,186] Furthermore, these measures can be made during the ventilatory cycle to define dynamic interactions.[186]

Patients with relative hypervolemia, a condition often associated with CHF, are at less risk of developing impaired venous return during initiation of mechanical ventilation, whereas hypovolemic patients are at increased risk. If positive airway pressure augments LV ejection in heart failure states by reducing LV afterload, then systolic arterial pressure should not decrease but actually increase during inspiration, so-called reverse pulsus paradoxus. This was what Abel et al[187] saw in ten postcardiac surgery patients. Perel et al[188–190] suggested that the relationship between ventilatory efforts

and systolic arterial pressure may be used to identify which patients may benefit from cardiac-assist maneuvers. Patients who increase their systolic arterial pressure during ventilation, relative to an apneic baseline, tend to have a greater degree of volume overload[189] and heart failure,[190] whereas patients who decrease systolic arterial pressure tend to be volume responsive. Perhaps more relevant to usual clinical practice is the identification of patients whose cardiac output will increase if given a volume challenge. The identification of preload responsiveness is important because only half of the hemodynamically unstable patients studied in several clinical series were actually preload-responsive.[191] Thus, nonspecific fluid loading will not only be ineffective at restoring cardiovascular stability in half the subjects, it will also both delay definitive therapy and may promote cor pulmonale or pulmonary edema. Finally, Michard et al[192] found, in a series of ventilator-dependent septic patients, that the greater the degree of arterial pulse-pressure variation during positive-pressure ventilation, the greater the subsequent increase in cardiac output in response to volume-expansion therapy. The recent literature has documented that both arterial pulse-pressure and LV stroke-volume variations[193,194] induced by positive-pressure ventilation are sensitive and specific markers of preload responsiveness. This literature was recently reviewed.[195] The greater the degree of flow or pressure variation over the course of the respiratory cycle for a fixed tidal volume, the more likely a patient is to increase cardiac output in response to a volume challenge, and the greater that increase. The overarching principles of this clinical tool have only recently been described.[173] There are several important caveats and limitations to this approach that need to be considered before the clinician proceeds to monitoring arterial pulse pressure or stroke volume variation during ventilation as a routine assessment of preload responsiveness.

First, and perhaps most importantly, being preload-responsive does not mean that the patient should be given volume. Otherwise healthy subjects under general anesthesia without evidence of cardiovascular insufficiency are also preload-responsive, but do not need a volume challenge. The presence of positive-pressure-induced changes in aortic flow or arterial pulse pressure does not itself define therapy. Independent documentation of cardiovascular insufficiency needs to be sought before the clinician attempts fluid resuscitation based on these measures. Second, these indices, which quantify the variation in aortic flow, stroke volume, and arterial systolic and pulse pressures, have routinely been demonstrated to outperform more traditional measures of LV preload, such as pulmonary occlusion pressure, Pra, total thoracic blood volume, RV end-diastolic volume, and LV end-diastolic area.[192,194] There appears to be little relation between ventricular preload and preload responsiveness. Ventricular filling pressures poorly reflect ventricular volumes, and measures of absolute ventricular volumes do not define diastolic compliance.[196,197] Patients with small left ventricles that are also stiff, as may occur with acute cor pulmonale, tamponade, LV hypertrophy, and myocardial fibrosis, will show poor volume responsiveness. Conversely, patients with large LV volumes, as often occurs with CHF and afterload reduction, may be quite volume responsive. Thus, preload does not equal preload responsiveness. Third, all the reported studies used positive-pressure ventilation to vary venous return. For such changes in venous return, however, to induce LV output changes, the changes must be of sufficient enough magnitude to cause measurable changes in preload.[69] If the increase in lung volume with each tidal breath is either not great enough to induce changes in pulmonary venous flow,[198] or if the positive-pressure breath is associated with spontaneous inspiratory efforts that minimize the changes in venous return,[199] then the cyclic perturbations to cardiac filling may not be great enough to induce the cyclic variations in LV filling needed to identify preload responsiveness. Furthermore, the degree of pressure or flow variation will be proportional to tidal volume, with greater tidal volumes inducing greater changes for the same cardiovascular state.[192,195,200] Thus, the means by which cyclic changes in lung volume and ITP are induced will affect the magnitude of arterial pressure and flow variations. Fourth, although the primary determinant of arterial pulse-pressure variation over a single breath is LV stroke-volume variation, because changes in aortic impedance and arterial tone cannot change that rapidly[201] over time, this limitation no longer applies. As arterial tone decreases, for example, then for the same aortic flow and stroke volume both mean arterial pressure and pulse pressure will be less. Accordingly, flow variation becomes more sensitive than pulse pressure variation as hemorrhage progresses.[193]

CLINICAL SCENARIOS

Initiating Mechanical Ventilation

NORMOVOLEMIC AND HYPOVOLEMIC PATIENTS

The process of initiating mechanical ventilation is a complex physiologic process for a variety of reasons. First, pharmacologic factors needed to allow for endotracheal intubation also blunt sympathetic responses, exaggerating the hemodynamic effects induced by increasing airway pressure and defining tidal volume and ventilatory frequency. This point is clearly demonstrated by comparing the relative benign impact that reinstituting ventilator support in a patient with a preexistent tracheotomy, with the impact of the initial intubation and ventilation of the same patient a few days or weeks earlier. As noted above, positive-pressure ventilation increases ITP, which must alter venous return. If the patient has reduced vasomotor tone, as commonly exists during induction of anesthesia, the associated increase in Pra will induce a proportional decrease in venous return, pulmonary blood flow and subsequently cardiac output.[1,35,152,202] If the associated tidal volumes are excessive for the duration of expiratory time available to allow for passive deflation, then dynamic hyperinflation will occur, increasing pulmonary vascular resistance and compressing the heart in the cardiac fossa, further decreasing further biventricular volumes.[127] If one were to examine the dynamic effects of ventilation on

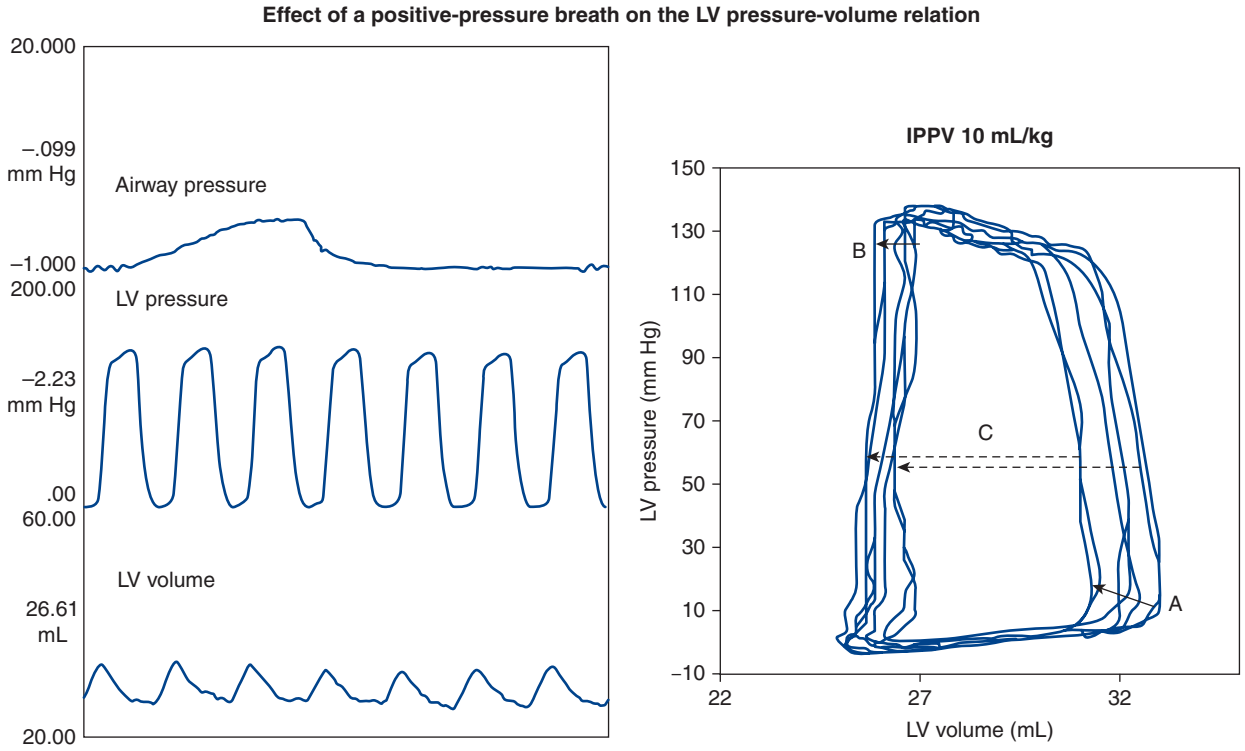

FIGURE 36-9 Dynamic effect of positive-pressure ventilation on the LV pressure-volume relation from end-expiration through a ventilatory cycle. Note the changes in LV filling (maximal end-diastolic volume), diastolic compliance (the slope of the LV pressure-volume relation as LV volume increases during filling: *lower horizontal line*), stroke volume (difference between maximal or end-diastolic volume and minimal or end-systolic volume for a given beat), and the end-systolic pressure-volume relation all change during the course of a single breath. Figure 36-10 shows how changes in tidal volume and intravascular volume alter these changes differently. *IPPV*, intermittent positive-pressure ventilation.

the LV pressure-volume relation over the course of a single breath, one would see a more complex effect, characterized by alterations in LV diastolic compliance, end-diastolic volume, stroke volume, and LV afterload (as exemplified by the leftward shift of the end-systolic pressure-volume relations; Fig. 36-9). Importantly, the impact of ventilation on LV performance, as described in the first part of this chapter, is overly simplified by this assumption that breathing alters only LV preload. Clearly, other factors also function simultaneously. The preload-reducing effects of tidal volume, however, are best described during hypovolemic states, as illustrated in the *right panel* of Figure 36-10. Note that

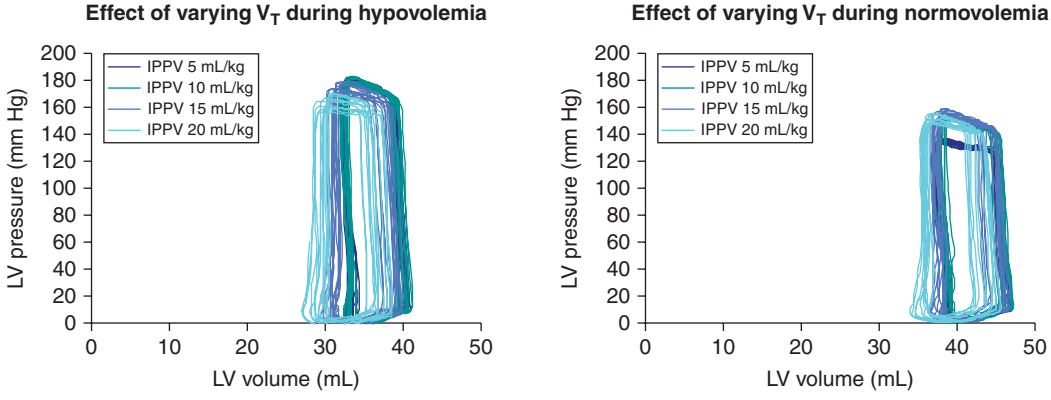

FIGURE 36-10 Effect of increasing tidal volume (V_T) on the LV pressure-volume relationship during normovolemic (*left*) and hypovolemic (*right*) conditions in an intact anesthetized canine model. Under normovolemic conditions, the preload-reducing effects of positive-pressure inspiration become more pronounced at end-inspiration as tidal volume increases. Under hypovolemic conditions, similar increases in tidal volume also tend to decrease the overall size and performance of the heart along lines consistent with pure reductions in LV preload (end-diastolic volume); that is, steady-state LV end-diastolic and end-systolic volumes decrease, end-systolic pressure decreases, and stroke volume decreases with increasing tidal volumes and airway pressures. *IPPV*, intermittent positive-pressure ventilation.

increasing tidal volumes limit ventricular filling, decreasing LV stroke volume under both normovolemic (*left panel*) and hypovolemic (*right panel*) conditions (Fig. 36-10), but this effect is markedly exaggerated by hypovolemia.

HYPERVOLEMIC AND HEART-FAILURE PATIENTS

Initiating mechanical ventilation in hypervolemic patients has far less effect on cardiac output than seen during normovolemic or hypovolemic conditions, because the impact of ventilation on venous return is much less (see *right-hand panel* of Fig. 36-7). Moreover, if such patients also have a component of acute RV volume overload, one may actually see LV diastolic compliance increase and LV output markedly improve. It is not clear, however, if these often-seen improvements in LV performance and cardiac output in hypervolemic conditions represents improved LV filling, reduced metabolic demands, or improved LV contraction. Regrettably, no clinical trials have examined the mechanisms by which such improvement occurs.

Comparing Different Ventilator Modes

Any hemodynamic differences between different modes of total mechanical ventilation at a constant airway pressure and PEEP are a result of differential effects on lung volume and ITP.[203] When two different modes of total or partial ventilator support have similar changes on ITP and respiratory effort, their hemodynamic effects are also similar, despite markedly different airway waveforms. Partial ventilator support with either intermittent mandatory ventilation or pressure-support ventilation give similar hemodynamic responses when matched for similar tidal volumes.[204] Similar tissue oxygenation occurred in ventilator-dependent patients when switched from assist-control, intermittent mandatory ventilation, and pressure-support ventilation with matched tidal volumes.[205] Numerous studies document cardiovascular equivalence when different ventilator modes are matched for tidal volume and level of PEEP.[206,207] Different ventilator modes will affect cardiac output to a similar extent for similar increases in lung volume.[112,208,209] When pressure-controlled ventilation with a smaller tidal volume was compared to volume-controlled ventilation, however, pressure-controlled ventilation was associated with a higher cardiac output.[209,210] Davis et al[211] studied the hemodynamic effects of volume-controlled ventilation versus pressure-controlled ventilation in twenty-five patients with ALI. When matched for the same mean Paw, both modes gave the same cardiac outputs. When Paw, however, was increased during volume-controlled ventilation from a sine-wave to a square-wave flow pattern, cardiac output fell. Furthermore, Kiehl et al found[212] cardiac output better during biphasic positive-airway pressure than during volume-controlled ventilation, leading to an increased $S\bar{V}O_2$ and indirectly increasing Pa_{O_2}. In eighteen ventilator-dependent but hemodynamically stable patients, Singer et al[213] showed that the degree of hyperinflation, not the Paw, determined the decrease in cardiac output. Finally, in an animal model of ALI, Mang et al[214] demonstrated that if total PEEP (intrinsic PEEP plus additional extrinsic PEEP) was similar, no hemodynamic differences were observed between conventional ventilation and inverse-ratio ventilation.

Upper Airway Obstruction

The cardiovascular effects of upper airway obstruction have been reviewed.[215] To understand the effects, it is useful to examine the effect of spontaneous inspiratory efforts against an occluded airway, referred to as a *Mueller maneuver*. This maneuver is easy to create in a graded fashion in the laboratory by having a subject inspire against an occluded airway connected to a manometer; the negative swings in Paw can be controlled by the subject. Based on the above physiologic discussion, it is clear that a Mueller maneuver will result in an increase in both venous return and LV afterload. The hemodynamic effects, however, of positive and negative swings in ITP may not be mirrored opposites of each other; the interactions are nonlinear. As ITP becomes more negative, venous return becomes flow limited as the veins collapse because their transmural pressure becomes negative. LV afterload, however, increases progressively and linearly.[182] Figure 36-4 illustrates these nonlinear effects. Changes in ITP will appear to shift the LV Frank-Starling curve to the left or right, with Pra on the *x* axis, equal to the change in ITP, because the heart is in the chest and acted upon by ITP, whereas venous return is from the body, which is outside of this pressure chamber. Accordingly, large negative swings in ITP will selectively increase LV ejection pressure without greatly increasing RV preload or LV diastolic compliance. This concept is important. Removing large negative swings in ITP without inducing positive swings in ITP, as would occur by endotracheal intubation or tracheotomy to bypass any upper airway obstruction, should selectively reduce LV ejection pressure (LV afterload) and not reduce venous return (LV preload).

Large negative swings in ITP commonly occur in critically ill patients. Upper airway obstruction is a medical emergency. The most common cause of upper airway obstruction is pharyngeal obstruction secondary to loss of muscle tone, which is manifest as snoring or obstructive sleep apnea. Laryngeal edema or vocal cord paralysis following extubation commonly present as acute upper airway obstruction immediately following extubation. Other causes of upper airway obstruction include epiglottis, retropharyngeal hematomas, tumors of the neck and vocal cords, and foreign-body aspiration. Because the site of obstruction is in the extrathoracic airway, increasing inspiratory efforts only cause the obstruction to become more pronounced. By markedly increasing LV afterload, inspiration against an occluded airway rapidly leads to acute pulmonary edema.[130,216–223] During an acute asthmatic attack in a child, peak negative ITP can be −40 cm H_2O and mean tidal ITP

maintained between −24 and −7 cm H_2O,[13] increasing both LV afterload[130,131] and promoting pulmonary edema.[216]

Chronic Obstructive Pulmonary Disease

The hemodynamic consequences of COPD reflect complex issues related to hyperinflation, a propensity to further dynamic hyperinflation and increased airway resistance. Hyperinflation within the context of preexisting reduced pulmonary vascular cross-sectional area and increased pulmonary vasomotor tone, are the primary reasons for ventilation-induced pulmonary hypertension and RV failure. RV afterload is often increased owing to loss of pulmonary parenchyma and hyperinflation. Ventilation–perfusion mismatch can promote further increases in pulmonary vasomotor tone through hypoxic pulmonary vasoconstriction. The ultimate effects of this process are to impede RV ejection and induce by RV dilation, and, if pulmonary hypertension persists, induce RV hypertrophy. An immediate increase in lung volume may decrease RV end-diastolic volume because of cardiac compression and an associated increase in Pra. Neurohumoral reflex mechanisms, however, acting through right atrial stretch receptors cause salt and water retention, causing blood volume and Pra to increase. The goal of this exercise is to restore venous return to its baseline level. Accordingly, the elevated Pra commonly seen in COPD patients reflects a survival strategy analogous to LV dilation in heart failure.

During exacerbations of COPD, hypoxemia, respiratory acidosis, increased intrinsic sympathetic tone, and increased, but inefficient, respiratory efforts combine to increase the work of breathing. The net result is often unpredictable, but certain scenarios often present themselves, which suggests the dominance of one process over the others. These differences are relevant because these identify specific, and often opposite, therapeutic strategies that are used to reverse the associated cardiovascular insufficiency. On a global level, however, any treatments that can reduce airway obstruction and bronchospasm will reduce work of breathing, minimize hyperinflation, and reverse respiratory acidosis and hypoxemia, decreasing RV afterload. Accordingly, the aggressive use of supplemental O_2, bronchodilating agents, and antibiotics to reduce airway infection and the volume and viscosity of secretion will all improve cardiovascular function. If mechanical ventilation can reverse hyperinflation and alveolar hypoxia, one will see reductions in Pra, increases in cardiac output, and less radical arterial pressure swings during ventilation. If, however, hyperinflation persists or is exaggerated by mechanical ventilation, then acute RV failure may occur.

ACUTE COR PULMONALE

Hyperinflation, in the setting of preexisting pulmonary hypertension or decreased pulmonary vessel cross-sectional area, can induce profound increases in pulmonary arterial pressure, promoting acute cor pulmonale. With the initiation of mechanical ventilation, it is easy to set tidal volume too large and inspiratory time too long, promoting dynamic hyperinflation.[224,225] Every effort should be made to minimize this life-threatening complication. Importantly, the cardiovascular management of this life-threatening process is to reduce RV wall strain and maintain or improve RV coronary perfusion. These considerations are briefly summarized. First, one almost always sees acute elevations of Pra, often accompanied by acute tricuspid regurgitation at end-inspiration. If a pulmonary arterial catheter is present, Pra equal or exceed pulmonary artery occlusion pressure. Furthermore, if the catheter has the ability to measure RV ejection fraction, it almost always reduced (<40%). Importantly, acute volume infusions will only compromise the dilated right ventricle further, such that both stroke volume and RV ejection fraction are decreased. These are clear signs of impending or existing cardiovascular collapse secondary to acute cor pulmonale. Because most of RV myocardial blood flow occurs in systole, maintaining aortic pressure higher than pulmonary arterial pressure to sustain RV myocardial perfusion is an essential aspect of the initial cardiovascular management.

LEFT-VENTRICULAR FAILURE

Although COPD is usually characterized by right-sided dysfunction owing to the alterations in pulmonary vascular biology, these subjects also tend to be smokers, elderly, and male, three demographic qualities that place them at high risk of coronary artery disease. With the exception of intubation-induced hypotension and reactive tachycardia, the risk of LV ischemia during intubation and sustained mechanical ventilation is relatively low in these patients. Because they are usually volume overloaded and have a reduced cardiac reserve before intubation, these patients usually benefit from a reduction in metabolic demands and reduced ventricular interdependence owing to the smaller RV volumes. Patients with COPD may fail weaning attempts because their work of breathing exceeds their cardiovascular reserve.[226,227] Just as these patients cannot climb two flights of stairs, they may wean because of impaired cardiovascular reserve. The combination of occult impaired cardiovascular reserve and the stress of spontaneous ventilation, with associated negative swings in ITP and positive swings intraabdominal pressure, which augment venous return, provide a primary reason for cases of weaning failure characterized by hypoxemia or transient pulmonary edema. Beach et al demonstrated many years ago that heart-failure patients who are ventilator-dependent may be weaned if pharmacologic support of the heart is subsequently introduced.[152]

Auto–Positive End-Expiratory Pressure

The hemodynamic effects of positive-pressure ventilation are caused by changes in ITP, not airway pressure. This concept greatly influences the analysis of heart–lung interactions in patients with lung disease. As discussed above (see the

section "Physiology of Heart-Lung Interactions"), the primary determinants of the hemodynamic responses to ventilation are secondary to changes in ITP and lung volume,[3] not Paw. The relation between Paw, ITP, pericardial pressure, and lung volume varies with spontaneous ventilatory effort, lung compliance, and chest wall compliance. Lung and thoracic compliance determine the relation between end-expiratory Paw and lung volume in the sedated paralyzed patient. If a ventilated patient, however, actively resists lung inflation or sustains expiratory muscle activity at end-inspiration, then end-inspiratory Paw will exceed resting Paw for that lung volume. Similarly, if the patient activity prevents full exhalation by expiratory braking, then for the same end-expiratory Paw, lung volume may be much higher than predicted from end-expiratory Paw values alone. Finally, even if inspiration is passive and no increased airway resistance is present, Paw may rapidly increase over minutes as chest wall compliance decreases. During inspiration, positive-pressure Paw increases as a function of both total thoracic compliance and airway resistance. Patients with marked bronchospasm will display a peak Paw greater than end-inspiratory (plateau) Paw. The difference between measured Paw and Palv is called *auto-PEEP*.[224,225] Changes in transpulmonary pressure and total thoracic compliance alter FRC, and FRC is the primary volume about which all hemodynamic interactions revolve.

FRC is a nefarious value. When one reclines from a standing position, FRC may decrease by as much as 500 mL in a 70-kg healthy male. PEEP and CPAP increase FRC by offsetting Palv. If a subject does not have sufficient time to exhale completely to FRC, however, then the next breath will stack upon the extra lung volume present. Bergman described this concept of dynamic hyperinflation many years ago.[224] Pepe and Marini coined the term "auto-PEEP" to connote the similarities between dynamic hyperinflation (also called occult PEEP) and extrinsically applied PEEP.[225] Auto-PEEP is not measured by the ventilator, as part of its usual parameters, and may go unappreciated. Yet, it functions identically to extrinsic PEEP in altering pulmonary vascular resistance and recruiting alveoli. The hemodynamic effect of this hyperinflation is to increase ITP and pulmonary vascular resistance, and compress the heart within the cardiac fossa. Thus, one may see Pra and pulmonary artery occlusion pressure progressively increase as arterial pulse pressure and urine output decrease. One may then make the erroneous diagnosis of acute heart failure, when all that is occurring is hyperinflation and the unaccounted increase in ITP. If one adds extrinsic PEEP to the ventilator circuit of patients with auto-PEEP, no measurable hemodynamic effects are seen until extrinsic PEEP exceeds auto-PEEP levels.[228] These data suggest that auto-PEEP and extrinsic PEEP have identical hemodynamic effects during controlled mechanical ventilation.

During assisted ventilator support, however, or spontaneous breathing, auto-PEEP adds an additional elastic workload on the respiratory muscles. This increased workload is often the cause of failure to wean because spontaneous breathing trials are often associated with tachypnea, which prevents adequate time for complete exhalation. Clinical signs and symptoms suggestive of hemodynamically significant auto-PEEP include increased anxiety and agitation during spontaneous breathing associated with a marked increase in respiratory efforts and paradoxical chest wall motion. Because changes in ITP are occurring even though no air movement initially takes place, an arterial pressure recording will show immediate decreases in diastolic arterial pressure without changes in pulse pressure until the inspiratory breath finally occurs. Finally, by adding progressive increases in extrinsic PEEP to the ventilator circuit during a spontaneous breathing trial, changes in arterial diastolic pressure and pulse pressure will start to occur in unison as ventilatory efforts recouple with the ability to cause airflow.

Acute Respiratory Distress Syndrome and Acute Lung Injury

Patients with ALI have decreased aerated lung volumes owing to alveolar collapse and flooding. Because lung expansion during positive-pressure inspiration pushes on the surrounding structures, distorting them, this expansion causes thoracic surface pressures to increase. The degree of lateral chest wall, diaphragmatic or juxtacardiac ITP increase, relative to each other as lung volume increases, will be a function of the compliance and inertance of their opposing structures.[71] Changes in pleural pressure (Ppl) induced by positive-pressure inflation are different among differing lung regions (Fig. 36-11). Pleural pressure close to the diaphragm increases least during inspiration, and juxtacardiac Ppl increases most, presumably because the diaphragm is very compliant whereas the mediastinal contents are not. If abdominal distension develops, however, then the diaphragm will become relatively noncompliant and ITP will increase similarly across the entire thorax. Increasing Paw to overcome chest wall stiffness (abdominal distension) in secondary acute respiratory distress syndrome should produce a greater increase in ITP, with greater hemodynamic consequences, but it should not improve gas exchange, because the alveoli are not damaged. Conversely, if lung compliance is reduced, as in primary acute respiratory distress syndrome, then for a similar increase in Paw, ITP will increase less, creating fewer hemodynamic effects, but also recruiting more collapsed and injured alveolar units, improving gas exchange. If lung injury induces alveolar flooding or increased pulmonary parenchyma stiffness, then greater increases in Paw will be required to distend the lungs to a constant end-inspiratory volume. Romand et al[82] demonstrated that although Paw increased more during ALI than under control conditions for a constant tidal volume, the increases in lateral chest wall Ppl and pericardial pressure were equivalent for both conditions if tidal volume was held constant (see Fig. 36-11). The primary determinant of the increase in Ppl and pericardial pressure during positive-pressure ventilation is lung volume change, not Paw change.[84]

The distribution of alveolar collapse and lung compliance in ALI is nonhomogeneous. Accordingly, lung distension

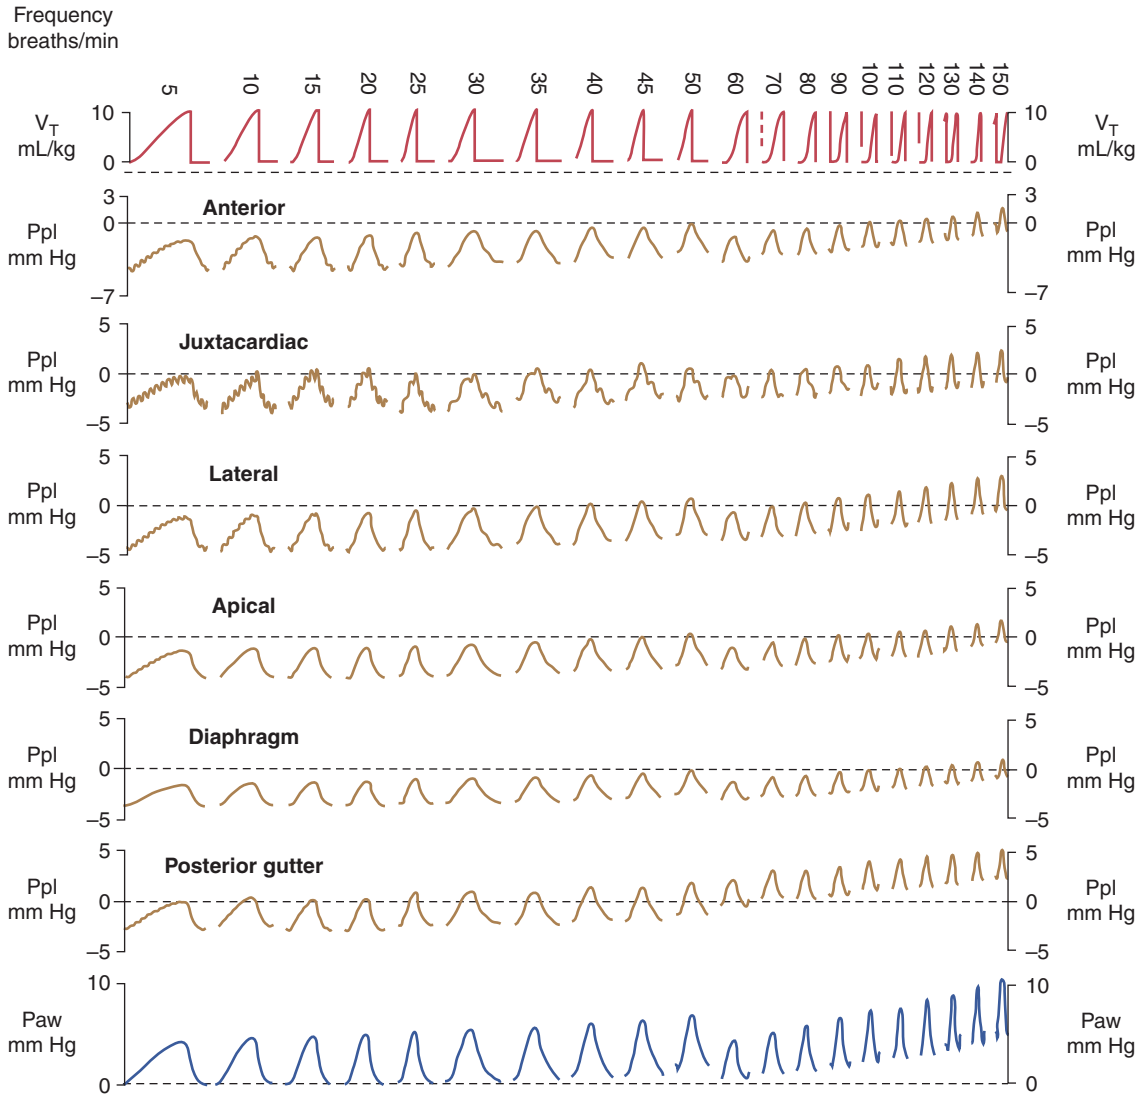

FIGURE 36-11 Effect of increasing ventilatory frequency on regional pleural pressure (Ppl) changes in the lung of an intact dog. Ppl (mean ± standard error [SE]) for six pleural regions of the right hemothorax of an intact supine canine model. *Paw*, airway pressure; V_T, tidal volume. (Reproduced, with permission, from Novak, et al. Effect of positive-pressure ventilatory frequency on regional pleural pressure. *J Appl Physiol.* 1988;65:1314–1323.)

during positive-pressure ventilation must reflect overdistension of some regions at the expense of poorly compliant regions because aerated lung units display a normal specific compliance.[85] Accordingly, Paw will reflect distension of lung units that were aerated before inspiration, but may not reflect the degree of lung inflation of nonaerated lung units. Pressure-limited ventilation assumes that this is the case and aims to limit Paw in ALI states so as to prevent overdistension of aerated lung units, with the understanding that tidal volume, and thus minute ventilation, must decrease. Thus, pressure-limited ventilation will hypoventilate the lungs, leading to "permissive" hypercapnia. In an animal model of ALI, when tidal volume was either kept constant at preinjury levels or reduced to match preinjury plateau pressure, both Ppl and pericardial pressure increased less as compared with either the pre–lung injury states or the ALI state, but with tidal volume set at the preinjury levels.[82] These points underlie the fundamental hemodynamic differences seen when different ventilator modes are compared to each other. Important for the hemodynamic effects of ventilation in ALI, vascular structures that are distended will have a greater increase in their surrounding pressure than collapsible structures that do not distend.[229] However, both Romand et al [82] and Scharf and Ingram[83] demonstrated that, despite this nonhomogeneous alveolar distension, if tidal volume is kept constant, then Ppl increases equally, independently of the mechanical properties of the lung. Thus, under constant tidal volume conditions, changes in peak and mean Paw will reflect changes in the mechanical properties of the lungs and patient coordination, but may not reflect changes in ITP.

Similarly, these changes in Paw may not alter global cardiovascular dynamics.

Positive-pressure ventilation can also have beneficial effects on hemodynamics in ALI patients. Intentional hyperinflation in subjects with ALI, induced by the use of supplemental PEEP to treat hypoxemia, may reduce pulmonary vascular resistance, if lung recruitment and aeration of hypoxic alveolar units reduces hypoxic pulmonary vasoconstriction; eventually, however, increase pulmonary vascular resistance must increase as all lung units are expanded above their normal resting volumes.[230] Applying the least amount of PEEP necessary to achieve an adequate Pa_{O_2} and fractional inspired oxygen concentration (FI_{O_2}) combination should be associated with the least-detrimental hemodynamic effects.

Congestive Heart Failure

Patients with CHF are difficult to wean from the ventilator because the increases in work of breathing, venous return, and intrathoracic blood volume during the transition from assisted to spontaneous ventilation may cause acute pulmonary edema. Rasanen et al documented that decreasing levels of ventilator support in patients with myocardial ischemia and acute LV failure worsened ischemia and promoted the development of pulmonary edema.[181,231] These effects could be minimized by preventing effort-induced negative swings in ITP by the use of CPAP while allowing the patient to continue to breathe spontaneously.[182] Thus, in these patients, it is not the work-cost of breathing that is inducing heart failure, but the negative swings in ITP. Presumably, the ability of CPAP to decrease ventricular explains the beneficial effects of CPAP during weaning trials.

If increases in ITP during positive-pressure ventilation decrease LV afterload, why then does positive-pressure ventilation not induce an increase in cardiac output in patients with CHF? The answer is that it does. Increases in cardiac output with Paw increases suggest the presence of CHF.[182,187] Grace and Greenbaum[232] noted that adding PEEP in patients with heart failure did not decrease cardiac output; cardiac output actually increased if pulmonary artery occlusion pressure exceeded 18 mm Hg. Similarly, Calvin et al[233] noted that patients with cardiogenic pulmonary edema had no decrease in cardiac output when given PEEP.[234] Finally, Pinsky et al demonstrated that ventilator-induced increases in ITP, using ventilatory frequencies of 12 to 20 breaths/min (phasic high intrathoracic pressure support; see Fig. 36-11) and increases in ITP synchronized to occur with each cardiac systole (cardiac cycle-specific where ventilator frequency equals heart rate; Fig. 36-12) greatly increased cardiac output in cardiomyopathy.[235,236] Note the similarities in the increase in mean cardiac output seen with systolic synchronized ventilation with the cardiovascular responses to similar systolic synchronized ventilation (see Fig. 36-8), which was derived in an acute animal model, wherein many more hemodynamic measures were made.

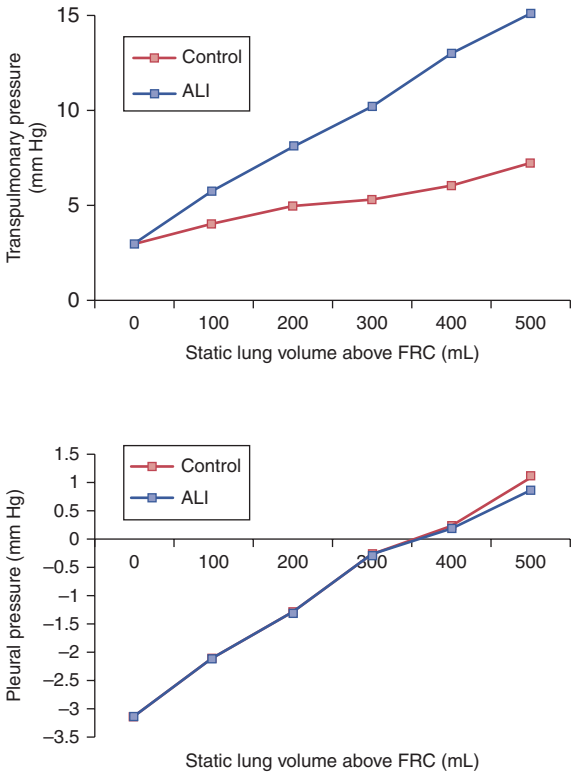

FIGURE 36-12 Relation between transpulmonary pressure (*top*) and pleural pressure (*bottom*) and lung volume as lung volume is progressively increased above functional residual capacity (FRC) in control and oleic acid-induced acute lung injury (ALI) conditions in a canine model. Note that despite greater increases in transpulmonary pressure for the same increase in lung volume during ALI as compared to control conditions, pleural pressure increases similarly during both control and ALI conditions for the same increase in lung volume. (Reproduced, with permission, from Romand, et al. Cardiopulmonary effects of positive pressure ventilation during acute lung injury. *Chest.* 1995;108:1041–1048.)

These beneficial effects do not required endotracheal intubation. They are realized with the use of mask CPAP. In fact, CPAP levels as low as 5 cm H_2O can increase cardiac output in patients with CHF. Cardiac output, however, decreases with similar levels of CPAP in both normal subjects and in patients with heart failure who are not volume overloaded. Nasal CPAP can also accomplish the same results in patients with obstructive sleep apnea and heart failure,[237] although the benefits do not appear to be related to changes in obstructive breathing pattern.[238] Prolonged nighttime nasal CPAP can selectively improve respiratory muscle strength and LV contractile function in the patients who have preexisting heart failure.[239,240] These benefits are associated with reductions of serum catecholamine levels.[241] There is no special effect of nonintubated CPAP on cardiac performance. In patients with hypovolemic CHF, as manifested by a pulmonary artery occlusion pressure equal to or less than 12 mm Hg, CPAP and biphasic positive airway pressure, at the same mean airway pressure, decrease cardiac outputs equally.[242]

If noninvasive ventilation improves LV performance in patients with both obstructive sleep apnea and CHF, can noninvasive ventilation then be useful in treating acute cardiogenic pulmonary edema? Several workers have asked this question. Rasanen et al[182] used mask CPAP to treat patients with acute coronary insufficiency and cardiogenic pulmonary edema. They demonstrated that myocardial ischemia was reversed by CPAP, but only after the level of CPAP was adjusted to prevent negative swings in ITP. CPAP levels below this threshold did not improve LV performance. The amount of CPAP needed to abolish negative swings in ITP, however, varied among patients. This is important, because subsequent clinical trials of CPAP to treat cardiogenic pulmonary edema used only fixed levels of CPAP, not CPAP levels titrated to abolish negative swings in ITP. Several early studies demonstrated that mask CPAP improved gas exchange and reduced the need for endotracheal intubation.[243,244] Mortality and hospital length of stay, however, were usually similar among patients on CPAP and conventional O_2,[245–247] suggesting that prevention of intubation is not a determinant of outcome from cardiogenic pulmonary edema. Consistent with an afterload-sparing effect of blocking negative swings in ITP, both CPAP and biphasic positive airway pressure, which decrease equally the negative swings in ITP, demonstrated similar improvement in oxygenation without changing long-term outcome.[248] The lack of long-term benefit from CPAP in acute cardiogenic pulmonary edema underscores the importance of separating outcome from acute processes characterized by symptoms (cardiogenic pulmonary edema) from underlying pathology (CHF). In fact, it would be surprising if mask CPAP had improved outcome as long as endotracheal intubation remained the default option for CHF. Still, abolishing negative swings in ITP acutely improves cardiac function in heart-failure patients.

One cannot, however, readily apply increasing ITP to augment LV performance because the effect rapidly becomes self-limited as venous return declines. This is analogous to phase 3 of the Valsalva maneuver. The effect of removing large negative levels of ITP, however, does not have the same effect on venous return as does increasing ITP. Because venous return if flow-limited below an ITP of zero, removing large negative swings in ITP will not alter venous return. The effect, however, of removing negative ITP swings on LV afterload will be identical millimeter of mercury for millimeter of mercury to adding positive ITP. Thus, any relative increase in ITP from very negative values to zero, relative to atmosphere, will minimally alter venous return, but markedly reduce LV afterload. Removing large negative swings in ITP by either bypassing upper airway obstruction (endotracheal intubation) or instituting mechanical ventilation or PEEP-induced loss of spontaneous inspiratory efforts, should selectively reduce LV afterload, without significantly decreasing either venous return or cardiac output.[87,100,117,131,166,182,249] The cardiovascular benefits of positive airway pressure on nonintubated patients can be seen by withdrawing negative swings in ITP, as created by using increasing levels of CPAP.[250,251]

Intraoperative State

Most elective surgery patients are kept relatively hypovolemic before surgery because of the risk of aspiration pneumonia during induction. They are not allowed food for 8 to 12 hours, nor anything by mouth for 6 hours before surgery, and they rarely are given intravenous fluids before coming into the operating room. Moreover, with the induction of general anesthesia, basal sympathetic tone is markedly reduced. Thus, it is amazing how little cardiovascular compromise occurs in this setting. Two factors may explain the lack of significant cardiovascular compromise. First, almost all patients are supine, and do not have to perform work; thus, venous return is maximized, and metabolic demand reduced. Second, almost all anesthesiologists insert an intravenous catheter to infuse anesthetic agents; usually they use this port to rapidly infuse large volumes of saline solutions as part of the induction. Nevertheless, to the extent that vasomotor tone is compromised, venous return will decrease, causing cardiac output to become a limiting cardiovascular variable.

Independent of these initial blood volume and vasomotor tone effects, other events can profoundly alter cardiovascular status. Both laparotomies and thoracotomies cause cardiac output to decrease by altering heart–lung interactions. Recall that the primary determinant of venous return is the pressure gradient between the venous reservoirs and Pra (see Fig. 36-4). Because a little over half of the venous blood resides in the abdomen, intraabdominal pressure represents a significant determinant of mean systemic pressure.[114] This point was illustrated earlier, when it was shown that diaphragmatic descent during positive-pressure inspiration pressurized the intraabdominal compartment, minimizing the decrease in venous return predicted by the associated increase in Pra (see Fig. 36-5). During abdominal surgery, however, the act of opening the abdomen and keeping it open abolishes the effect of diaphragmatic descent on intraabdominal pressure. Accordingly, an open laparotomy induces a fall in cardiac output by making the pressure gradient for venous return dependent only on changes in Pra. From the opposite side of the venous return curve, changes in Pra are dependent on changes in ITP. Thus, an open thoracotomy, by abolishing the end-expiratory negative ITP, induces an immediate increase in Pra, causing cardiac output to decrease.

During general anesthesia, most intubated patients have their ventilation completely controlled by the ventilator. Under these conditions, assuming that tidal volume and PEEP remain constant, the hemodynamic effects of ventilation remain remarkably constant. One can use this phasic-forcing function to assess preload responsiveness, as discussed above (see the Clinical scenarios, Initiating mechanical ventilation and Figure 36-9). Specifically, positive-pressure ventilation induces a cyclic change in LV end-diastolic volume, owing to complex and often different processes. But these ventilation phase-specific changes in LV end-diastolic occur anyway. Thus, in patients whose global cardiovascular system is preload-responsive, they will also manifest ventilation-induced

changes in LV stroke volume and arterial pulse pressure. When quantified as a pressure-induced stroke-volume variation or pulse-pressure variation, numerous studies show that these measures reflect robust and profoundly simple means to assess preload responsiveness.[192–194,200,252,253]

STEPS TO LIMIT OR OVERCOME DETRIMENTAL HEART–LUNG INTERACTIONS

Two major approaches can be used to minimize deleterious cardiovascular interactions while augmenting the beneficial ones: those focusing on ventilation and those focusing on cardiovascular status. All these approaches, however, are relative.

Minimize Work of Breathing

The most obvious technique for minimizing work of breathing during spontaneous ventilation is to decrease airway resistance and recruit collapsed alveolar units. Because ventilation is exercise, minimizing the metabolic load on the respiratory muscles allows blood flow to be diverted to other organ systems in need of O_2. Bronchodilator therapy and recruitment maneuvers accomplish these effects.

Minimize Negative Swings in Intrathoracic Pressure

It is important to minimize the negative swings in ITP during spontaneous breathing because these swings account for the increased intrathoracic blood volume and increased LV afterload, and can induce acute LV failure and pulmonary edema. Still, allowing normal negative swings in ITP at end-expiration promotes normal venous return and maintains cardiac output higher than during positive-pressure ventilation in patients with hemorrhagic shock. Although promoting inspiratory strain to augment cardiac output is the logical extension of this concept,[122] this logic is self-limiting because the associated increase in metabolic demand exceeds the associated increase in blood flow. Numerous studies, cited above, document the improvements in myocardial O_2 demand, ischemia, and cardiovascular reserve achieved by this strategy. All these effects can be realized in nonintubated patients using noninvasive mask CPAP and biphasic positive airway pressure (Figs. 36-13 and 36-14).

Prevent Hyperinflation

Third, by preventing overdistension of the lungs, pulmonary vascular resistance will not increase, cardiac filling will not be impeded, and venous return will remain at or near maximal levels. Several important caveats, however, need to be listed. First, hyperinflation is not PEEP. Recruitment

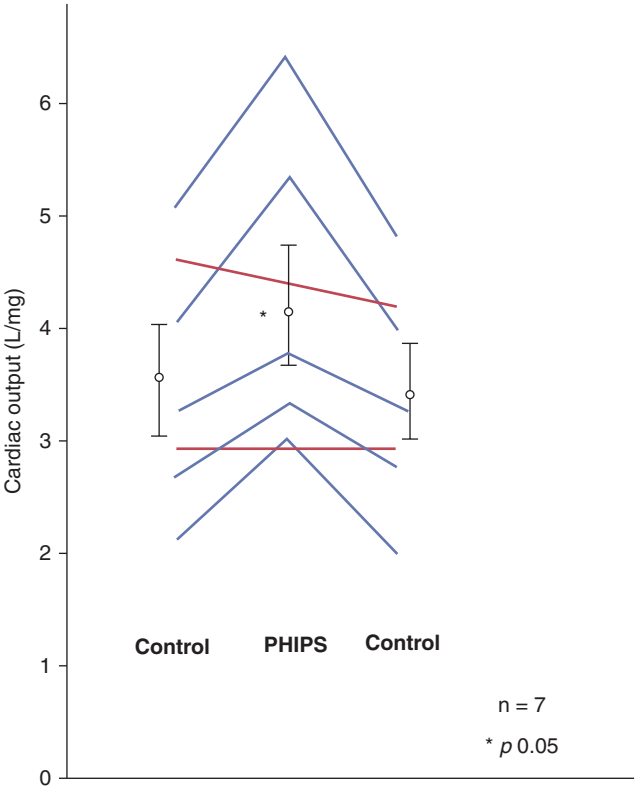

FIGURE 36-13 Effect of phasic high intrathoracic pressure support (PHIPS) on cardiac output in ventilator-dependent patients. (Used, with permission, from Pinsky MR, Summer WR. Cardiac augmentation by phasic high intrathoracic pressure support (PHIPS) in man. *Chest*. 1983;84:370–375.)

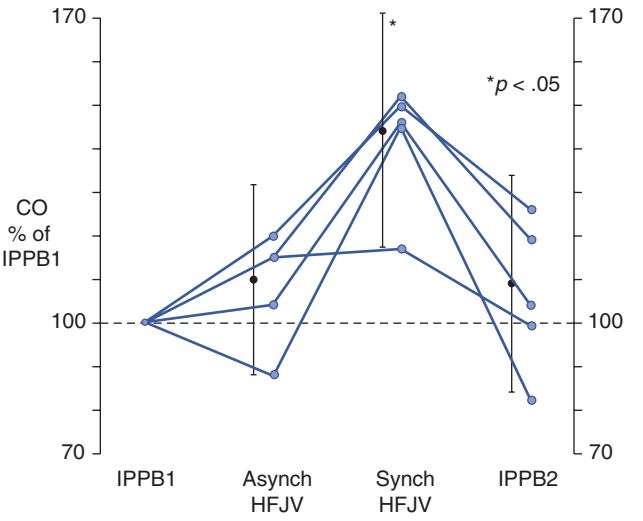

FIGURE 36-14 Effect of cardiac cycle–specific increases in airway pressure, delivered by a synchronized high-frequency jet ventilator in intraoperative patients with congestive heart failure. Note that for the same mean airway pressure, tidal volume, and ventilatory frequency, the placement of the inspiratory pulse within the cardiac cycle has profoundly different effects. (Used, with permission, from Pinsky et al. Ventricular assist by cardiac cycle-specific increases in intrathoracic pressure. *Chest*. 1987,91:709–715.).

of collapsed alveoli and stabilization of injured alveoli in an aerated state often requires the use of PEEP, which itself may reduce pulmonary vascular resistance. Although overdistension of aerated alveoli will improve gas exchange further, it will also increase pulmonary vascular resistance. Thus, one should use the lowest level of PEEP required to create adequate oxygenation. Second, in CHF, lung inflation improves LV ejection effectiveness[254] and may itself reflect a type of ventricular support.

Fluid Resuscitation during Initiation of Positive-Pressure Ventilation

The act of endotracheal intubation is often accompanied by complex manipulations, including the use of anesthetic and analgesic agents, and institution of positive-pressure ventilation. The consequent reduction in sympathetic tone and increase in Pra act synergistically to reduce venous return. These combined effects can be lifesaving in patients with cardiogenic pulmonary edema. In otherwise healthy subjects or in patients with hypovolemia (e.g., trauma), however, these additive effects can induce hypovolemic cardiovascular collapse. Thus, the bedside caregiver should be prepared to rapidly infuse intravascular volume to potentially hypovolemic patients during the act of endotracheal intubation.

Prevent Volume Overload during Weaning

The transition from positive-pressure to spontaneous ventilation must reduce ITP and increase oxygen consumption. Thus, patients are at risk of developing or worsening pulmonary edema, myocardial ischemia, and acute LV failure during weaning trials. Before initiating a spontaneous breathing trial, it is important to ensure that a patient is not volume overloaded. Steps to minimize volume overload include limiting fluids before weaning trials, forced diuresis in the setting of overt volume overload and pleural effusion, and gradual reduction in the level of positive-pressure through the use of partial support modes, so as to allow fluid shifts to be excreted in urine. Furthermore, in patients with markedly increased total-body water, fluid resorption often accelerates as Pra decreases. Thus, attention to subsequent fluid overload over the days following extubation and the use of limited intravascular fluids or forced diuresis is often needed to prevent reintubation. A clinician cannot presume that a patient with clear evidence of increased extravascular water has been successfully extubated when an endotracheal tube has been removed or even several hours later. Although detailed studies on the pathophysiology of extubation failure have not been conducted, and while failure may be multifactorial, cardiovascular compromise secondary to subsequent volume overload from either fluid resorption or intravascular volume loading (often manifested by increased secretions, wheezing, and hypoxemia) is likely to be one important cause.

Augment Cardiac Contractility

Because spontaneous breathing trial is exercise, it may precipitate acute coronary insufficiency, even in patients who are successfully weaned. Almost 40 years ago, Beach et al demonstrated that many ventilator-dependent patients can be successfully weaned if they are simultaneously given a positive inotropic agent, such as dobutamine.[152] Although no prospective clinical trial has ever been done to address this issue, many physicians support such patients with dobutamine infusions for 12 to 24 hours before a spontaneous breathing trial. If one were to use this approach, then the inotropic agent may still be needed following extubation and weaned thereafter, because the work of breathing may remain high even if the endotracheal tube is not contributing to the increase in airway resistance.

IMPORTANT UNKNOWNS

Perhaps the most important unknown in assessing the hemodynamic effect of ventilation is the assessment of cardiovascular reserve and the effects of breathing on hyperinflation and the swings in ITP. To date, no set of physiologic variables derived from measures of respiratory performance or ventilatory reserve have proven reliable in predicting weaning outcome in the setting of acute ventricular failure. In large part, we believe, this failure reflects an underappreciation of the role that cardiovascular responsiveness plays in weaning and the inadequate methods for assessing cardiovascular reserve. In essence, physicians have chosen an oversimplistic approach, and now institute blind daily spontaneous breathing trials to define when a patient is capable of weaning. Although this approach is commendable in its simplicity, it still places patients who would obviously fail such trials at risk of coronary ischemia, ongoing respiratory muscle fatigue, and impaired gas exchange secondary to LV failure and hydrostatic pulmonary edema. Because the breathing pattern can change in just one breath, and physiologically significant hyperinflation can occur in a single breath, it is probably impossible to predict with accuracy whether one can wean or not from mechanical ventilatory trials using static measures.

THE FUTURE

The future of heart–lung interactions is wedded to both new and evolving methods of mechanical ventilation and our increasing reliance on clinical techniques, like the spontaneous breathing trial, to predict weaning success and the need for supplemental cardiovascular support. To the extent that new techniques of ventilator support follow the principle of proportional assist ventilation, they will limit the detrimental effects of positive-pressure ventilation and patient–ventilator dyssynchrony, minimizing the work of breathing. Mask CPAP will need to be titrated to minimize negative swings in

ITP. To the extent that mask CPAP abolishes swings in ITP, it promotes LV ejection efficiency and minimizes LV failure. The use of pressure-limited ventilation in patients with ALI has resulted in decreases delivered tidal volume. Because increases in ITP are linked to changes in lung volume, these newer ventilatory strategies must result in less cardiovascular dysfunction than were seen with use of higher tidal volumes and peak airway pressures used in the past.

Acute care medicine is evolving from a static treatment and monitoring center into a proactive diagnostic and treatment center. We now use pulse pressure and stroke volume variation during positive-pressure ventilation to identify those hemodynamically unstable patients who are likely to respond to a volume challenge with an increase in cardiac output, and by how much. In the future, patients would be better served if clinicians were to examine the immediate hemodynamic effects of spontaneous breathing trials before patients progressed to ventilatory and cardiovascular deterioration. Invasive and noninvasive measures of tissue oxygenation using data derived from pulmonary artery catheters, central venous catheters, pulse oximetry, and newer evolving noninvasive technologies will result in a dynamic assessment of impending respiratory failure and its causes. The future is upon us, and will be led by the firms that are developing newer noninvasive technologies that address these specific issues.[255]

SUMMARY AND CONCLUSIONS

Our understanding of clinically relevant cardiopulmonary interactions has advanced far over the past 50 years. What was once cloaked with much mystery, now seems obvious. Still, complacency in the application of these principles at the bedside should be avoided. Just as we thought we knew all there was to know about COPD 20 years ago, the entire management scheme was altered with a better understanding of dynamic hyperinflation and auto-PEEP.[224,225] Similarly, the exact nature by which heart–lung interactions define myocardial ejection efficiency and myocardial O_2 requirements in both ALI states and severe airflow obstruction remain to be defined.

The hemodynamic effects of ventilation are multiple and complex, but can be grouped into four clinically relevant concepts. First, spontaneous ventilation is exercise. In patients' increased work of breathing, initiation of mechanical ventilation improves O_2 delivery to the remainder of the body by decreasing O_2 consumption. To the extent that mixed venous P_{O_2} increases, arterial P_{O_2} will also increase without any improvement in gas exchange. Similarly, weaning from mechanical ventilatory support is a cardiovascular stress test. Patients who fail weaning exhibit cardiovascular insufficiency during the failed weaning attempts. Improving cardiovascular reserve or supplementing support with inotropic therapy may allow patients to wean.

Second, changes in lung volume alter autonomic tone and pulmonary vascular resistance, and high lung volumes compress the heart in the cardiac fossa, similarly to cardiac tamponade. As lung volume increases, so does the pressure difference between airway and Ppl. When this pressure difference exceeds pulmonary artery pressure, pulmonary vessels collapse as they pass from the pulmonary arteries into the alveolar space, increasing pulmonary vascular resistance. Thus, hyperinflation increases pulmonary vascular resistance and pulmonary artery pressure, which impede RV ejection. Decreases in lung volume below FRC, as occurs in ALI and alveolar collapse, also increase pulmonary vasomotor tone by the process of hypoxic pulmonary vasoconstriction. Recruitment maneuvers, PEEP, and CPAP may reverse hypoxic pulmonary vasoconstriction and reduce pulmonary artery pressure.

Third, spontaneous inspiratory efforts decrease intrathoracic pressure. Because diaphragmatic descent increases intraabdominal pressure, these combined effects cause Pra inside the thorax to decrease but venous pressure in the abdomen to increase, which markedly increases the pressure gradient for systemic venous return. Furthermore, the greater the decrease in intrathoracic pressure, the greater the increase in LV afterload for a constant arterial pressure. Mechanical ventilation, by abolishing the negative swings in intrathoracic pressure, selectively decreases LV afterload, as long as the increases in lung volume and intrathoracic pressure are small.

Finally, positive-pressure ventilation increases ITP. Because diaphragmatic descent increases intraabdominal pressure, the decrease in the pressure gradient for venous return is less than would otherwise occur if the only change were an increase in Pra.[3] In hypovolemic states, however, positive-pressure ventilation can induce profound decreases in venous return. Increases in intrathoracic pressure decreases LV afterload and will augment LV ejection. In patients with hypervolemic heart failure, this afterload reducing effect can result in improved LV ejection, increased cardiac output, and reduced myocardial O_2 demand.

EFFECT OF MECHANICAL VENTILATION ON GAS EXCHANGE

Roberto Rodriguez-Roisin
Antoni Ferrer

The major function of the lung is to exchange physiologic (respiratory) gases, namely oxygen (O_2) and carbon dioxide (CO_2). Once the lungs fail as a gas exchanger, arterial hypoxemia, hypercapnia, or both appear and respiratory failure ensues. Arterial P_{O_2} (Pa_{O_2}) and P_{CO_2} (Pa_{CO_2}) are the measurable end-point variables used routinely by clinicians to manage patients with acute respiratory failure. When the latter is severe, mechanical ventilation is then considered the final strategy for treating patients.

RELEVANCE

Classically, the mechanisms of hypoxemia are alveolar hypoventilation, limitation of alveolar to end-capillary O_2 diffusion, intrapulmonary shunt, and ventilation–perfusion ($\dot{V}_A/\dot{Q}$) imbalance; the major causes of hypercapnia are alveolar hypoventilation and $\dot{V}_A/\dot{Q}$ mismatching.[1] Ideally, it would be of great interest to solely manage respiratory blood-gas measurements, such as alveolar-arterial P_{O_2} difference $P(A\text{-}a)O_2$, venous admixture ratio ($\dot{Q}_S/\dot{Q}_T$), and physiologic dead space (dead-space-to-tidal-volume ratio [V_D/V_T]), as a general marker of the overall function of the lung. Thus, impaired or improved results of these variables, whose principal merits are their simplicity and relative ease of measurement, could reflect impaired or improved pulmonary gas exchange. Unfortunately, all these variables reflect not only the state of the lung, but also the conditions under which the lung is operating. These conditions, which uniquely determine the P_{O_2} and P_{CO_2} in any single gas-exchange unit of the lung, are the $\dot{V}_A/\dot{Q}$ ratio, the composition of inspired gas, and the composition of mixed venous blood heavily modulated by the behavior of the cardiac output.[2,3] It is important to appreciate the key role played by these three factors governing the respiratory gases in any single gas-exchange unit.[3]

PHYSIOLOGY: MULTIPLE INERT GAS ELIMINATION TECHNIQUE

This chapter reviews the effect of ventilator support on pulmonary gas exchange using the multiple inert gas elimination technique (MIGET), an approach that represents a major conceptual breakthrough in our understanding of pulmonary medicine pathophysiology in disease states.[4–7] MIGET has three major advantages. First, it estimates the pattern of pulmonary blood flow and alveolar ventilation and calculates the mismatch of $\dot{V}_A/\dot{Q}$ relationships. Second, it partitions the $P(A\text{-}a)O_2$ into determinants of intrapulmonary shunt, $\dot{V}_A/\dot{Q}$ inequality, and diffusion limitation to O_2. Third, it apportions and unravels arterial oxygenation into intrapulmonary, namely the latter three factors, and extrapulmonary components, that is, inspired P_{O_2}, overall ventilation, cardiac output, and O_2 consumption. Of paramount importance is the ability to perform measurements at any

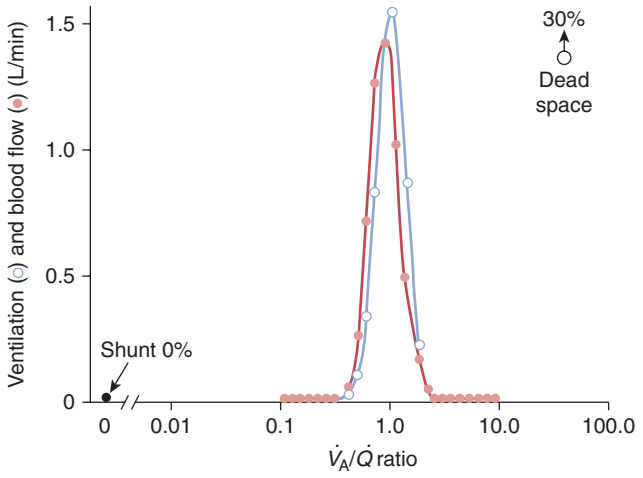

FIGURE 37-1 Distributions of alveolar ventilation and pulmonary blood flow plotted versus $\dot{V}_A/\dot{Q}$ ratio. For further explanation, see text.

fractional inspired oxygen concentration (FI_{O_2}) without perturbing the vascular and bronchomotor tones.[8]

Figure 37-1 illustrates the $\dot{V}_A/\dot{Q}$ distribution obtained with MIGET in a healthy, young individual at rest breathing ambient air. Each data point represents a particular amount of blood flow or alveolar ventilation. Both overall pulmonary perfusion and total ventilation correspond to the sum of the respective data points (the lines have been drawn for clarity only). These quantities (distributions) are plotted against a broad range (50) of $\dot{V}_A/\dot{Q}$ ratios, from zero (intrapulmonary shunt) to infinity (dead space), on a log scale. The unimodal profile of each distribution has three main characteristics: symmetry, location around a $\dot{V}_A/\dot{Q}$ ratio of 1, and narrowness (very little dispersion). Note that there is no inert-gas shunt (contrasted with the concept of venous admixture ratio), because the tracer nature of inert gases utilized for MIGET is insensitive to the presence of postpulmonary shunt (i.e., the bronchial and thebesian circulations). Inert-gas physiologic dead space is also slightly lower than Bohr dead space because it does not include the alveolar units, which have an alveolar P_{CO_2} that is lower than Pa_{CO_2}.

NATURE OF GAS EXCHANGE IN DISEASE STATES

From a clinical standpoint, the three principal mechanisms of altered arterial respiratory gases during spontaneous breathing in any pulmonary disease state are $\dot{V}_A/\dot{Q}$ mismatching, increased intrapulmonary shunt, and alveolar hypoventilation. The role of diffusion limitation to O_2 is modest and plays a role in patients with pulmonary fibrosis[9] and in healthy individuals under very extreme conditions at high altitude.[10] During mechanical ventilation, however, alveolar hypoventilation is controlled in such a way that Pa_{CO_2} does not represent a problem. $\dot{V}_A/\dot{Q}$ inequalities play a pivotal role in disorders characterized by chronic lung disease ("dry lung"), namely during exacerbations of chronic obstructive pulmonary disease (COPD) and bronchial asthma, which have in common expiratory airflow limitation and large pulmonary volumes. Increased intrapulmonary shunt is a key determinant of hypoxemia in conditions characterized by acute lung injury ("wet lung"), such as acute lung injury (ALI), and its most severe form, acute respiratory distress syndrome (ARDS), and life-threatening pneumonia, all of which have small lung volumes.[11]

The main mechanisms of pulmonary gas exchange are extensively reviewed (see the section Acute Respiratory Failure "Wet Lung") during mechanical ventilation in ALI or ARDS, pneumonia, COPD, and asthma—the most common conditions in the critical care setting. In each condition, the gas-exchange abnormalities at maintenance FI_{O_2} and while breathing 100% O_2 are addressed. Likewise, the effects of external positive end-expiratory pressure (PEEP) and intrinsic PEEP (PEEPi) on gas exchange, and the effects of several ventilator settings are considered.

Acute Respiratory Failure ("Wet Lung")

This section reviews the two most frequent disorders seen in the intensive care unit, ARDS and severe life-threatening pneumonia, together with a short review of gas exchange in patients with head trauma and following cardiac surgery. It can be difficult to differentiate ALI or ARDS from the other disorders—after all, ALI or ARDS is a constellation of many entities, among which pneumonia and the other conditions of acute respiratory failure are common causes. From a gas-exchange viewpoint, however, ALI or ARDS and pneumonia show different functional findings. Furthermore, the response to high FI_{O_2} differs substantially.

ACUTE LUNG INJURY OR ACUTE RESPIRATORY DISTRESS SYNDROME

Severe acute respiratory failure in previously healthy subjects may result from a primary infectious lung process or a more widespread, noninfectious process, namely either ALI or ARDS. The latter entity is characterized by severe hypoxemia refractory to high FI_{O_2}, and differences are related to the severity of gas-exchange abnormalities.[12]

MECHANISMS OF HYPOXEMIA

The main cause of hypoxemia in patients with ALI or ARDS is a characterized by an increased intrapulmonary shunt, averaging 20% or more of cardiac output. In approximately half the patients, however, there are considerable additional areas with low $\dot{V}_A/\dot{Q}$ ratios: A moderate percentage of total pulmonary blood flow is distributed to areas of the lung with reduced ventilation.[13]

Figure 37-2 illustrates the profiles of two representative $\dot{V}_A/\dot{Q}$ distributions of patients with ARDS during mechanical ventilation with PEEP (at FI_{O_2}, 0.5).[14] Although both

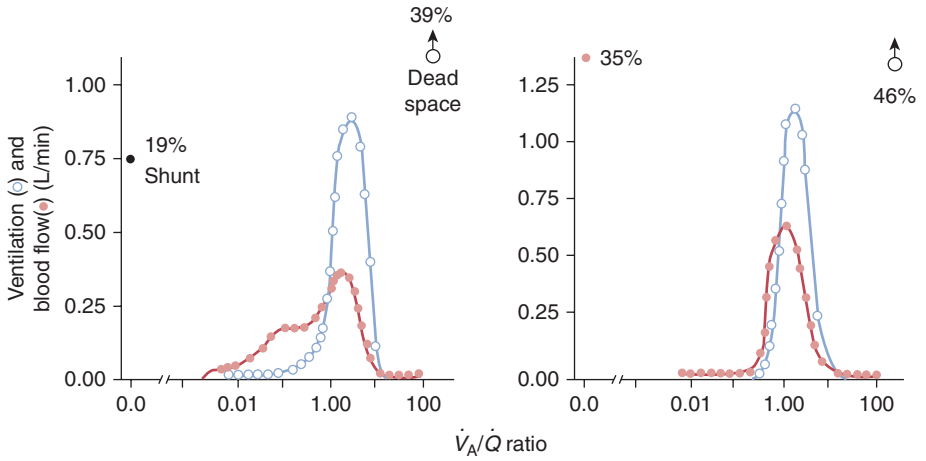

FIGURE 37-2 Two patterns of $\dot{V}_A/\dot{Q}$ distributions in patients with ARDS (with PEEP). Note that intrapulmonary shunt and dead space were considerably increased in both individuals. Notice also the presence of some amount of blood flow distributed to units with low $\dot{V}_A/\dot{Q}$ (*left panel*). (Reprinted with permission of the American Thoracic Society. Copyright © 2012 American Thoracic Society. Reyes A, Roca J, Rodriguez-Roisin R, et al. Effect of almitrine on ventilation-perfusion distribution in adult respiratory distress syndrome. *Am Rev Respir Dis.* 1988;137:1062–1067. Official Journal of the American Thoracic Society. Modified with permission of the American Thoracic Society.)

patterns show marked amounts of shunt and dead space, the main body of the dispersion of blood flow is different. In one patient, the dispersion is narrowly unimodal (*right panel*). In the other, the pattern of perfusion is broadly unimodal, that is, blood flow is distributed to areas with low $\dot{V}_A/\dot{Q}$ ratios (usually less than 10% of cardiac output) (*left panel*). The former profile reflects an "all-or-none" phenomenon: pulmonary perfusion is essentially diverted to two lung areas, those with ventilation that is normal and proportional to blood flow, and those that are completely unventilated.[15] The presence of areas with low $\dot{V}_A/\dot{Q}$ ratios suggests the coexistence of areas with partially filled alveolar spaces or alveolar units in which ventilation is reduced compared to blood flow (because of increased airways resistance) or both. A few patients showed an increase of alveolar ventilation distributed to high $\dot{V}_A/\dot{Q}$ ratios, including a bimodal pattern of the dispersion of ventilation; in contrast, dead space was increased in most patients. These two findings may reflect areas with reduced pulmonary blood flow secondary to the effects of external PEEP, although an additional influence of pulmonary vascular derangement cannot be ruled out.[16]

There was no limitation to the diffusion of O_2, as reflected by the close agreement between predicted Pa_{O_2} (according to MIGET, this reflects the underlying amount of intrapulmonary shunt and $\dot{V}_A/\dot{Q}$ mismatch only) and measured Pa_{O_2} (Fig. 37-3).[15,17] When measured Pa_{O_2} is not significantly different from the predicted Pa_{O_2}, this suggests that other potential causes of hypoxemia, namely diffusion limitation for O_2, increased postpulmonary shunt, and/or augmented intrapulmonary O_2 consumption,[18] are not occurring.

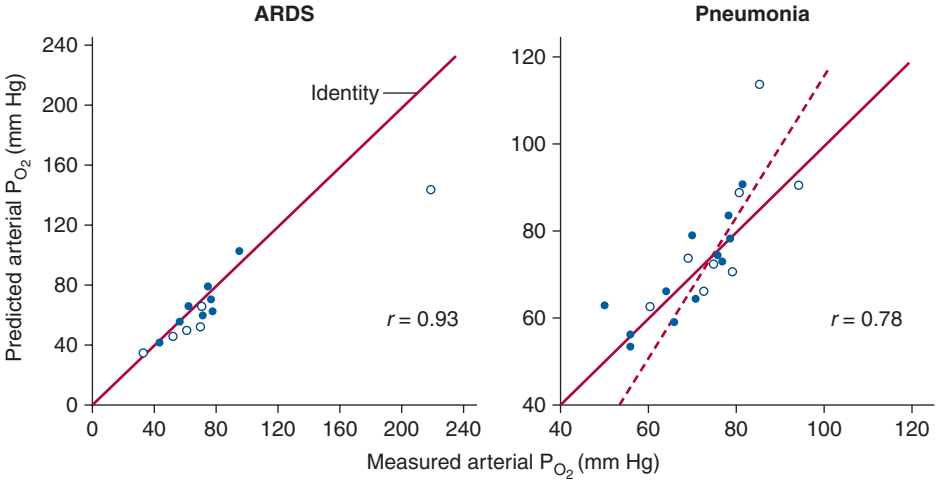

FIGURE 37-3 Plots of predicted (estimated by MIGET) Pa_{O_2} versus measured Pa_{O_2} in patients with ARDS (*left panel; open symbols* = without PEEP; *closed symbols* = with PEEP) and with severe pneumonia (*right panel; open symbols* = with mechanical ventilation; *closed symbols* = without mechanical support). Note the good agreement between both variables in each clinical condition (*dashed line* = regression line). (Used, with permission, from Dantzker et al.[15] and Gea et al.[17])

BREATHING 100% OXYGEN

The concept of an increase in intrapulmonary shunt while breathing 100% oxygen in patients with acute respiratory failure is old.[19,20] Earlier data using MIGET, however, did not support this view.[16] It was considered that areas with critical inspiratory $\dot{V}_A/\dot{Q}$ ratios may remain partly open and facilitate O_2 transfer; potential mechanisms include the efficiency of collateral ventilation, interdependence of surrounding lung parenchyma, or the interaction of mechanical forces exerted during artificial ventilation.[8] No studies, however, properly addressed this question.

We have shown that Pa_{O_2} increases modestly (≤300 mm Hg) and intrapulmonary shunt increases considerably (approximately 35%) during hyperoxic breathing over 1 hour, suggesting the development of reabsorption atelectasis (Fig. 37-4).[8,21] The increase in intrapulmonary shunt was noticed within less than half an hour, confirming the theoretical analysis on the minimum time required for collapse of alveolar units with various fixed inspired $\dot{V}_A/\dot{Q}$ ratios according to the different levels of FI_{O_2}.[8] The limited increase in Pa_{O_2} while breathing 100% O_2 indicates that increased intrapulmonary shunt is the key determinant of hypoxemia in ALI and ARDS. Furthermore, the increments in shunt persisted for 1 hour after resuming maintenance FI_{O_2}, indicating the persistence of atelectasis. Of note, this worsening of shunt was also accompanied by a small but significant increase in Pa_{CO_2}, possibly explained by the Haldane effect (Fig. 37-5). The Haldane effect is the increase in Pa_{CO_2} at a given arterial CO_2 content that occurs in response to an increase in arterial O_2 saturation. The dispersions of blood flow and alveolar ventilation remained unchanged.

The increase in shunt not accompanied with release of hypoxic pulmonary vasoconstriction in patients with ALI or ARDS is compatible with the concept that, at any level of FI_{O_2}, units with low $\dot{V}_A/\dot{Q}$ cannot redistribute blood flow from areas of intrapulmonary shunt or very low $\dot{V}_A/\dot{Q}$ ratios, because their vascular resistance remains unchanged.[8]

EFFECTS OF POSITIVE END-EXPIRATORY PRESSURE

The gas-exchange response to external PEEP illustrates one of the best examples of the complex interplay between intrapulmonary and extrapulmonary determinants of respiratory gases.[5,16] Several studies have assessed this action in patients with ALI or ARDS.

In a seminal study,[15] which measured $\dot{V}_A/\dot{Q}$ distributions at increasing levels of PEEP, two distinct patterns were shown (Fig. 37-6). In some patients, the $\dot{V}_A/\dot{Q}$ pattern remained unchanged despite progressive increases of PEEP. In others, there was a broadening of the dispersion of ventilation because areas with high $\dot{V}_A/\dot{Q}$ ratios increased and ventilation was redistributed to infinity $\dot{V}_A/\dot{Q}$ ratios. In each patient, however, PEEP led ultimately to a marked decrement in cardiac output distributed to unventilated (shunt) areas or poorly ventilated $\dot{V}_A/\dot{Q}$ units and to a considerable increase in dead space. The final result was a substantial optimization of Pa_{O_2}.

Subsequently, the $\dot{V}_A/\dot{Q}$ response to external PEEP was investigated while cardiac output was kept constant at control values with dopamine.[22] During PEEP, Pa_{O_2}, mixed venous P_{O_2}, and oxygen delivery increased significantly, whereas the venous admixture ratio decreased markedly. Similarly, shunt decreased substantially, and pulmonary blood flow was redistributed from nonventilated units with zero $\dot{V}_A/\dot{Q}$ ratios to areas with normal $\dot{V}_A/\dot{Q}$ ratios. Dead space increased slightly, but the dispersion of the alveolar ventilation did not vary. Because PEEP causes redistribution of extravascular lung water from alveoli to peribronchial and perivascular spaces,[23] these data suggest that the improvement in pulmonary gas exchange with external levels of PEEP results from the reopening of collapsed airways and alveoli. The key message from this study is that the avoidance of the reduction of cardiac output during PEEP application enhances a more optimal gas exchange.

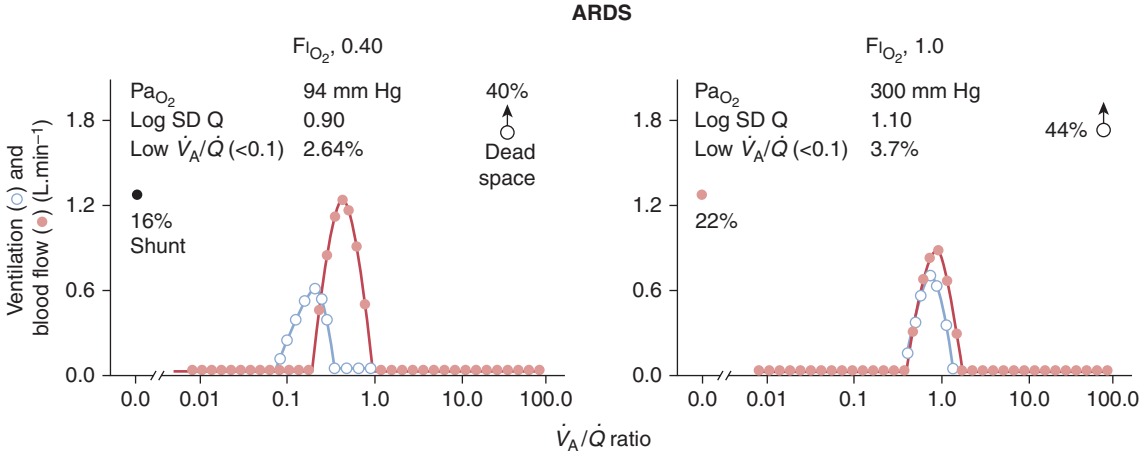

FIGURE 37-4 Effect of breathing 100% oxygen (*right panel*) in a representative patient with ARDS (with PEEP). Compared with low FI_{O_2} (*left panel*), Pa_{O_2} increased modestly (approximately 300 mm Hg), but intrapulmonary shunting increased moderately; in contrast, both the dispersion of blood flow (*Log SD Q*) and the amount of blood flow distributed to areas with low $\dot{V}_A/\dot{Q}$ ratios remained unchanged. This suggests the development of reabsorption atelectasis without release of hypoxic vasoconstriction. Dead space tended to increase.

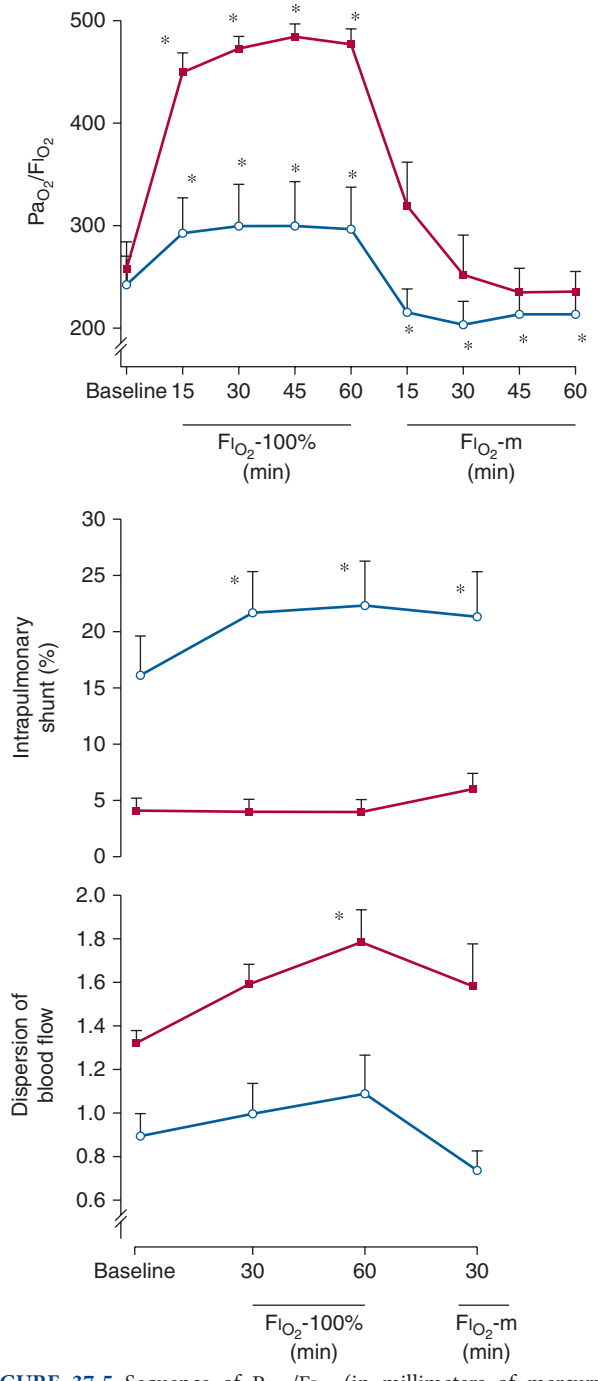

FIGURE 37-5 Sequence of Pa_{O_2}/FI_{O_2} (in millimeters of mercury), shunt (in percentage of cardiac output), and Log SD Q (dimensionless). In patients with ALI (*open circles*) arterial oxygenation and Log SD Q remained almost unchanged, whereas shunt increased significantly, suggesting reabsorption atelectasis. In contrast, in patients with COPD (*solid squares*), Log SD Q and arterial oxygenation substantially increased whereas shunt remained low and unvaried, indicating release of hypoxic vasoconstriction. For further explanation, see text. (Used, with permission, from Santos et al.[21])

In another study,[24] the gas-exchange response to increments in PEEP was studied. In most patients, Pa_{O_2} improved substantially because of a decrease in intrapulmonary shunt or in the zone of low $\dot{V}_A/\dot{Q}$ ratio, or a derecruitment of blood flow from areas with shunt to those with low or normal $\dot{V}_A/\dot{Q}$ ratio; blood flow reductions to low $\dot{V}_A/\dot{Q}$ areas were less predictable. When Pa_{O_2} did not vary in response to PEEP, there were no variations in the $\dot{V}_A/\dot{Q}$ relationships. An increase either in poorly perfused $\dot{V}_A/\dot{Q}$ units or in dead space was shown in only a few individuals. The beneficial effect of PEEP on Pa_{O_2} could not be predicted by the etiology of ARDS or the severity of abnormal gas exchange. As expected, cardiac output and mixed venous P_{O_2} decreased progressively as PEEP was increased. The mean change in cardiac output was essentially similar between PEEP trials irrespective of the improvement in Pa_{O_2}.

Experimentally, low levels of PEEP (5 to 10 cm H_2O) decrease physiologic dead space by reducing both shunt and $\dot{V}_A/\dot{Q}$ mismatch.[25] At higher levels of PEEP, however, physiologic dead space increases because both ventilation to high $\dot{V}_A/\dot{Q}$ regions and anatomic dead space increase while the efficiency of CO_2 elimination by the lungs is diminished.

All in all, these studies are of interest for two reasons. First, these findings indicate that the beneficial effects of PEEP in ALI and ARDS essentially result from a redistribution of blood flow from severely injured (shunt) areas to poorly or normally ventilated alveolar units. This seems to be related to the reopening of collapsed alveoli and airways rather than to a decrease of cardiac output by itself. Alternatively, the depression of cardiac output may reduce shunt or blood flow distributed to units with poorly ventilated $\dot{V}_A/\dot{Q}$ ratios.[2] It has been shown both clinically and experimentally, using pharmacologic and mechanical techniques, that changes in cardiac output lead to directionally similar changes in shunt. Likewise, in many instances, the shunt fraction also changes in a similar direction to changes in the mixed venous P_{O_2} and negatively with pulmonary vascular resistance.[26]

Second, in two of the studies in which the values of mixed venous P_{O_2} were reported, this variable either increased[22] or remained stable[24] when cardiac output was reduced. Arterial P_{O_2} increased during PEEP because the beneficial effects on gas exchange, essentially secondary to the reduction in shunt (intrapulmonary factor), were not offset by the simultaneous deleterious effect on Pa_{O_2} secondary to decreased cardiac output (extrapulmonary factor), which had allowed mixed venous P_{O_2} to decrease, other factors being equal. If the reduction in cardiac output had been more severe, Pa_{O_2} would have remained unaltered or even decreased despite the reduction in shunt.[16] Alternatively, the observation that mixed venous P_{O_2} values did not always vary in the same direction as cardiac output raises the question of the pathologic supply dependence between O_2 delivery and the O_2 consumption.[27] Such patients may respond to the depression of cardiac output during PEEP by reducing O_2 consumption.

The development of high $\dot{V}_A/\dot{Q}$ peaks and the moderate-to-severe increments of dead space during PEEP are consistent with experimental data indicating that the reduction of

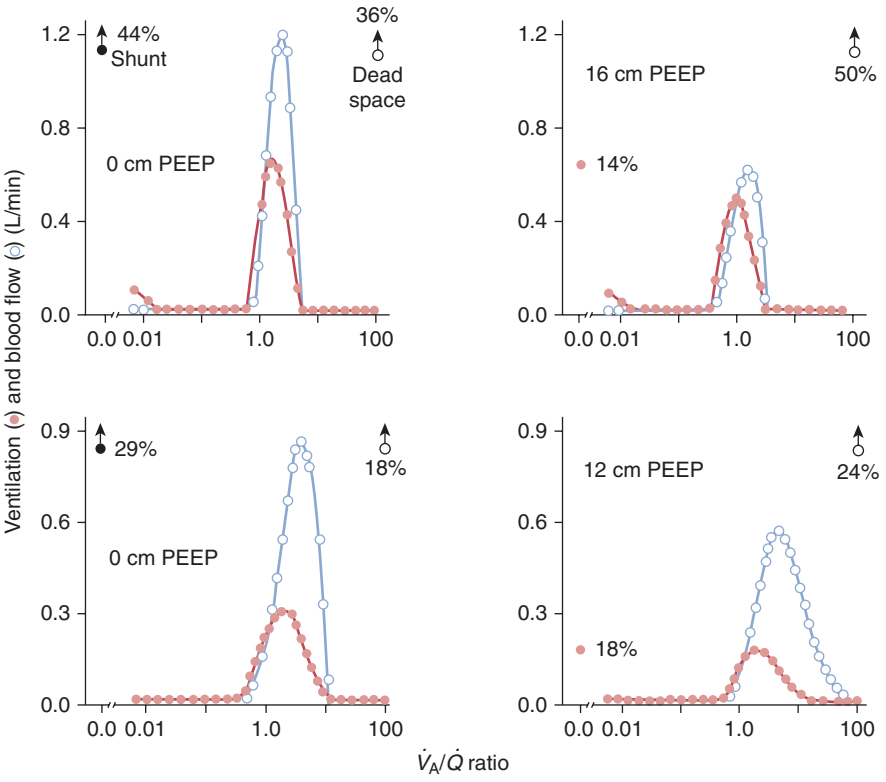

FIGURE 37-6 The application of 16 cm H_2O of PEEP in a patient with ARDS induced a reduction of shunt and an increase of dead space, whereas $\dot{V}_A/\dot{Q}$ distributions remain essentially unaltered (*top, from left to right*). In another patient, 12 cm H_2O of PEEP caused similar effects on shunt and dead space, but $\dot{V}_A/\dot{Q}$ distributions are broadened (*bottom, from left to right*). For further explanation, see text. (Reprinted with permission of the American Thoracic Society. Copyright © 2012 American Thoracic Society. Dantzker DR, Brook CJ, Dehart P, et al. Ventilation-perfusion distributions in the adult respiratory distress syndrome. *Am Rev Respir Dis.* 1979;120:1039–1052. Official Journal of the American Thoracic Society. Modified with permission of the American Thoracic Society.)

cardiac output and the depression of perfusion in the uppermost regions of the lung determine changes in the pattern of ventilation with PEEP.[28]

VENTILATOR MODALITIES

Over the last 10 years, increasing emphasis has been placed on avoiding ventilator-associated lung injury and the use of a protective ventilator strategy, accepting an increase in Pa_{CO_2} if necessary (permissive hypercapnia), in patients with ALI or ARDS. Ventilator-associated lung injury[29] is defined as lung damage with characteristic features of ARDS that can occur in patients receiving mechanical ventilation. The two most important factors responsible for ventilator-associated lung injury are thought to be: (a) the association of alveolar overdistension and high transpulmonary pressure; and (b) repeated alveolar collapse and reopening owing to ventilation at inappropriate tidal ranges of transpulmonary pressure. The prevention of alveolar overdistension by reducing tidal volume has been investigated in combination with relatively low levels of PEEP and high levels of PEEP. We describe them separately.

Permissive Hypercapnia with Low Tidal Volume and Low Positive End-Expiratory Pressure. Four recent controlled studies[13,30–32] have compared the outcome with use of low (6 to 7 mL/kg) versus high (10 to 12 mL/kg) tidal volumes with standard levels of PEEP (8 to 11 cm H_2O). Only one study[13] showed a significant (20%) decrease in mortality, likely because of a superior statistical power and a larger difference between the low-tidal-volume and high-tidal-volume branches. Use of low tidal volume, however, can worsen pulmonary gas exchange, necessitating higher FI_{O_2} requirements, secondary to reduction in alveolar ventilation and increased shunt caused by both alveolar collapse and increased cardiac output, which may further worsen intrapulmonary shunt in patients with ARDS.[15]

The induction of permissive hypercapnia by reducing tidal volume and maintaining constant standard levels of PEEP was shown to increase cardiac output, decrease Pa_{O_2}, and increase shunt, but had no effect on the dispersion of blood flow (Log SD Q).[33] When baseline tidal volume was reinstated and cardiac output was maintained with use of dobutamine, both shunt and Pa_{O_2} remained unchanged. Thus, low tidal volume with standard PEEP increased intrapulmonary shunt and the deterioration in gas exchange was caused by the combined effects of increased cardiac output and decreased alveolar ventilation. In another study,[34] the effects of permissive hypercapnia were compared in two groups of patients with ARDS, with and without hyperdynamic sepsis. Permissive hypercapnia was induced by decreasing tidal volume and increasing PEEP to prevent alveolar recruitment. In both groups of

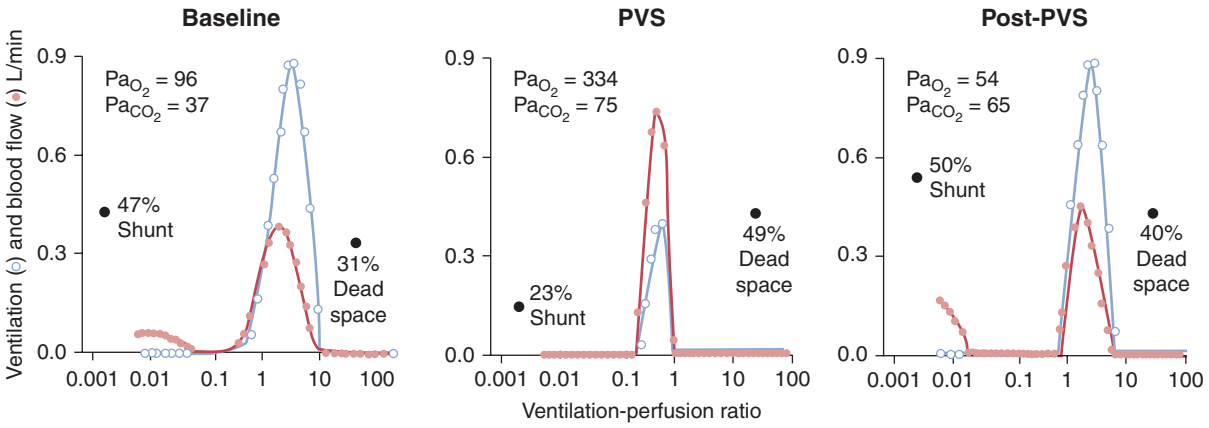

FIGURE 37-7 Representative patient with ARDS at baseline (*left*), during protective ventilator support (PVS) (*center*), and after PVS (*right*). During PVS, shunt decreased and arterial oxygenation improved; dead space increased as a result of low tidal volume and high PEEP. (Reproduced, with permission, from Mancini et al.[37])

patients, permissive hypercapnia increased shunt but did not worsen Pa_{O_2} because of an increase in mixed venous P_{O_2} secondary to an increased cardiac output. In septic patients, Pa_{O_2} remained unchanged, and in nonseptic patients, it increased. Dead space and the descriptors of $\dot{V}_A/\dot{Q}$ imbalance remained unchanged in both subsets of patients.

Permissive Hypercapnia with Low Tidal Volume and High Positive End-Expiratory Pressure. The combination of low tidal volume, to avoid alveolar overdistension, and high PEEP, to prevent sequential collapse and reopening of alveolar units throughout the ventilatory cycle, has been advocated as an alternative strategy to decrease ventilator-associated lung injury. In patients with ARDS,[35] this approach achieved a significant reduction in mortality at 4 weeks, but hospital mortality was not decreased. The protective ventilation group had a higher rate of weaning from mechanical ventilation and a lower rate of barotrauma. This type of permissive hypercapnia produced an acute hyperdynamic state,[36] with transient systemic vasodilation and increased cardiac output. The acute hemodynamic effects were in part related to acute respiratory acidosis, and progressively attenuated during the first 36 hours of ventilation despite persisting hypercapnia. The gas-exchange response to this ventilator strategy[37] revealed superior efficacy in early ARDS (Fig. 37-7), mainly through recruitment of previously collapsed alveoli and redistribution of pulmonary blood flow from unventilated alveolar units to normal units. Arterial P_{O_2} improved and intrapulmonary shunt decreased. Recruitment of previously collapsed alveolar units was the key factor underlying the decreased intrapulmonary shunt. The beneficial effects of this approach on gas exchange fully overcame the deleterious effect of permissive hypercapnia on arterial oxygenation (i.e., reduced alveolar P_{O_2}). Moreover, the increase in cardiac output secondary to systemic vasodilatation[36] did not result in a proportional increase in intrapulmonary shunt, as one might expect in patients with ARDS,[15] likely because pulmonary blood flow was appropriately redistributed to normal alveolar units secondary to the concomitant efficiency of alveolar recruitment (Fig. 37-8). The substantial improvement in

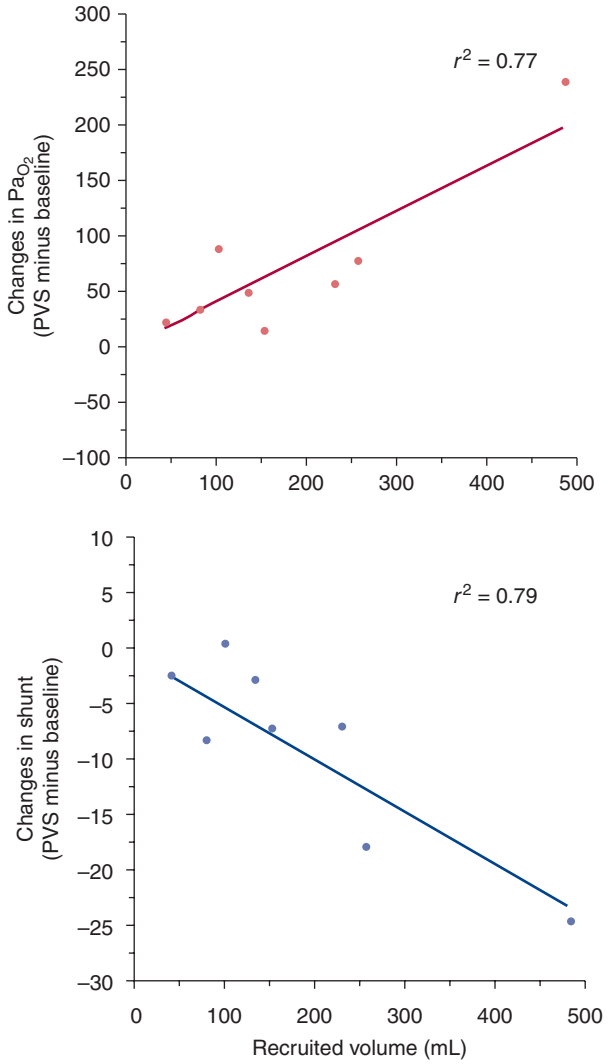

FIGURE 37-8 Correlations between increased Pa_{O_2} (*top*) and decreased shunt (*bottom*) and recruited lung volume during protective ventilator support (PVS) in patients with ARDS (*dots,* individual patients; *lines,* regression lines). (Reproduced, with permission, from Mancini et al.[37])

$\dot{V}_A/\dot{Q}$ imbalance, indicated by decreased blood flow dispersion (Log SD Q), may have been caused by the reduction of the overall $\dot{V}_A/\dot{Q}$ ratio secondary to the concomitant effects of both decreased alveolar ventilation and increased cardiac output (induced by this ventilator modality). Under these circumstances, a more efficient distribution of pulmonary blood flow toward areas with normal $\dot{V}_A/\dot{Q}$ ratios cannot be ruled out. Likewise, the marked increase in dead space observed with the protective strategy can be explained by the combination of a decrease in alveolar ventilation and an increase in functional residual capacity induced by high levels of PEEP. This study showed a strong relationship between improvement of alveolar gas exchange and the amount of PEEP-induced alveolar recruitment. Overall, these findings strongly support the combination of low tidal volumes and high PEEP levels as the most appropriate approach, at least in early ARDS, although further studies are warranted. The growing knowledge that therapeutic hypercapnia per se may prevent pulmonary and systemic damage in patients with ARDS[38,39] adds further complexities.

Inverse Inspiratory-to-Expiratory Ratio Ventilation. Before the advantages of protective ventilation with permissive hypercapnia were known, inverse inspiratory-to-expiratory (I:E) ratio ventilation was used in ARDS to improve oxygenation at lower-than-conventional peak airway pressures. Because of discrepant results in several studies, the gas-exchange response was investigated.[40] Compared to conventional volume-controlled ventilation with PEEP, the application of equivalent levels of PEEP during inverse-ratio ventilation did not result in a superior Pa_{O_2}. Pressure-controlled ventilation with inverse I:E ratio did not affect Pa_{O_2} either, although it decreased Pa_{CO_2} because of a concomitant decrease in dead space with a shift to the right of $\dot{V}_A/\dot{Q}$ distributions.

Postural Changes. The $\dot{V}_A/\dot{Q}$ distributions during pressure-controlled ventilation in the prone position[41] revealed an improvement in Pa_{O_2} of more than 10 mm Hg after 30 minutes in two-thirds of patients (responders), whereas the remaining patients showed no change in Pa_{O_2} (nonresponders). In the responders, the prone position caused a substantial decrease in shunt regions with a concomitant increase of areas with normal $\dot{V}_A/\dot{Q}$ ratios in the dorsal zones, which were now less gravitationally dependent. Returning the patient to the supine position reversed the improvement in gas exchange. These changes suggest that the redistribution of blood flow away from shunt areas is most likely caused by efficient recruitment of previously atelectatic, but nondiseased, zones induced by altered gravitational forces. Continuous axial rotation might be another method for acutely reducing $\dot{V}_A/\dot{Q}$ imbalance in patients with ALI or ARDS[42]; continuous axial rotation on a kinetic-treatment table reduced intrapulmonary shunt and improved Pa_{O_2}. The positive response to continuous rotation was only demonstrated in patients with mild-to-moderate ALI; in patients with progressive ARDS, the acute response was limited.

Partial Ventilator Support. A study comparing the effects of airway pressure release ventilation, with and without spontaneous breathing, and pressure support ventilation, in which both modalities were delivered with equal airway pressure limits or minute ventilation, on pulmonary gas exchange in patients with ARDS,[43] showed that spontaneous breathing with airway pressure release ventilation improved $\dot{V}_A/\dot{Q}$ mismatching, as revealed by decreases in intrapulmonary shunt, dead space, and the dispersions of blood flow and ventilation. Pressure support did not improve $\dot{V}_A/\dot{Q}$ imbalance when compared with airway pressure release ventilation without spontaneous breathing. These findings indicated that uncoupling of spontaneous and mechanical ventilation during airway pressure release ventilation improves $\dot{V}_A/\dot{Q}$ inequalities in ARDS, presumably by recruiting nonventilated lung units. As compared with controlled ventilation, inspiratory assistance during pressure support is not sufficient to counteract the $\dot{V}_A/\dot{Q}$ imbalance caused by alveolar collapse in patients with ARDS, and does not provide any complementary advantage in cardiopulmonary function or pulmonary gas exchange.

PNEUMONIA

Mechanisms of Hypoxemia. In pneumonia, arterial hypoxemia is basically determined by the presence of a considerable shunt (average: 20% of cardiac output) together with moderate to severe amounts (range: 10% to 20% of cardiac output) of blood flow distributed to units with low $\dot{V}_A/\dot{Q}$. In general, the pattern of the dispersion of perfusion is bimodal (Fig. 37-9).[17,44] These functional findings are consistent with the main pathologic findings, namely extensive consolidation of areas of the lungs, with alveoli completely or partially filled with edema, leukocytes and other cells, causative bacteria, and fibrin.[45] Dead space is, by and large, slightly increased, and some patients can exhibit areas wherein ventilation is diverted to high $\dot{V}_A/\dot{Q}$ ratios. The latter findings may reflect the use of PEEP, which is commonly used in these patients. There is good agreement between predicted Pa_{O_2} and measured Pa_{O_2}, suggesting therefore that additional intrapulmonary factors determining hypoxemia (diffusion limitation to O_2, increased intrapulmonary O_2 uptake, and postpulmonary shunt), other than shunt and $\dot{V}_A/\dot{Q}$ mismatch, can be ruled out.[17,44] The coexistence of increased intrapulmonary O_2 consumption within the parenchyma[18] and increased postpulmonary shunt,[46] previously suggested as an additional mechanism contributing to hypoxemia, was not observed in patients with severe pneumonia.[17]

Breathing 100% Oxygen. Breathing 100% O_2 induced no changes in inert-gas shunt or in venous admixture ratio, as might be expected, at least theoretically, in patients whose lungs contain abundant critical alveolar units at risk of undergoing collapse, thereby developing reabsorption atelectasis.[8,21] This suggests that, in lungs with more localized lung injury, low $\dot{V}_A/\dot{Q}$ areas are less liable to collapse during oxygen breathing, probably because of the efficiency of

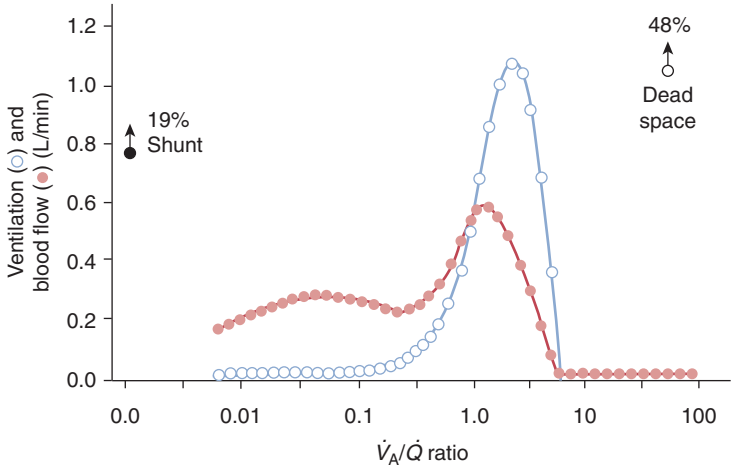

FIGURE 37-9 Ventilation–perfusion distributions in a patient with severe pneumonia requiring mechanical ventilation with PEEP. Note that shunt and dead space are markedly increased; likewise, a considerable amount of blood flow is distributed to a zone with low $\dot{V}_A/\dot{Q}$ ratios (below 0.1). Compared with patients with ARDS (see Fig. 37-2), the bimodal pattern of pulmonary perfusion is more accentuated. (Reproduced, with permission, from Gea et al.[17])

collateral ventilation and the interaction between mechanical forces within the lung. Nevertheless, there was further $\dot{V}_A/\dot{Q}$ deterioration, as assessed by the marked increase in the dispersion of blood flow, indicating release of hypoxic pulmonary vasoconstriction. This finding indicates a considerable hypoxic vascular response of the lung, which may play a protective role against further worsening of gas exchange. In contrast, the dispersion of ventilation tended to decrease (improve) and dead space remained unaltered (Table 37-1). Conceivably, this mild reduction in the dispersion of alveolar ventilation might reflect blood flow redistribution from high- to low-$\dot{V}_A/\dot{Q}$ regions, where hypoxic vasoconstriction takes place.

Postural Changes. Ventilation–perfusion distributions have been studied in a few patients with unilateral lung disease (presence of infiltrates) needing mechanical ventilation.[47] Two patients displayed a predominant decrease in intrapulmonary shunt and two other patients showed an improvement in $\dot{V}_A/\dot{Q}$ distributions when the uninvolved lung side was dependent. Although this difference in response may be related to the lack of clinical uniformity in the small number of patients studied, both responses resulted in increases in Pa_{O_2} when the healthy lung was dependent.

TABLE 37-1: CHARACTERISTICS OF PULMONARY GAS EXCHANGE IN ACUTE LUNG INJURY "WET LUNG"

	ALI or ARDS	Pneumonia
Principal mechanisms		
Shunt	Severe ≥20%	Severe ≥20%
$\dot{V}_A/\dot{Q}$ mismatch	Absent/mild	Mild/moderate
O_2 diffusion limitation	Absent	Absent
100% Oxygen effects		
Increase in Pa_{O_2}	Mild/moderate (≤300 mm Hg)	Marked (≥300 mm Hg)
Increase in shunt	Mild/moderate	Absent
Hypoxic vascular response	Absent	Increased

HEAD TRAUMA

Patients with head trauma with normal chest radiology and without clinical neurogenic pulmonary edema show mild-to-severe $\dot{V}_A/\dot{Q}$ mismatch, essentially characterized by the presence of areas of low $\dot{V}_A/\dot{Q}$ ratios and mild shunt (less than 10% of cardiac output) (without PEEP). Although no satisfactory explanation has been given for such gas-exchange abnormalities,[48] subclinical pulmonary edema on days before admission, atelectasis, and/or decreased lung compliance have been suggested as potential mechanisms.

When mechanical ventilation was discontinued, shunt remained almost unchanged, while $\dot{V}_A/\dot{Q}$ distributions were less homogeneous and less unimodal, with a substantial increase in perfusion to regions of low $\dot{V}_A/\dot{Q}$ ratio units. Functional residual capacity, minute ventilation, and cardiac output were no different between both conditions, but pulmonary arterial pressures increased significantly when patients were removed from the ventilator. Two patients improved dramatically in a few days with considerable, although incomplete, restoration of $\dot{V}_A/\dot{Q}$ mismatch to normal. This suggested the return of normal hypoxic pulmonary vasoconstriction.

CARDIAC SURGERY

Gas exchange has been studied in patients on the day after coronary bypass surgery for myocardial revascularization[49–51] or aortic valvular replacement.[52] Overall, shunt was mildly to moderately increased (less than 15% to 20% of cardiac output) and $\dot{V}_A/\dot{Q}$ distributions showed a variable degree of

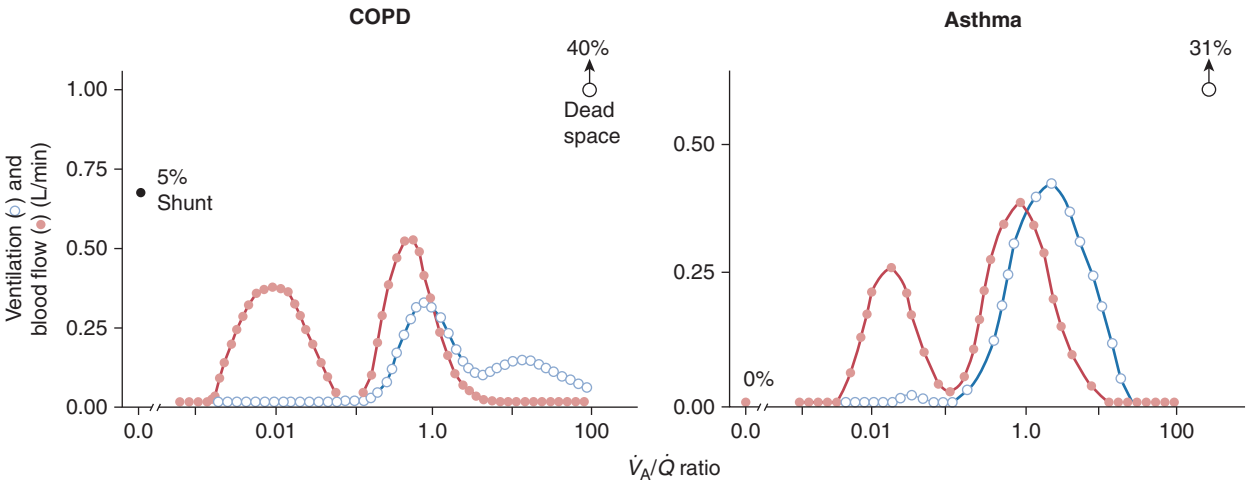

FIGURE 37-10 *Left panel.* Typical bimodal patterns of both blood flow and alveolar ventilation in a representative patient with COPD needing mechanical ventilation. Both shunt and dead space are modestly increased. (*Right panel*) Typical bimodal pattern of blood flow in a representative patient with asthma needing mechanical ventilation. At variance with the COPD patients shunt is absent and dead space is modestly decreased. For further explanation, see text. (Reproduced, with permission, from Rodriguez-Roisin.[16])

severity, in general akin to preoperative findings, with variable patterns (broadly unimodal or clearly bimodal) of $\dot{V}_A/\dot{Q}$ abnormalities. The presence of relatively abundant shunt was also consistent with the presumed underlying multifactorial pathology in these patients. Shunt has been attributed to noncardiogenic pulmonary edema related to cardiopulmonary bypass, reduced functional residual capacity, surfactant alterations, increased closing volume secondary to retained secretions, abnormal hypoxic pulmonary vasoconstriction, and reabsorption atelectasis from a high FI_{O_2}. Breathing 100% O_2 increased the dispersion of blood flow, but neither intrapulmonary shunt nor dispersion of alveolar ventilation increased.[49] These findings were interpreted as release of hypoxic pulmonary vasoconstriction.

In one study,[52] measurements were repeated while the uninvolved (good) right lung was down. Gas-exchange abnormalities in these patients had been previously reported to be more common in the left lung.[52] The improvement of Pa_{O_2} on moving the patient from supine to the right lateral decubitus position was associated with an improvement in $\dot{V}_A/\dot{Q}$ relationships but not in shunt, although a beneficial effect on overall gas exchange, secondary to a simultaneous increase of cardiac output, could not be ruled out. These results are at variance with those in patients with unilateral lung disease, in whom either intrapulmonary shunting or $\dot{V}_A/\dot{Q}$ mismatch improved when the uninvolved (good) lung was down.[47]

Chronic Airflow Limitation ("Dry Lung")

Although exacerbations of COPD and acute severe asthma have a common functional hallmark, chronic airflow obstruction with or without associated reversibility, they show substantial pathophysiologic differences. A contrasting feature of pulmonary gas exchange in patients with "dry lung" and in patients with "wet lung" is that the functional findings observed during exacerbations can be better interpreted in light of the findings observed during the stable state.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE EXACERBATIONS

Patients with COPD show up to four different patterns of $\dot{V}_A/\dot{Q}$ distributions (Fig. 37-10). One pattern may be characterized by a mode that includes a substantial amount of blood flow diverted to lung units with very low $\dot{V}_A/\dot{Q}$ regions, known as "low $\dot{V}_A/\dot{Q}$ mode" (type L).[53,54] Another profile may include alveolar units with high $\dot{V}_A/\dot{Q}$ regions, named "high $\dot{V}_A/\dot{Q}$ mode" (type H). This pattern likely suggests that most of the alveolar ventilation is distributed to zones with higher $\dot{V}_A/\dot{Q}$ ratios. A third profile is a mixed high-low $\dot{V}_A/\dot{Q}$ mode (type H-L), which consists of additional modes above and below the main body of $\dot{V}_A/\dot{Q}$ ratios. A fourth pattern has only two broadly unimodal dispersions. All in all, the dispersions of blood flow or ventilation, or both, tend to be severely increased. Intrapulmonary shunting is slightly elevated and dead space is mildly to moderately increased. The minimal amount of shunt suggests that the efficiency of collateral ventilation is very active or that complete airway obstruction does not occur functionally except in a few airways that are completely occluded, possibly by inspissated bronchial secretions.

An important concept is that patients with a COPD exacerbation, whether requiring or not requiring ventilator support, exhibit mild amounts of shunt (usually less than 10% of cardiac output) although quantitatively more severe $\dot{V}_A/\dot{Q}$ patterns than do patients with stable COPD.[53,54] If a patient with an exacerbation of COPD shows moderate-to-severe amounts of shunt (i.e., 20% of cardiac output) despite normal chest radiology—which excludes collapse, consolidation, or

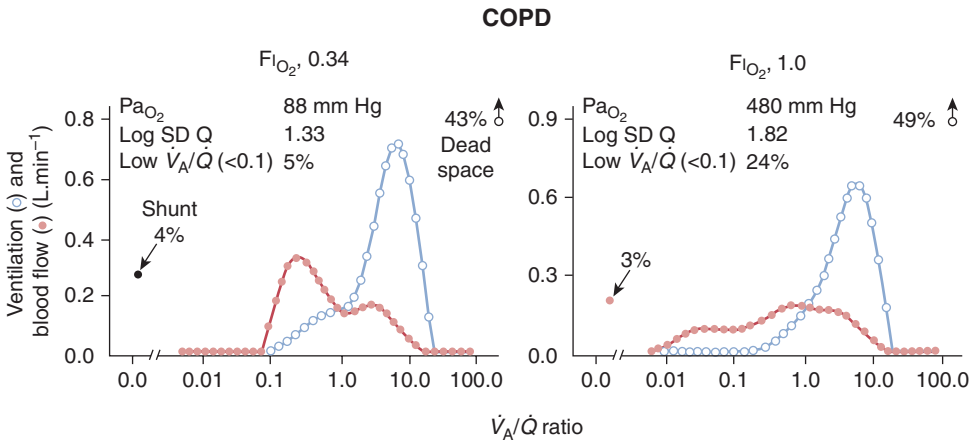

FIGURE 37-11 Effects of breathing 100% oxygen (*right panel*) in a representative patient with COPD. Compared with low FI_{O_2} (*left panel*), Pa_{O_2} increased substantially (≥400 mm Hg) but intrapulmonary shunt remained unaltered; in contrast, the dispersion of blood flow (Log SD Q) and the amount of blood flow distributed to areas with low $\dot{V}_A/\dot{Q}$ ratios increased markedly. This suggests release of hypoxic vasoconstriction without developing reabsorption atelectasis. Dead space tended to increase. Compare these data with those in patients with ARDS (see Fig. 37-2).

edema within the lung—then the possibility of a reopening of the foramen ovale should be considered.[55,56]

Breathing 100% Oxygen. During COPD exacerbations, administration of 100% O_2 rapidly produces full nitrogen washout of alveolar units, even in patients with low or very low $\dot{V}_A/\dot{Q}$ ratios. A steady state is reached by approximately half an hour, resulting in Pa_{O_2} values close to 500 mm Hg.[21,57] These data indicate that shunt is trivial (less than 10% of cardiac output) or negligible.

Breathing 100% O_2 always worsens $\dot{V}_A/\dot{Q}$ relationships, as assessed by a significant increase in the dispersion of blood flow (Log SD Q). In addition, there is a discrete decrease of the dispersion of alveolar ventilation, and dead space tends to increase (Fig. 37-11). As discussed above, the further worsening in $\dot{V}_A/\dot{Q}$ relationships suggests attenuation of hypoxic pulmonary vasoconstriction, even though both pulmonary arterial pressure and vascular resistance remain essentially unaltered. This $\dot{V}_A/\dot{Q}$ deterioration results in a slight but significant increase in Pa_{CO_2}, which also can be influenced by the Haldane effect. The latter was more strongly demonstrated in patients with COPD exacerbations while spontaneously breathing 100% O_2.[58] Alternatively, the slight decrease in the ventilation dispersion could reflect some redistribution of blood flow, from areas of high to areas of low $\dot{V}_A/\dot{Q}$, induced by the accentuated hypoxic vascular response. The lack of increase of shunt in patients with COPD, unlike in patients with ALI or ARDS, indicates that reabsorption atelectasis does not take place. This suggests that either collateral ventilation is very efficient or regional airway occlusion is never functionally complete.

Another striking finding is that when maintenance FI_{O_2} is resumed, Pa_{O_2} rapidly (in less than half an hour) regains the values observed before the institution of breathing 100% O_2.[21] This indicates that nitrogen washout of alveolar units rapidly ceases, even in patients with severe airflow limitation, an observation at variance with ARDS (see Fig. 37-5).[21]

Effects of Positive End-Expiratory Pressure. The potential effects of PEEPi (auto-PEEP)[59] on gas exchange should be kept in mind in patients with COPD requiring mechanical ventilation. In these patients, alveolar pressure can remain positive throughout the respiratory cycle despite the absence of PEEP set on the ventilator.[59]

Because low levels of external PEEP may offset the deleterious effects of PEEPi, investigators assessed the effects of both PEEP and PEEPi on $\dot{V}_A/\dot{Q}$ relationships in patients with chronic airflow obstruction (all but one patient with acute severe asthma had COPD).[60] At low levels of external PEEP (approximately 50% of PEEPi), arterial blood gases improved secondary to an overall optimization of $\dot{V}_A/\dot{Q}$ relationships without changes in pulmonary mechanics or hemodynamics. With further increases in external PEEP so that PEEP was equal to PEEPi, airway pressures slightly increased without further $\dot{V}_A/\dot{Q}$ improvement. The investigators also showed that the use of "permissive" or "controlled" hypoventilation[61] to deliberately reduce PEEPi (by 50%) optimized O_2 delivery secondary to a simultaneous increase in cardiac output. Accordingly, the use of low levels of external PEEP together with "permissive" hypoventilation may be advantageous in patients with COPD needing ventilator support. PEEP may improve gas exchange with less risk of barotrauma. These findings have been strengthened by a study[62] in patients with expiratory flow limitation (i.e., COPD and asthma exacerbations) and PEEPi that showed that application of external PEEP below measured PEEPi did not cause hyperinflation or increased intrathoracic pressure, and resulted in no alteration in lung mechanics, hemodynamics, or gas exchange.

Weaning. $\dot{V}_A/\dot{Q}$ relationships in patients with COPD during weaning from mechanical ventilation has been investigated (Fig. 37-12).[57] No major differences in pulmonary and systemic hemodynamics were shown between mechanical and spontaneous breathing, although cardiac output increased

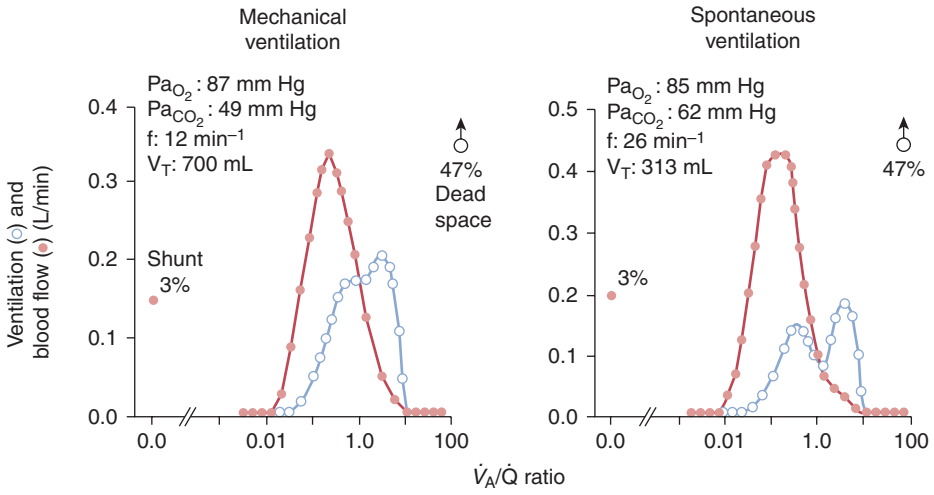

FIGURE 37-12 Effect of ventilator weaning in a representative patient with COPD. Compared with mechanical ventilation (*left panel*), weaning (*right panel*) induced rapid and shallow breathing resulting in increased Pa_{CO_2}. Arterial P_{O_2} did not decrease because the simultaneous increase in cardiac output (not shown) when mechanical ventilation was removed tended to improve Pa_{O_2}, the final result being an unaltered Pa_{O_2}. (Reprinted with permission of the American Thoracic Society. Copyright © 2012 American Thoracic Society. Torres A, Reyes A, Roca J, et al. Ventilation-perfusion mismatching in chronic obstructive pulmonary disease during ventilator weaning. *Am Rev Respir Dis.* 1989;140:1246–1250. Official Journal of the American Thoracic Society. Modified with permission of the American Thoracic Society.)

significantly when patients were removed from the ventilator. Arterial P_{O_2} and O_2 consumption did not change between the two conditions, but mixed venous P_{O_2} and O_2 delivery increased significantly when patients were weaned from the ventilator. During spontaneous breathing, minute ventilation remained essentially unchanged, but respiratory frequency increased and tidal volume fell, resulting in rapid shallow breathing, increased Pa_{CO_2}, and decreased pH.

A considerable increase in the percentage of blood flow to areas of low $\dot{V}_A/\dot{Q}$ was observed during spontaneous ventilation. In contrast, shunt, dispersion of blood flow, and dead space did not change. Therefore, there was further $\dot{V}_A/\dot{Q}$ worsening during spontaneous ventilation after removal of ventilator support. This worsening can be explained by alterations in the breathing pattern and also by changes in cardiac output. Yet, Pa_{O_2} did not undergo major changes, indicating that arterial blood gases were not sufficiently sensitive to detect $\dot{V}_A/\dot{Q}$ changes because other factors, such as minute ventilation and cardiac output were modulating pulmonary gas exchange. Indeed, cardiac output increased substantially after cessation of mechanical ventilation because of a simultaneous abrupt increase in venous return. Similarly, there were increases in mixed venous P_{O_2} and O_2 delivery secondary to the increased cardiac output. Nevertheless, the resulting beneficial effect of the increased cardiac output on Pa_{O_2} was counterbalanced by the simultaneous $\dot{V}_A/\dot{Q}$ worsening, induced in turn by a less-efficient breathing pattern and an increased overall blood flow. Furthermore, using pressure-support ventilation during weaning in patients with exacerbations of COPD prevented worsening of $\dot{V}_A/\dot{Q}$ relationships during the transition from positive-pressure ventilation to spontaneous breathing.[63] Gas-exchange and hemodynamic abnormalities were no different between assist-control and pressure-controlled ventilation when both strategies provided similar levels of ventilator assistance.

Similar results, although without further $\dot{V}_A/\dot{Q}$ worsening, were observed during weaning from mechanical ventilation in patients following coronary artery bypass (half of whom had chronic airflow limitation).[64] Patients with head trauma[48] showed a similar gas-exchange response upon discontinuation of mechanical ventilation, although without associated changes in ventilation and cardiac output.

The key role played by hemodynamic changes has been also emphasized during unsuccessful weaning in patients with COPD.[64] Additional factors contributing to weaning failure include preexisting cardiovascular disease, which may be aggravated by dramatic changes in venous return. An increase of gastric pressure during spontaneous ventilation with subsequent increased splanchnic flow could be an additional mechanism.[65] Oxygen consumption also increases significantly. Inert gas and isotopic studies subsequently revealed that the critical alteration of the ventilation during weaning caused the development of basal regions with very low $\dot{V}_A/\dot{Q}$ ratios.[66]

The increased metabolic demands in these patients could have further negatively influenced the final Pa_{O_2}, thus offsetting the positive effects of the increased cardiac output. In patients with COPD, switching mechanical ventilation to either continuous positive-pressure ventilation or pressure support, increased O_2 consumption and decreased minute ventilation, with marked increments Pa_{CO_2} and no change in Pa_{O_2}.[67] Conceivably, the simultaneous increase in cardiac output (not measured) prevented a fall in Pa_{O_2}. Subsequently, it was observed that patients needing mechanical ventilation (mostly with COPD and cardiac disorders) who failed a trial of spontaneous breathing developed a progressive reduction of mixed venous O_2 saturation secondary to the combined effect of a relative decrease in O_2 transport, possibly related to a decreased right-ventricular and left-ventricular afterload, and an increase in O_2 extraction by the tissues.[68]

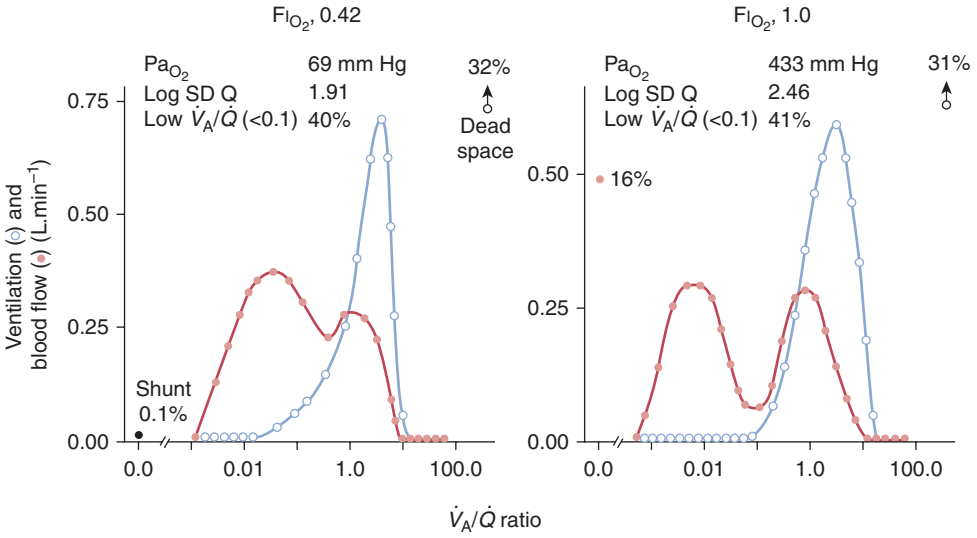

FIGURE 37-13 Effect of breathing 100% O_2 (*right panel*) in a representative patient with acute severe asthma. Compared with low $F_{I_{O_2}}$ (*left panel*), Pa_{O_2} increased substantially (≥400 mm Hg) associated with increases in intrapulmonary shunt, the dispersion of blood flow (Log SD Q), and the amount of blood flow distributed to areas of low $\dot{V}_A/\dot{Q}$ ratios. This suggests the development of reabsorption atelectasis (or selective redistribution of pulmonary blood flow) accompanied with the release of hypoxic vasoconstriction. Compare these data with those seen in patients with COPD (see Fig. 37-12).

Noninvasive Ventilation. The short-term effect of noninvasive ventilation for an exacerbation of COPD has been investigated by our group.[69] The beneficial effect on pulmonary gas exchange—decreased Pa_{CO_2} and increased Pa_{O_2} and pH—was essentially achieved by a more efficient ventilatory pattern (slower and deeper breathing) without a favorable influence on $\dot{V}_A/\dot{Q}$ imbalance. A significant decrease in cardiac output during mechanical support, because of increased intrathoracic pressure, did not decrease Pa_{O_2}.

Acute Severe Asthma

In postmortem studies in patients with sudden fatal asthma, bronchioles reveal increased amounts of luminal occlusion, increased smooth-muscle thickness, and inflammatory infiltrate with both mononuclear cells and eosinophils. Muscular pulmonary arteries adjacent to occluded and inflamed peripheral airways showed a marked inflammatory process in their walls more noticeably when close to airways.[70]

MECHANISMS OF HYPOXEMIA

Patients with life-threatening status asthmaticus who need mechanical ventilation show the most abnormal $\dot{V}_A/\dot{Q}$ pattern in patients with asthma: a marked bimodal blood flow profile that may include 50% or more of cardiac output (Fig. 37-13).[71,72] Severe airways obstruction produces regions of low $\dot{V}_A/\dot{Q}$ that remain perfused but poorly ventilated. This must increase blood flow dispersion more than ventilation dispersion. Conceivably, the high $F_{I_{O_2}}$, together with high doses of bronchodilators with potential vasodilating effects, may attenuate hypoxic pulmonary vasoconstriction, hence contributing to the increase in perfusion of areas with low $\dot{V}_A/\dot{Q}$ ratios. The relatively well-preserved Pa_{O_2} in the presence of such severe $\dot{V}_A/\dot{Q}$ mismatch is noteworthy. This can be attributed to the inordinately high levels of both cardiac output and overall ventilation, which reinforce the major role played by the extrapulmonary determinants of Pa_{O_2} in modulating gas exchange.[5,11,16]

Unexpectedly, shunt was negligible or trivial in these patients. Given the presence of abundant, tenacious, and viscous secretions, one would expect alveolar units distal to narrowed airways to be collapsed. This, however, need not be the case. Collateral ventilation and hypoxic pulmonary vasoconstriction are exceptionally efficient. Moreover, airway occlusion is never functionally complete. Another unexpected finding was the presence of normal dead space, the mechanism of which remains unsettled. The coexistence of diffusion limitation for O_2 was also ruled out (Table 37-2).

TABLE 37-2: CHARACTERISTICS OF PULMONARY GAS EXCHANGE IN CHRONIC AIRFLOW LIMITATION ("DRY LUNG")

	COPD	Asthma
Principal mechanisms		
Shunt	Mild (<10% of Q_T)	Absent
$\dot{V}_A/\dot{Q}$ mismatch	Severe (nonuniform pattern)	Severe (uniform pattern)
O_2 Diffusion limitation	Absent	Absent
100% Oxygen effects		
Increase in Pa_{O_2}	Marked (≥500 mm Hg)	Marked (≥500 mm Hg)
Increase in shunt	Absent	Mild/moderate
Hypoxic vascular response	Increased	Increased

BREATHING 100% OXYGEN

Breathing 100% O_2 induced mild amounts of shunt (less than 10% of cardiac output) in patients with asthma (see Fig. 37-13), suggesting either the presence of critical alveolar units leading to reabsorption atelectasis, or redistribution of pulmonary blood flow of preexisting small shunts, or both.[71] In addition, $\dot{V}_A/\dot{Q}$ mismatch substantially deteriorated, as shown by a considerable increase of the dispersion of pulmonary blood flow. This suggests that hypoxic pulmonary vasoconstriction was decreased. These data are consistent with the morphologic postmortem findings[70] showing that muscular pulmonary arteries adjacent to occluded peripheral airways had marked inflammatory wall involvement that was not characteristic of that associated with chronic hypoxia. Conceivably, these structural abnormalities may reflect pulmonary vascular leakage related to the release of inflammatory mediators.[73] In contrast, the dispersion of alveolar ventilation decreased significantly. A redistribution of blood flow from areas with units of high to areas with units of low $\dot{V}_A/\dot{Q}$ ratio is a potential explanation. A tendency toward an increase in dead space, also shown during 100% O_2 breathing, could reflect hyperoxic bronchodilation.

EFFECTS OF POSITIVE END-EXPIRATORY PRESSURE

The use of PEEP in patients with severe asthma is controversial. Anecdotal reports in patients with life-threatening asthma show conflicting results. Although some studies showed improvement in gas exchange and lung mechanics,[74,75] others found marked increases in Pa_{O_2} associated with gas trapping and increased airway and intrathoracic pressures with decreased cardiac output.[76] From a therapeutic viewpoint, a study by our group[60] of patients with COPD and acute respiratory failure suggests that low levels of PEEP, combined with some degree of "permissive" hypoventilation, might help in optimizing gas exchange in patients with acute severe asthma needing mechanical ventilation.

EFFECT OF SPECIAL MODES OF VENTILATION

High-Frequency Ventilation

During the 1980s there was much interest in mechanical ventilation using small tidal volumes combined with very high frequencies. Few techniques of mechanical ventilation have stimulated as much excitement in the minds of investigators as high-frequency ventilation (HFV), resulting in hundreds of research studies. A reduction in complications such as hemodynamic depression and barotrauma associated with conventional modes was invoked as one of the major advantages.[77]

A comparison of HFV and controlled mechanical ventilation (CMV) in a canine model showed that the efficiency of Pa_{O_2} was no different, but the amount of areas of high $\dot{V}_A/\dot{Q}$ was increased.[78,79] Additional experiments showed that there was an enhanced transport of high-solubility inert gases (approximately twice that for other inert gases) along the airways during HFV. It was suggested that this enhanced transport was dependent on the wet luminal surface of conducting airways.[78]

Although the mechanism of gas delivery by HFV remains to be elucidated, one of the hypotheses is based on augmented dispersion.[80] The theory posits that augmented dispersion during HFV should be less dependent on airway resistance and pulmonary compliance than during CMV. Accordingly, regions of low $\dot{V}_A/\dot{Q}$ might be better ventilated than during CMV. In a canine model of extensive areas of low $\dot{V}_A/\dot{Q}$ but little shunt associated with bronchoconstriction and mucus secretion, HFV was no more effective in delivering fresh gas to such areas than was CMV.[81]

Continuous-Flow Ventilation

Continuous-flow ventilation (CFV) is achieved by delivering continuous streams of gas through cannulas directed down the two main bronchi, in the absence of tidal excursions in lung volume. When CFV was compared to CMV in an animal model,[82] CFV caused significant deterioration in $\dot{V}_A/\dot{Q}$ matching secondary to an increase in the amount of dispersion of pulmonary blood flow. This suggested that CFV induced a nonuniform ventilation distribution and a redistribution of pulmonary perfusion.

In supine dogs, CO_2 elimination was more efficient with endotracheal insufflation than with tracheal insufflation, but the $P(a\text{-}a)O_2$ was larger during CFV than during CMV irrespective of the type of insufflation.[83] Conversely, elimination of CO_2 and $P(a\text{-}a)O_2$ was lower when prone than when supine. In the prone position, gas distribution was uniform with both modes of ventilation. The increased $P(a\text{-}a)O_2$ when supine during CFV was negatively correlated with the decreased ventilation of the dependent zones of the lung, suggesting further $\dot{V}_A/\dot{Q}$ inequalities. The improved gas exchange during CFV in dogs lying prone reflects a more efficient $\dot{V}_A/\dot{Q}$ matching, presumably because the distribution of pulmonary blood flow is nearly uniform.

IMPORTANT UNKNOWNS

The lung is a complex system deriving its chief function from the interaction of two very complicated networks that respectively determine regional perfusion and ventilation. It is now well accepted that the normal lung is exquisitely sensitive to gravity, which normally causes regional differences in blood flow, alveolar ventilation, pleural pressures, and parenchymal stress.

The most common model of pulmonary gas exchange proposes a gravity-induced vertical distribution of perfusion and ventilation, and regional matching of ventilation and

perfusion is accomplished primarily by the shared effects of gravity. Radioactive gases and chest wall scintillation counters were used by a number of investigators in the early 1960s to estimate regional ventilation and perfusion within anterior–posterior cores of lung tissue.

Despite being quantitative, studies using MIGET could not identify the topographical distribution or size of low $\dot{V}_A/\dot{Q}$ units or determine the extent to which the distribution of pulmonary perfusion changes in different experimental and clinical interventions. There have been, however, a few complex attempts to interpret pulmonary perfusion heterogeneity within the context of the gravitational model as random noise. Fractal analysis, a revolutionary mathematical science, demonstrated that this "error" can be analyzed as a fundamental property of the biologic system. Fractal analysis permits characterization of processes or structures that are not easily represented by traditional analytical tools and provides insights and tools for constructing new models. The primary incentive for developing a fractal model of pulmonary blood flow distribution was to explore a unifying mechanism that explains the heterogeneity of perfusion as well as the observation that neighboring lung regions have similar magnitudes of flow.[84]

Another approach has been the use of positron emission tomography imaging of intrapulmonary kinetics of intravenously infused tracer nitrogen-13 (^{13}NN) to measure the regional distribution of ventilation and perfusion.[85]

Ideally, one would like to have a tool to timely measure both ventilation and perfusion taking into account many of the alluded-to caveats. This should include the overcoming of the great difficulties of achieving real steady-state conditions while invasiveness is minimized to cope with cost and time investments.

THE FUTURE

Until the development of some completely new noninvasive, simple technique, it is difficult to anticipate what the future holds for research on pulmonary gas exchange. Over the past three decades, we have witnessed hundreds of elegant studies, of both an experimental and clinical nature. These studies have extensively, and complementarily, unravelled the basic mechanisms of gas exchange across a spectrum of acute and chronic respiratory conditions. Key to the gains in knowledge has been parallel advances that have broadened and deepened our understanding of the clinical management of these conditions. Given this high level of research excellence, it is difficult to predict what will come next. Nevertheless, several worthwhile questions remain to be addressed, particularly in the area of clinical management.

One recent MIGET study was undertaken in patients experiencing a severe exacerbation of COPD,[86] and it addressed the gas-exchange response to a common therapy. It has long been recognized that nebulized, short-acting β_2-agonists can induce mild arterial hypoxemia in patients with COPD, but most of the published work was conducted in the setting of stable COPD. The new study, conducted in patients experiencing a severe exacerbation of COPD requiring hospitalization, revealed no significant gas-exchange abnormalities after use of nebulized salbutamol. During convalescence, however, the same patients experienced small decrements in Pa_{O_2}, secondary to $\dot{V}_A/\dot{Q}$ worsening, on administration of a β_2-agonist. This study addressed not only the salbutamol-induced interplay between extrapulmonary (ventilatory, metabolic, and vascular effects) and intrapulmonary mechanisms (consequences of $\dot{V}_A/\dot{Q}$ mismatching), providing a better insight into the role of gas-exchange pathophysiology in the management of COPD exacerbations. It further confirmed that short-acting bronchodilators are safe when used in the therapy of life-threatening exacerbations of COPD.

CONCLUSION

Arterial P_{O_2} and P_{CO_2} are the end-point outcomes of the gas-exchange state and are governed by the interplay of several intrapulmonary and extrapulmonary components. The most remarkable intrapulmonary factors are $\dot{V}_A/\dot{Q}$ mismatching and intrapulmonary shunt; in contrast, diffusion limitation to O_2 plays a marginal role. Among the extrapulmonary factors, inspired P_{O_2}, overall ventilation, cardiac output, and O_2 consumption are viewed as the most influential.

While breathing 100% O_2, despite substantial Pa_{O_2} improvements, $\dot{V}_A/\dot{Q}$ relationships worsen characteristically according to the underlying nature of acute respiratory insufficiency. In patients with "wet lung" (ALI or ARDS), shunt increases secondary to the development of reabsorption atelectasis without release of hypoxic pulmonary vasoconstriction. In patients with "dry lung" (COPD or asthma), hypoxic vasoconstriction is ultimately released while shunt remains unchanged. Gas-exchange abnormalities may be influenced by changes in cardiac output depending on different ventilator modalities, in particular during weaning from mechanical ventilation.

AIRWAY MANAGEMENT

Aaron M. Joffe
Steven Deem

"Airway management" implies the provision of assistance to a patient in maintaining a patent airway. This chapter will review airway anatomy and basic airway management techniques.

AIRWAY ANATOMY

The Nose and Nasopharynx

The nose is lined with vessel-rich mucosa designed to warm and humidify the air. Bypassing the nose causes dry gases to reach the respiratory tract and necessitates warming and humidification of gases during mechanical ventilation.

The two nares are divided by a nasal septum that is often not midline. In each naris are three turbinates (Fig. 38-1) that help to condition the inspired gases. Underneath each turbinate lies the opening of perinasal sinus. When these openings are occluded by nasogastric or nasotracheal tubes, fluid tends to accumulate in the sinuses as reflected by a high incidence of radiographic sinus opacification.[1]

The floor of the nose leading to the nasopharynx is in the same plane as the nasal orifices. When a tube is introduced into the nose, it should be directed straight back rather than caudad (Fig. 38-2), and advanced carefully to avoid injuring the turbinates.

Mouth

Oral structures relevant to airway management include the lips, teeth, and tongue as each may either impede introduction of airway devices into the pharynx or diminish upper airway patency or both during artificial breathing.

Pharynx

The pharynx is shaped like a cone (Fig. 38-3) and includes the nasopharynx and the oropharynx, which join to form the hypopharynx. The walls of the pharynx are typically soft and compliant, but may become stiff, increase in volume, or both when inflamed from any cause.

The digestive and respiratory tracts share a common lumen in the pharynx. The posterior portion of the pharynx continues to form the esophagus whereas the anterior portion ends in a series of pouches or fossae surrounding the larynx. The epiglottis forms the posterior wall of the anterior pouch. The region anterior to the epiglottis is called the vallecula and is an important landmark for endotracheal intubation as the tip of a curved laryngoscope blade is typically placed in this fossa.

The epiglottic cartilage is shaped like a leaf and is attached to the posterior surface of the thyroid cartilage.

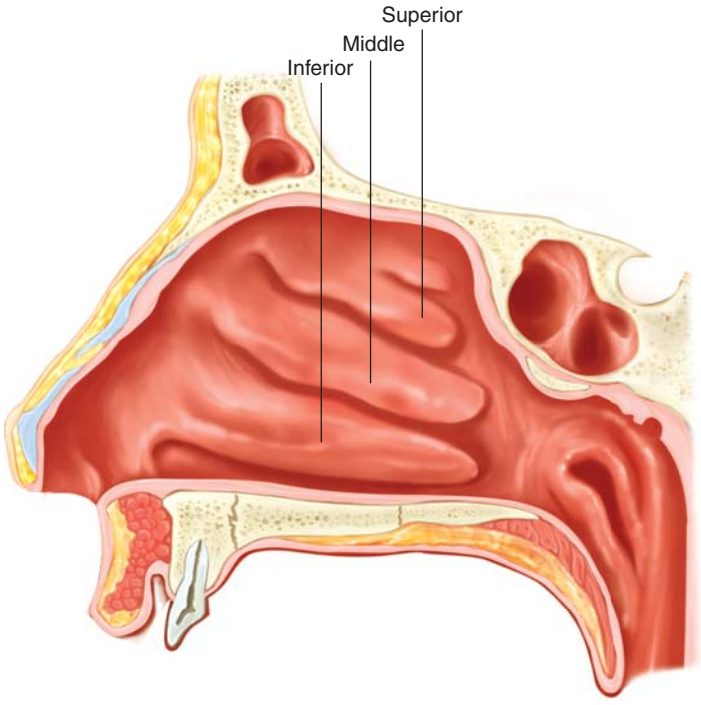

FIGURE 38-1 The nasal turbinates. Note that these are easily traumatized during nasal instrumentation. (Used, with permission, from Pierson DJ, Kacmarek R, eds. *Foundations of Respiratory Care.* New York, NY: Churchill Livingstone; 1992.)

Functionally, the epiglottis directs food away from the larynx by sitting like a tent over the epiglottic opening. This represents an impediment to visualization of the laryngeal aperture and must be lifted out of the way, either by traction or direct lifting from underneath.

FIGURE 38-2 Insertion of a catheter in the nose. The catheter should be directed in parallel with the floor of the nose. (Used, with permission, from Pierson DJ, Kacmarek R, eds. *Foundations of Respiratory Care.* New York, NY: Churchill Livingstone; 1992.)

Larynx

The laryngeal skeleton consists of a group of cartilages extending between the fourth and sixth cervical vertebrae. The major portion of the laryngeal body consists of the thyroid cartilage anteriorly and the cricoid cartilage posteriorly. The cricoid cartilage is actually a complete ring with a wide posterior portion and a narrow anterior portion, which is palpable just inferior to the thyroid cartilage. Between the two cartilages is a small depression that represents the cricothyroid membrane.

The arytenoid cartilages sit posteriorly atop the cricoid cartilage. These small paired cartilages provide support to the posterior portions of the true vocal cords. The mucosa of the vocal cords covers these cartilages, and movement of the cartilages occurs during respiration. The arytenoids are an important landmark insofar as they may be the only portion of the glottic inlet visible during attempted laryngoscopy.

AIRWAY MANAGEMENT WITHOUT INTUBATION

Face-mask ventilation, commonly referred to as bag-valve-mask ventilation, is an essential airway management skill. Although considered a "basic" skill, it is not always easy and requires considerable practice, best mastered in a controlled setting such as the operating room. Face-mask ventilation

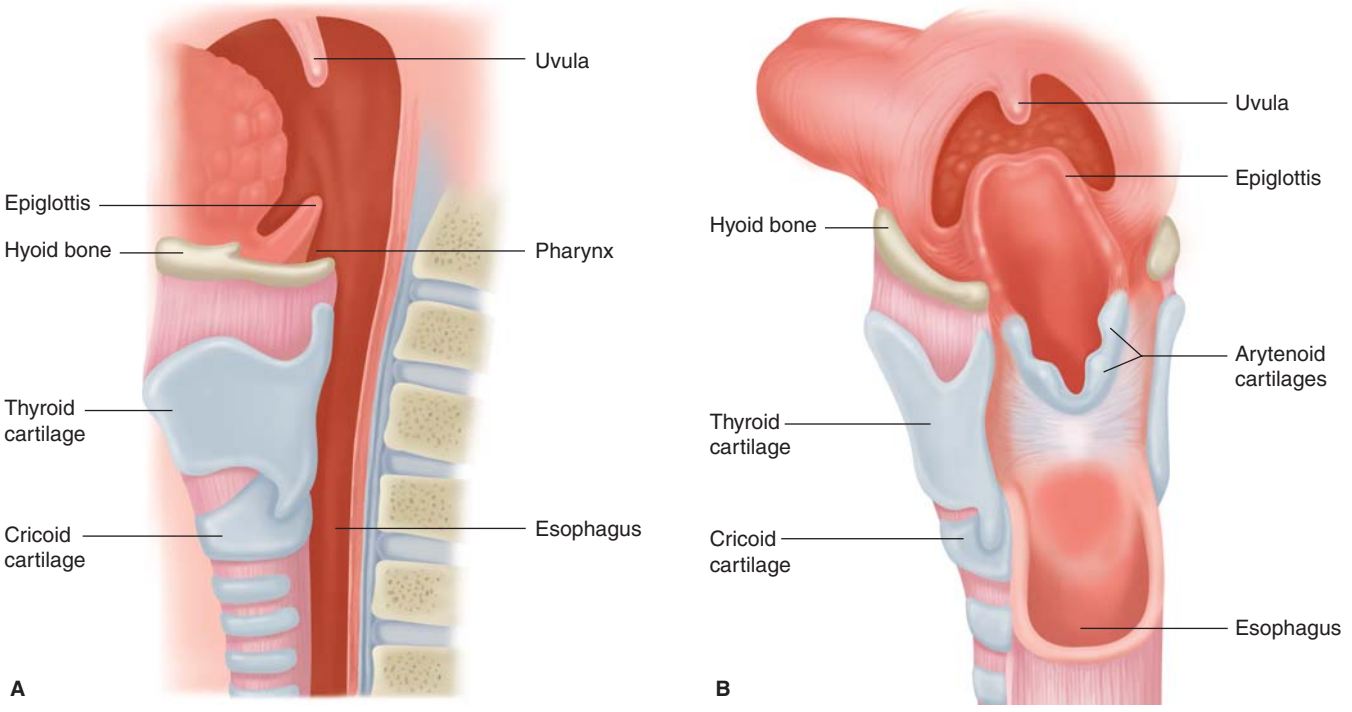

FIGURE 38-3 Lateral (**A**) and posterior oblique (**B**) views of the pharynx and larynx, including the laryngeal skeleton. (Reproduced, with permission, from Pierson DJ, Kacmarek R, eds. *Foundations of Respiratory Care.* New York, NY: Churchill Livingstone; 1992.)

may be required as an initial resuscitative measure, when the need for ventilation is very brief, or when tracheal intubation proves difficult or impossible. Face-mask ventilation may be difficult or impossible because of imperfect patient–face-mask interface or airways obstruction, chiefly of the upper airways but also of the lower airways. If there is high risk of regurgitation of gastric contents ("full stomach"), active vomiting, or bleeding that might result in massive aspiration, face-mask ventilation should only be used as a rescue technique when severe hypoxemia is present.

Risk Factors for Difficult and Impossible Mask Ventilation

Currently, there is no accepted, single definition of what constitutes difficult mask ventilation. Lack of clinical signs of gas exchange, such as "adequate chest rise" or an oxygen saturation by pulse oximetry less than 90%, and the need for oral or nasal airways or the use of a second operator to help with face-mask ventilation are the most referenced surrogates for difficulty.[2] Using these definitions, difficult mask ventilation has been reported in less than 2% of patients.[3] Impossible mask ventilation is a rare event, reported in only 1.5/1000 patients.[4] Caution is advised, however, as these data come from the operating room environment, chiefly in the setting of elective surgery, in patients with stable, managed, or anticipated comorbidities who have been well preoxygenated, rather than in the emergency setting. Risk factors may be segregated by considering operator-dependent factors and patient-related factors, which themselves can be split into those that inhibit proper mask fit and those that may result in upper or lower airways obstruction. Table 38-1 summarizes reported risk factors for difficult and impossible mask ventilation; these factors are highly predictive of difficult mask ventilation, in contrast to the poor positive and negative predictive value of external exams to predict difficult laryngoscopy.[3–6] When a patient exhibits multiple risk factors for difficult mask ventilation, immediate tracheal intubation ("rapid-sequence") or an alternative to facemask ventilation, such as placement of a supraglottic airway, should be performed, preferentially at the outset of airways management.

Most modern face masks are teardrop shaped, made of clear plastic with large, highly compliant, inflatable borders that conform to a wide variety of faces. A tight seal between the mask and the patient's face is critical to achieve adequate ventilation. This is most commonly attempted using a generic left-handed technique in which the operator grips with the fifth finger at the left mandibular angle and the third and fourth fingers on the left mandibular ramus while controlling the mask with their first finger and thumb (Fig. 38-4). In the event that initial face-mask ventilation is difficult or impossible, knowledge of the common anatomic locations of upper airway obstruction allows the airway manager to rapidly perform a variety of maneuvers to relieve the obstruction specific to the site.

TABLE 38-1: RISK FACTORS FOR DIFFICULT OR IMPOSSIBLE MASK VENTILATION

Difficult Mask Ventilation
Increased BMI
History of snoring/OSA
Presence of a beard
Lack of teeth
Age older than 55 years
Mallampati III or IV
Limited mandibular protrusion
Male gender
Cervical spine limitation
Airway masses/tumors
Impossible Mask Ventilation
Neck radiation changes
Male gender
OSA
Mallampati III or IV
Presence of a beard

Abbreviations: BMI, body mass index; *OSA,* obstructive sleep apnea.
Data from Kheterpal et al,[3,4] Langeron et al,[5] and Yildiz et al.[6]

FIGURE 38-4 The generic, single, left-handed mask-hold technique. The operator grips with the fifth finger at the left mandibular angle and the third and fourth fingers on the left mandibular ramus (in the shape of a letter E) while controlling the mask with his or her first finger and thumb (in the shape of a letter C). The *dotted line* represents the line of the jaw. (Image courtesy A. Joffe.)

Head Position

As consciousness is lost, upper airway caliber diminishes and obstruction may occur. The so-called sniffing position, used to optimize visualization during direct laryngoscopy, is ideal for providing face-mask ventilation because it decreases the passive collapsibility of the pharynx and pulls the epiglottis and tongue away from the posterior pharynx.[7] Another maneuver that may open the glottis is to advance the mandible so that the bottom teeth are anterior to the upper teeth.

Nasopharyngeal and Oral Airways

The insertion of an oropharyngeal airway maintains the mouth in an open position and bypasses the nasopharynx and base of the tongue. Hypopharyngeal patency may also be augmented. Nasopharyngeal airways relieve obstruction at the level of the nares and soft palate with the potential to improve the patency of the airway at the level of the base of the tongue and hypopharynx (Fig. 38-5). Oropharyngeal airways are tolerated by anesthetized patients, whereas a nasopharyngeal airway is better tolerated in awake individuals. The major hazards of inserting a nasopharyngeal airway are bleeding or fracture of a turbinate. In nonemergent situations, prior application of a topical vasoconstrictor will ease insertion and prevent bleeding. Thrombocytopenia or a coagulation disorder are relative contraindications to insertion of a nasal airway. Proper sizing and careful placement of all pharyngeal airways is important. Improperly placed oropharyngeal airways can push the base of the tongue down into the hypopharynx, while both oropharyngeal and nasopharyngeal airways that are too large for the patient's airway have the potential to displace the epiglottis caudad toward the vocal cord inlet, causing worsened upper airway obstruction.

OPTIMIZING FACE-MASK VENTILATION

If initial maneuvers prove unsuccessful in allowing adequate face-mask ventilation, additional techniques include placing the base of the face-mask just caudad to the lower lip rather than into the mandibular groove in edentulous patients; this decreases the leak around the mask and may substantially increase tidal volume (Fig. 38-6).[8] As Figure 38-7 shows, a two-handed face mask technique with one person securing the mask and a second operator (out of view in the figure) providing ventilation by squeezing the bag may also increase tidal volumes.[9] A solo operator can also utilize a two-handed mask technique by using an intensive care unit ventilator set to deliver pressure-control ventilation with a limit of 20 cm H_2O as the "second operator."[10] In patients with factors that predict difficult mask ventilation, it may be advisable to employ all available maneuvers initially to provide for an optimal first attempt at face-mask ventilation.

TRACHEAL INTUBATION: INDICATIONS, PREPARATION, AND STANDARD TECHNIQUES

The indications for tracheal intubation are varied, but for the most part can be categorized into (a) the need for maintenance and protection of the airway, (b) the need for high

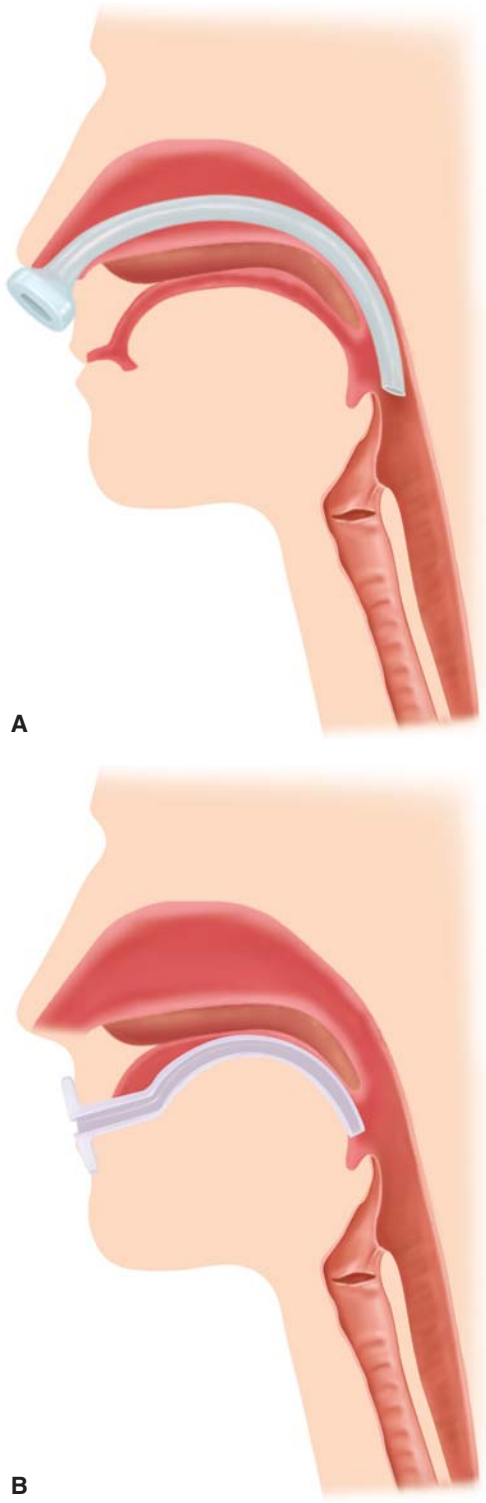

FIGURE 38-5 Nasal (**A**) and oral (**B**) airways in place. These improve the airway by separating the tongue and epiglottis from the posterior pharyngeal wall. (Used, with permission, from Pierson DJ, Kacmarek R, eds. *Foundations of Respiratory Care.* New York, NY: Churchill Livingstone; 1992.)

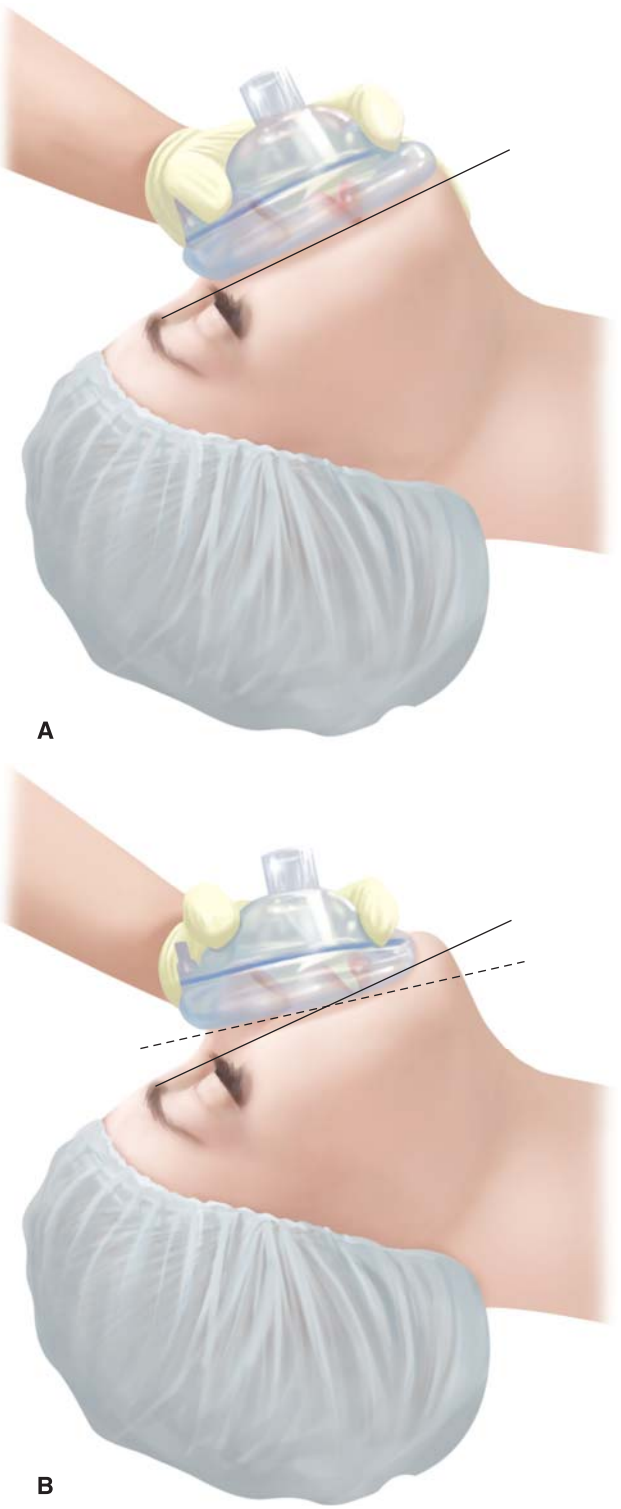

FIGURE 38-6 A comparison of the traditional location of the mask in relation to the patient's face (*top*) with the top of the mask over the bridge of the nose and the base of the mask over the mandibular groove. The *continuous line* represents the plane between the nose and the mandible. When the mask is moved caudally (*bottom*), the base of the mask becomes positioned above the lower lip. The *dashed line* represents the contact between the mask and the face. This "lower lip" placement is particularly advantageous in edentulous patients. (Images courtesy A. Joffe.)

FIGURE 38-7 A two-handed jaw-thrust mask-hold technique. The key to the maneuver is providing sufficient anterior traction to effect maximal mandibular advancement such that the mandibular teeth are forward of the maxillary teeth. This pulls the tissues supported by the mandible—the tongue and epiglottis—away from the posterior pharynx, thereby increasing the airway caliber. In addition, traction may increase the patency of the glottic aperture. (Photograph courtesy A. Joffe.)

inspired oxygen concentrations, or (c) the need for application of positive pressure to the airway. Significant overlap may exist in individual patients. Specific etiologies of respiratory failure and the need for mechanical ventilation are covered in detail in Chapter 4.

Airway Evaluation

A substantial body of research has been directed toward identification of patients with "difficult airways"; unfortunately, anatomy-based predictors of the difficult airway are notoriously insensitive and have only moderate specificity.[11–13] Nonetheless, a basic history should be obtained and an airway examination performed to the extent possible in all patients to identify risk factors for difficult ventilation and/or intubation. Factors associated with difficult intubation include a previous history difficult intubation; morbid obesity;[14,15] obstructive sleep apnea;[16,17] and gross physical abnormalities, including marked prognathia or retrognathia, other congenital deformities, a marked overbite, facial swelling, postradiation fibrosis, and facial dressings. A basic examination includes a view of the patient's facial anatomy from the frontal and lateral perspectives, an oral examination with the mouth maximally open and tongue extended, an assessment of neck extension, and measurement of the distance from the tip of the mandible to the thyroid cartilage. Additional factors to consider in evaluating the airway are discussed below.

Based on oral examination, Mallampati devised a classification scheme to predict difficult intubation (Fig. 38-8).[18] In general, the likelihood of difficult intubation increases from Class 1 to Class 4, although the test has only approximately 50% sensitivity at identifying difficult airways, and is most useful as a positive predictor at the extreme (Class 4).[18,19] In addition, this test is often impractical in emergency settings, where patient cooperation with the examination is not possible.

The size of the mandible provides some measure of the space available to displace the tongue during laryngoscopy (Fig. 38-9). This can be assessed by measurement of the distance between the tip of the mandible and the thyroid cartilage (thyromental distance) using either a ruler or finger-breadths that have previously been calibrated against a ruler. A thyromental distance of less than 6 to 7 cm has a specificity of approximately 90% in identifying the difficult airway, but the test has very poor sensitivity (approximately 30%).[12] Complementary to the absolute distance between

FIGURE 38-8 Mallampati Airway Classification. *From left to right:* Class 1: soft palate, fauces, uvula, and anterior and posterior tonsillar pillars visible; Class 2: soft palate, fauces, uvula visible; Class 3: soft palate, base of uvula visible; and Class 4: hard palate only.

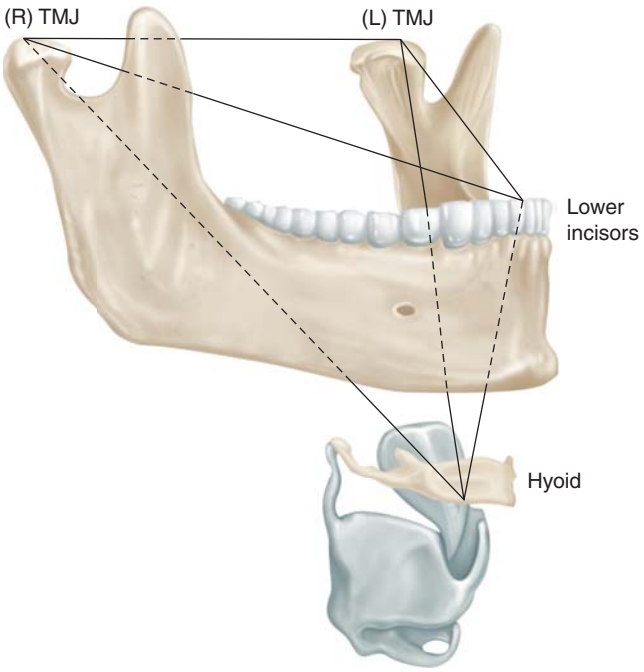

FIGURE 38-9 The submandibular space represented by an inverted pyramid bounded by the right and left temporomandibular joints (*TMJs*), lower incisors, and hyoid bone. This represents the potential space for tissues to be displaced anteriorly and away from the posterior pharynx and lines of sight during airway-management maneuvers. (Adapted, with permission, from Greenland KB. A proposed model for direct laryngoscopy and tracheal intubation. *Anaesthesia.* 2008;63:156–161.)

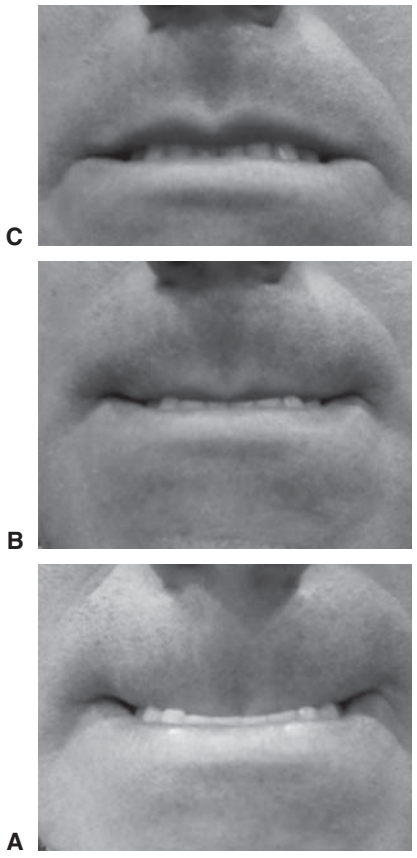

FIGURE 38-10 A frontal view of the upper-lip bite test. *From bottom to top (best to worst):* In Class 1, the lower incisors are able to bite the upper lip past the vermilion border, making the mucosa of the upper lip totally invisible **(A).** In Class 2, a portion of the lip below the vermilion border remains visible **(B).** In Class 3, the lower incisors fail to bite any portion of the upper lip **(C).** (Images courtesy A. Joffe.)

the mentum and thyroid cartilage is the potential distance as assessed by the upper-lip bite test. To perform the test, the patient is simply asked to bite his or her upper lip and is classified as follows: Class 1, lower incisors can bite the upper lip above the vermilion line; Class 2, lower incisors can bite the upper lip below the vermilion line; and Class 3, lower incisors cannot bite the upper lip (Fig. 38-10). Specificity and accuracy of the upper-lip bite test are significantly higher than that reported for thyromental distance alone.[20]

Extension of the head on the neck is necessary to bring the pharyngeal and laryngeal axes into alignment during direct laryngoscopy. Head and neck mobility can be assessed by simple examination, or quantitated by measuring the distance from the sternum to the tip of the mandible (sternomental distance) at maximum neck extension.[21] A sternomental distance of equal to or less than 13.5 cm has greater than 50% sensitivity and specificity at predicting difficult intubation, although this test has not been studied as extensively as either the Mallampati classification or the thyromental distance.[20]

Common sense dictates that a combination of the above tests may prove more useful at predicting the difficult airway than the individual tests. There is some literature to support this notion, although the predictive value of these tests remains modest even when used in combination.[22,23] When possible in the context of the critically ill patient, a minimal exam, which assesses mouth opening, the size of the tongue, cervical spine motion, and mandibular protrusion may be helpful to assess potential problems with laryngoscopy.

Other factors that may complicate emergency intubation and require special consideration include:

1. Risk factors for regurgitation and tracheal aspiration of gastric contents, including recent oral intake; gastroparesis because of drugs; intraabdominal infection, trauma, or diabetic neuropathy; increased intraabdominal pressure (pregnancy, ascites); and bowel obstruction. Most critically ill patients should be considered at risk for regurgitation and aspiration during intubation.
2. Hypovolemia and/or shock predisposes to severe hemodynamic depression during tracheal intubation because of sedative/hypnotic drugs and the initiation of positive pressure ventilation. Vascular access, drugs, fluids, and equipment for resuscitation should be present.

TABLE 38-2: SUPPLIES FOR ADULT TRACHEAL INTUBATION

Routine Supplies
Standard disposable inflatable-rimmed teardrop-shaped face mask in small, regular, and large adult sizes
Oropharyngeal (80 to 100 mm) and nasopharyngeal (28 to 32 Fr) airways
Self-inflating resuscitator circuit ("Ambu Bag" or modified Mapleson circuit)
Yankauer-type suction catheter
Standard and short laryngoscope handle
Blade of choice (curved or straight) in two sizes
Tracheal tube introducer (Eschmann, Frova, etc.)
Supraglottic airways to accommodate small to large adults (30 to 100 kg, laryngeal mask, laryngeal tube, other)
Tracheal tubes (size 7- to 8-mm internal diameter)
Resuscitation drugs and defibrillator immediately available
Device for tube placement confirmation (carbon dioxide detector, self-inflating bulb, other)
Medications
Sedative-hypnotics
Neuromuscular blocking drugs
Additional Difficult Airway Equipment
Indirect video laryngoscope (GlideScope, Airtraq, other)
Intubating laryngeal mask airway (LMA-Fastrach, Air-Q)
Fiber-optic bronchoscope
Aintree intubating catheter, Arndt wire-guided catheter exchange set
Prepackaged cricothyrotomy kit (Melker, Ardnt, other) *or* #11 or 20 scapel with 6.0 inner diameter tracheal tube for cricothyrotomy

3. Increased intracranial pressure, which can be exacerbated by direct laryngoscopy and tracheal intubation.
4. Acute trauma poses multiple problems during attempted intubation, including possible airway injury, head and brain injury, cervical spine injury, and hypovolemia. Intubation in the presence of known or possible cervical spine injury must proceed without movement of the spine (inline manual spine stabilization).
5. Severe hypoxemia reduces the time available for laryngoscopy and intubation before severe oxyhemoglobin desaturation occurs.

EQUIPMENT AND SETUP

Table 38-2 lists supplies that should be present at the site of tracheal intubation, some of which may be institution specific, particularly the equipment available for the anticipated or unanticipated difficult airway. In emergent situations, the endotracheal tube (ETT) should be prefitted with a stylet with a slight anterior bend on the tip ("hockey stick"), which may facilitate placement if the laryngeal view is suboptimal.

TABLE 38-3: INTUBATION CARE BUNDLE

Preintubation
1. Presence of two operators
2. Fluid loading (isotonic saline 500 mL or equivalent) in absence of cardiogenic pulmonary edema
3. Preparation of intensive care unit sedatives (bolus or infusions)
4. Preoxygenate (3 to 5 minutes with tight-fitting high-flow nonrebreather mask or noninvasive positive pressure ventilation in case of acute respiratory failure with FI_{O_2} 100%, pressure support 5 to 15 cm H_2O to obtain expiratory tidal volume of 6 to 8 mL/kg and PEEP of 5 cm H_2O)
Intubation
5. Rapid sequence induction, with or without application of cricoid pressure (see Table 38-4)
Postintubation
6. Immediate confirmation of tube placement
7. Vasopressor administration for postintubation hypotension
8. Initiate sedation
9. Initial ventilator settings to achieve lung protection

Abbreviations: FI_{O_2}, fractional inspired oxygen concentration; *PEEP*, positive end-expiratory pressure.

Adapted, with permission, from Jaber et al.[24]

Preparation for emergency tracheal intubation by following a checklist or bundle is recommended. Use of an intubation bundle incorporating preoxygenation, the presence of two operators, a rapid sequence induction, cricoid pressure, postintubation capnography, low-tidal volume lung-protective ventilation, fluid loading, and preparation and early administration of sedative and vasopressor infusions has been reported to significantly reduce the occurrences of cardiac arrest or death, severe cardiovascular collapse, and hypoxemia occurring within 60 minutes of emergency intubation in the intensive care unit (Table 38-3).[24]

Standard Intubation Techniques

ORAL VERSUS NASAL INTUBATION

The decision to place an oral or nasal tracheal tube is based on a variety of considerations. In general, the oral route is preferred. A larger tube can be placed orally than nasally, resulting in less airways resistance,[25] higher minute ventilation, easier passage of fiber-optic bronchoscopes, and more effective pulmonary toilet. Nasal tubes occlude the sinus ostia, potentially leading to a higher incidence of bacterial sinusitis compared to oral tubes.[1,26] Nasal intubation is contraindicated in the presence of coagulopathy or anticoagulation, basilar skull fracture, or significant nasal or sinus deformity.

PATIENT PREPARATION: RAPID SEQUENCE INDUCTION OF ANESTHESIA

In most cases, the most rapid way to secure the airway is to induce general anesthesia with a sedative and/or hypnotic, followed by administration of a neuromuscular blocking drug, followed by direct laryngoscopy with tracheal intubation. Table 38-4 describes a "rapid sequence induction." This approach, when combined with the application of cricoid pressure (Sellick maneuver) (Fig. 38-11), may minimize the chances of massive aspiration. Note that recent investigations have determined that the mechanism by which cricoid pressure may prevent regurgitation of gastric contents into the pharynx is related to occlusion of the hypopharynx (rather than the esophagus) by downward pressure on the cricoid cartilage.[27,28]

"Preoxygenation," or "denitrogenation," consists of allowing the patient to breathe 100% oxygen for 3 to 5 minutes before induction of anesthesia. Preoxygenation allows utilization of the functional residual capacity as an oxygen reservoir. When functional residual capacity and oxygen consumption are normal, preoxygenation allows 8 or more minutes of apnea before oxyhemoglobin desaturation, and greatly increases the margin of safety should there be difficulties in managing the airway.[29] Preoxygenation, however, is far less effective in patients with acute hypoxemic respiratory failure,[30] and increasing the duration of preoxygenation from 4 to 8 minutes is of only marginal benefit in these patients.[31] On the other hand, the use of noninvasive positive-pressure ventilation in critically ill, hypoxemic patients provides more thorough denitrogenation and longer apnea times than tidal breathing with a non–rebreather mask, and should be considered when staff and equipment are readily available.[32] At a minimum, if patients are already receiving noninvasive positive-pressure ventilation before intubation, it should be continued until laryngoscopy rather than switching to conventional face-mask preoxygenation.

TABLE 38-4: STEPS FOR RAPID-SEQUENCE INDUCTION AND TRACHEAL INTUBATION

1. Prepare equipment and position patient; use of styletted tubes is recommended
2. Preoxygenate patient (this may be occurring simultaneously or can precede #1 above)
3. Apply cricoid pressure (optional depending on circumstance)
4. Rapid administration of induction agent followed by a neuromuscular blocking drug
5. Wait for fasciculations (succinylcholine only) or a full 60 seconds (either succinylcholine or rocuronium), whichever comes first[a]
6. Direct laryngoscopy and tracheal intubation[b]
7. Verification of correct tube placement

[a]Depending on circumstances (suspected full stomach or not), mask ventilation may be briefly attempted before intubation attempts. The ability to provide mask ventilation assures the operator that if laryngoscopy is difficult or impossible, face-mask ventilation will suffice while other intubation pathways are pursued. If face-mask ventilation is unsuccessful in this circumstance, immediate placement of a supraglottic airway or performance of cricothyroidotomy may be necessary should initial intubation attempts fail.

[b]Initial attempts may be made by indirect video laryngoscopy via a supraglottic airway, or by fiber-optic bronchoscope, depending on the situation and the experience of the operator.

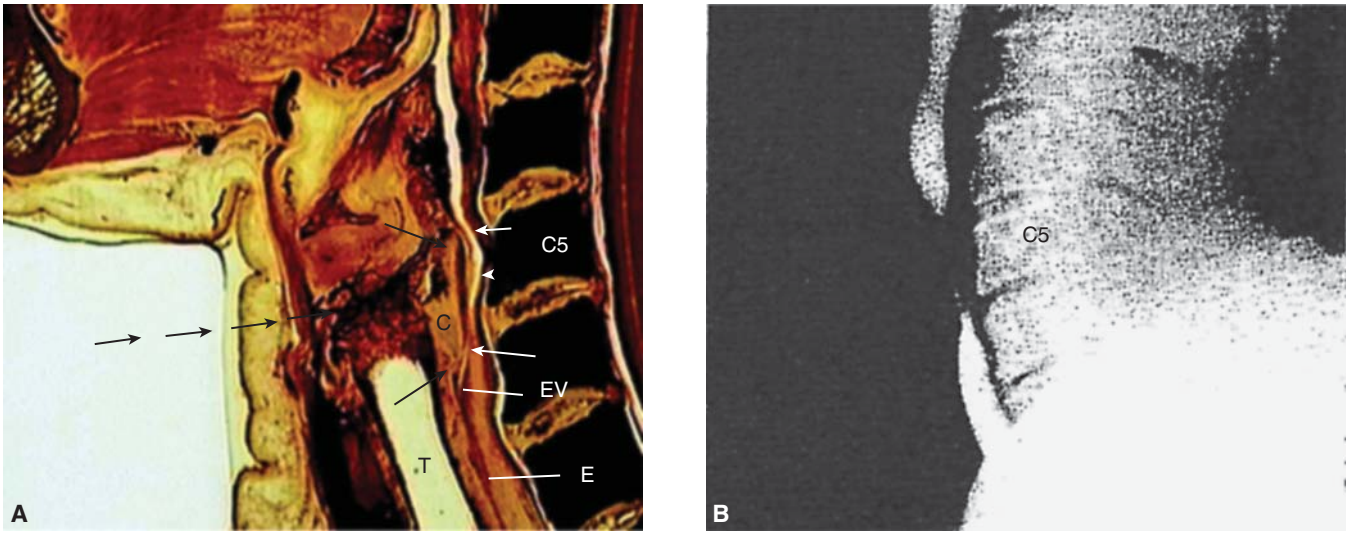

FIGURE 38-11 (**A**) A sagittal cadaver image of the cricoid pressure anatomic unit. The cricoid cartilage (*C*) is the foundation of the cricoid-pressure unit with its superior and inferior aspects indicated by *black arrows.* The postcricoid hypopharynx muscular wall and lumen (*white arrowhead*) and its superior and inferior limits (*white arrows*) have a constant and intimate relationship with the cricoid cartilage. As pressure is applied anteriorly (*serial black arrows*), the unit is compressed against the vertebral body (*C5*), sealing off the esophagus (*E*) at the esophageal verge (*EV*). Because the esophagus is well below the level of the seal, its position is irrelevant to the integrity of the seal produced by the pressure on the unit. (**B**) An image from Sellick's original report showing obliteration of the lumen by cricoid pressure at the fifth cervical vertebra. *T,* trachea. (Used, with permission, from Rice MJ, Mancuso AA, Gibbs C, et al. Cricoid pressure results in compression of the postcricoid hypopharynx: the esophageal position is irrelevant. *Anesth Analg.* 2009;109(5):1546–1552.)

If rapid sequence induction of anesthesia is not indicated, induction may proceed at a more measured pace, without application of cricoid pressure. On the other hand, preoxygenation should be attempted in all emergency intubations, recognizing that it may be neither possible nor effective in some circumstances.

DIRECT LARYNGOSCOPY

Intubation using direct laryngoscopy may be the fastest and surest way of securing an airway. This may be particularly true where use of video laryngoscopes or a fiber-optic bronchoscope may be hindered by airway soiling with secretions, blood, or vomitus. This important lifesaving skill, however, can result in great harm if performed incorrectly. The major, feared complications are failure to ventilate and intubate the trachea, and unrecognized esophageal intubation, both of which can lead to severe neurologic injury and death. The likelihood of successful intubation is increased with experience, in addition to the use of proper equipment and suitable pharmacologic adjuncts. Gaining expertise in manual face-mask ventilation and direct laryngoscopy in a controlled setting before attempting these maneuvers in an emergency cannot be overemphasized. The specifics and technical considerations of direct laryngoscopy are beyond the scope of this chapter. A brief description of the basic technique follows.

Numerous laryngoscope blades have been devised for various special situations but most intubations are performed using one of two categories of blades: (a) blades intended to be used to lift the epiglottis directly ("straight" blades); (b) blades designed to lift the epiglottis indirectly by placing anterior traction on the hyoepiglottic ligament in the vallecula ("curved" blades) (Fig. 38-12). In our experience, the curved laryngoscope blade is more easily mastered and more commonly used than the straight blade, although facility with both is ideal as each has distinct advantages. Laryngoscope blades are most commonly designed to be held by the left hand (for right-handed individuals), although right-handed blades are available.

Before starting, the patient's head should be positioned near the top of the bed so the laryngoscopist's arms are not fully extended. The force applied during the average intubation is 25 newtons (N),[33] the equivalent of lifting a mass of approximately 2.5 kg. This force is most easily applied when the elbow is flexed and relatively close to the laryngoscopist's body.

Classical teaching is that laryngoscopy is facilitated by flexion of the neck at the cervical–thoracic junction and extension of the neck at the atlantooccipital joint ("sniffing position"); this position brings the laryngeal and pharyngeal axes into alignment. The sniffing position is accomplished by raising the occiput with a firm pillow, folded towels, or other support. Recent studies, however, suggest that cervical extension is the most important component of this maneuver, and that the addition of neck flexion on the thorax improves the laryngoscopic view only in patients with limited neck extension and/or morbid obesity.[34,35]

FIGURE 38-12 Typical straight ("Miller," *top*) and curved ("Macintosh," *below*) blades for direct laryngoscopy. Straight blades directly lift the epiglottis. Although this often provides a clear view of the glottis, the room available for inserting the endotracheal tube into the mouth is limited compared to curved blade. The curved blade, the most common variant of which is the Macintosh, is directed into the vallecula and then pulled forward. This lifts the epiglottis away from the glottis. (Photograph courtesy S. Deem.)

Laryngoscopy proper begins by positioning the blade in the right side of the patient's mouth; the mouth opening can be facilitated with the right hand. The right hand can then move to the occiput to extend or flex the neck into optimal position. The blade is then slowly advanced and the tongue swept to the left. The uvula and then the epiglottis should be identified, and are useful landmarks for maintaining a midline position. The blade should be advanced either into the vallecula (curved blade), or beyond the epiglottis toward the glottis (straight blade), and traction then applied at a 45-degree angle with floor. The wrist should remain firm, as flexing the wrist may cause pressure on the upper incisors and will push the epiglottis in front of the larynx. Traction at a 45-degree angle pulls the epiglottis forward to reveal the glottic opening. If the glottis is still not visible, external application of *b*ackward (toward the spine), *u*pward (toward the head), *r*ightward (toward the patient's right side) *p*ressure on the thyroid cartilage ("BURP" maneuver) may push the larynx into view; an assistant can then hold the larynx in this position.[36] Once the laryngeal aperture is visualized, the ETT can be advanced through the glottis, the stylet removed, and the cuff inflated; the correct position should be verified as described below.

If the nasal route is used, application of a topical vasoconstrictor before intubation is of critical importance in increasing the size of the nasal passage and minimizing bleeding. Topical 4% cocaine is effective, providing both vasoconstriction and anesthesia, but may be toxic at doses greater than 3 to 4 mg/kg. An effective alternative is to use a phenylephrine or oxymetazoline nasal spray several minutes before instrumenting the nose, particularly if topical anesthesia is not necessary. Both nostrils should be sprayed in case one side is partially obstructed. The nasal passage can be prelubricated by inserting a nasopharyngeal airway coated with either 2% lidocaine gel (for awake intubations) or water-soluble gel. In addition, briefly warming the ETT in 37°C (98.6°F) water will make it much more pliable and less likely to injure the mucosa. Nasal tubes (without a stylet) should be inserted with gentle pressure, directed posteriorly and advanced into the pharynx. Direct laryngoscopy is then performed, and the tube is guided into the larynx by manipulating the end extending out of the nose. Frequently, the tube tip must be guided with a Magill forceps while an assistant advances the tube.

THE DIFFICULT AIRWAY

The term *difficult airway* is best defined as the development of any airway management problem that requires an escalation of interventions to establish mask ventilation and/or tracheal intubation. For purposes of standardization in studies, difficult intubation is often defined as that requiring more than two attempts at laryngoscopy, or by a grade 3 or 4 laryngoscopic view as described by Cormack and Lehane (Fig. 38-13), although considerable subjectivity exists for all definitions.[37] "Failed" intubation implies that either attempts were aborted, or that the airway was secured surgically. The estimated incidence of difficult tracheal intubation in the operating room is approximately 5%, and failed intubation is less than 0.5%.[12] The reported incidence of difficult intubation in the emergency setting varies widely, but on the average is similar to that for the operating room. The reported incidence of failed intubation, however, is much higher (up to 5%), as is the incidence of other intubation-associated complications such as hypoxemia, aspiration, cardiac arrest, and death.[38–41]

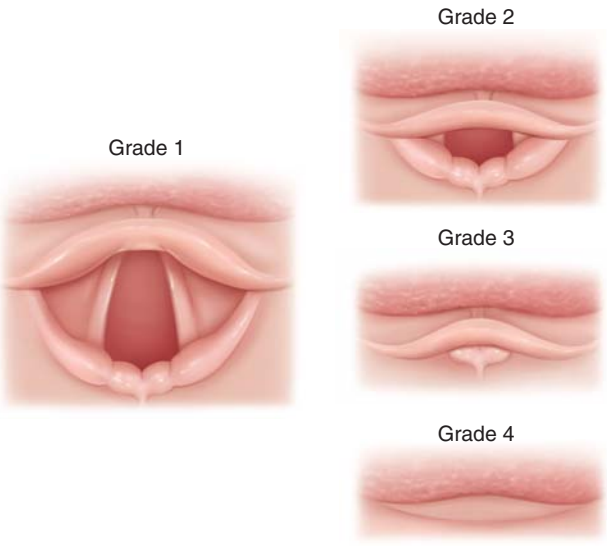

FIGURE 38-13 Laryngoscopy grading, usually referred to as Cormack-Lehane grade after the physicians who originally described them. *From left to right:* Grade 1: entire glottic opening can be visualized; Grade 2: only the posterior glottis or posterior arytenoids can be visualized; Grade 3: only the epiglottis is visible; Grade 4: no recognizable structures are visible.

It is not surprising that difficulties in managing the airway are more likely to occur during emergency intubation than during an elective situation given the comorbidities that may complicate emergency intubation. Emergency intubation also poses an additional problem in that the patient cannot be awakened and the intubation postponed, particularly as critically ill patients often require intubation because of inadequate oxygenation and/or ventilation.

Guidelines for management of the difficult airway based on available literature and expert opinion have been developed locally (at the hospital or practice level) and regionally or nationally.[12,42–45] The American Society of Anesthesiology was the first organization to publish such guidelines (including an accompanying algorithm), with the last update several years old at the time of this writing.[43] It is the general perception that difficult airway guidelines and algorithms have resulted in fewer airway mishaps. This appears to be true regarding airway management at the induction of anesthesia. The same conclusion, however, is not supported with respect to airway management during other phases of anesthesia or in locations outside of the operating room.[46] Thus, other groups have developed guidelines that are more prescriptive.[45]

Despite the lack of hard supporting evidence, common sense dictates that all airway providers should gain expertise in difficult airway management skills, and should have an algorithm for dealing with the difficult airway. Which published algorithm iteration is used is likely not as important as the act of learning and implementing it. Institutional specific algorithms based upon the types of patients to be cared for, the local experience, and available equipment may have a greater impact than broader, society-based difficult airway algorithms. Recent reports support this notion for elective surgical patients and in the prehospital setting.[47,48] Every institution should have an organized team for responding to critical airways, with minimal training standards for all designated responders, equipment standards, and a mechanism for providing the rare emergency surgical airway.

Predicted Difficult Airway: Awake Intubation

If the patient has a recognized difficult airway and is not combative or uncooperative, an awake intubation is generally preferable. This can be accomplished by one of several techniques, including blindly placing a nasotracheal tube, placing an oral or nasal tube using fiber-optic guidance, using awake direct laryngoscopy, or using a retrograde tube-over-guide technique. Alternatively, the airway may be surgically secured primarily by an awake tracheotomy or, in emergent situations, by an emergency cricothyrotomy. Preparation of the patient and some awake intubation techniques are outlined below.

PATIENT PREPARATION FOR AWAKE INTUBATION

Awake intubation can be performed with surprisingly little discomfort to the patient if topical anesthesia is first applied. Administration of an antisialagogue such as glycopyrrolate decreases secretions that impair visibility and enables better uptake of local anesthetics by the mucous membranes. If intubation is emergent or urgent, there may be insufficient time for the antisialagogue to become effective, however.

Topical anesthesia of the soft palate, pharynx, and larynx can be obtained by administration of atomized or nebulized lidocaine (2% to 4%) or benzocaine spray, and/or by asking the patient to gargle with viscous lidocaine solution. Caution is warranted regarding the use of benzocaine, as methemoglobinemia has been reported with this agent, and toxicity is not necessarily related to the administered dose.[49,50] Patients receiving benzocaine should be monitored for the development of cyanosis; the arterial saturation as estimated by pulse oximetry may fall, but this monitor underestimates the true oxyhemoglobin saturation.[51] A high level of suspicion is necessary, and methemoglobinemia can be confirmed by cooximetry. If lidocaine is used, the total administered dose should be limited to less than 300 mg as absorption via the mucosa is significant and can lead to central nervous system toxicity.

Anesthesia of the trachea can be achieved by nebulization of lidocaine, by spraying lidocaine through a fiber-optic bronchoscope, or via transtracheal injection of lidocaine, with the transtracheal approach providing the best anesthesia.[52] This can be accomplished by rapid injection of 2 to 3 mL of 4% lidocaine with a 22-gauge needle at end-exhalation; the subsequent cough helps distribute the anesthetic.

Direct or indirect video laryngoscopy can be performed in awake patients, provided that adequate topical anesthesia has been applied, although supplemental sedative may be required. Additional awake techniques are discussed below.

AWAKE BLIND NASAL

Blind nasal intubation has the advantage of not requiring a laryngoscope (or bronchoscope), can be performed even when blood or secretions are present in the airway, and can be performed on a patient in the sitting position. The technique is especially suited to dyspneic patients, as they breathe more comfortably when sitting, have easily heard breath sounds, and tend to maintain their glottis open. Once the tube is in the nasopharynx, it should be directed caudad, using breath sounds as a guide, and advanced through the glottis during inspiration. The course of the tube can sometimes be determined by external palpation of the neck. The larynx can often be pushed gently toward one side if the tube is slightly misaligned. Rotation of the tube and flexion or extension of the neck may also be useful if the tube does not initially enter the trachea. The overall success rate for blind nasal intubation is approximately 90% in experienced hands.[53]

FIBER-OPTIC TRACHEAL INTUBATION

Fiber-optic-aided intubation allows direct visual guidance, can be accomplished in the awake patient via either the nasal or oral route, and is less stimulating than direct laryngoscopy. In emergency situations, however, when blood, vomitus, or copious secretions are present, it may be quite difficult.

Preparation of the patient for awake fiber-optic intubation is described under Patient Preparation for Awake Intubation; the neck should be neutral or slightly extended. The scope and light source should be verified to be in working order, the bronchoscope lubricated, and the tube passed over it to ensure proper fit. Oxygen can be insufflated through the suction port of the scope, or direct through the patient's nose or mouth, depending on what intubation route is used. The nasal route may provide the best angle for viewing and entering the larynx. The ETT can be passed into the nose and advanced into the nasopharynx, and the bronchoscope then introduced. If the oral route is chosen, an oral intubating airway may facilitate passage of the scope

TABLE 38-5: A COMPARISON OF SOME COMMONLY USED VIDEO LARYNGOSCOPES

Device	Blade Shape	Monitor	Reusable/Disposable	Size Range
GlideScope	Angulated	Separate, 3.5-in. (ranger) or 7-in. LCD monitor	Reusable, single-use blades (cobalt, ranger)	Pediatric–large adult, depending on model
Storz C-Mac, D-Mac	Standard Macintosh blade, angulated	Separate, 7-in. TFT monitor	Reusable	Sizes 2 to 4
McGrath	Angulated	Integrated, 1.7-in. LCD monitor	Single-use blades	Three adult lengths
Pentax-AWS	Anatomically shaped with guide channel	Integrated, 2.4-in. LCD monitor	Single-use blades	One size only
Airtraq	Anatomically shaped with guide channel	None (with eyepiece) or external monitor	Single-use blades	Pediatric, small adult, regular adult, double-lumen

Abbreviations: LCD, liquid crystal display; *TFT,* thin-film transistor.

Data from Niforopoulou P, Pantazopoulos I, Demestiha T, et al. Video-laryngoscopes in the adult airway management: a topical review of the literature. *Acta Anaesthesiol Scand.* 2010;54(9):1050–1061.[128]

through the mouth and pharynx. Alternatively, an assistant can grasp and gently pull the patient's tongue with a gauze pad. This opens the pharynx and facilitates visualization of the larynx. If the patient is sedated or uncooperative, a bite block should be inserted to prevent biting of the scope. After the scope enters the trachea, the ETT can be advanced, and its position relative to the carina confirmed before withdrawing the scope. If the tube does not easily pass through the glottis, a 90-degree clockwise rotation may allow passage beyond the right vocal cord.

VIDEO (INDIRECT) LARYNGOSCOPY

A number of indirect laryngoscopes with video capability are commercially available and are generally classified into steering and nonsteering devices, although it is also useful to differentiate them by whether or not the device incorporates an integrated channel for delivery of the tracheal tube. Five devices, two of which are channeled, are currently available or soon will be. Table 38-5 compares the features unique or shared amongst the devices.

The most important feature shared amongst videolaryngoscopes is their ability to "look around the corner" enabling an almost universally improved view of the glottic structures compared to those obtained with direct laryngoscopy; the technique has recently been reviewed in detail.[54] Videolaryngoscopes can be used preferentially as an "optimal" first attempt at intubation, for rescue after failed direct laryngoscopy, after topicalization of the airway for awake intubation, or to inspect the airway and rule out airway edema or obstructing masses before extubation of the difficult airway.

THE UNRECOGNIZED DIFFICULT AIRWAY

The term *unrecognized* implies that the initial attempt by any method of airway instrumentation, but chiefly direct laryngoscopy, was not straightforward as expected. As mentioned previously, prediction of difficult intubation is an inexact science, and it is not uncommon to have unexpected difficulties with tracheal intubation after induction of anesthesia and paralysis. Furthermore, in the critically ill patient, awake intubation or postponement of intubation are frequently not options either because of patient combativeness or the immediate need for control of the airway or severe hypoxemia. Thus, perhaps the most essential component of airway management skills is the ability to rapidly and systematically respond to difficulties with intubation and/or face-mask ventilation. At the first sign of airway difficulties, help should be summoned, difficult airway equipment obtained if not already present, and a difficult airway algorithm followed.

The first laryngoscopy attempt should be the optimal attempt and thus particular attention must be paid to equipment setup, patient positioning, ergonomics of the operator, and the surrounding conditions such as support staff, lighting, and ambient noise. Potential technique modifications occurring at the time of laryngoscopy include adjustment of head and neck position, and external laryngeal manipulation/ bimanual laryngoscopy ("BURP" maneuver). Based upon the best laryngoscopic view obtained, intubation can be attempted by direct placement of the tracheal tube, use of an Eschmann introducer or bougie, or immediate switch to an alternate laryngoscope blade or device for a second attempt. For example, in large patients where the blade is not long enough to reach the vallecula, a longer blade (i.e., Macintosh #4 instead of Macintosh #3 blade) may be useful; in patients with a long, floppy epiglottis, switching from a curved to a straight blade may be helpful. If initial intubation attempts fail but mask ventilation is adequate, the situation remains controlled. In general, however, no more than two attempts at direct laryngoscopy should be made before choosing an alternate technique, as multiple laryngoscopies are associated with increased morbidity.

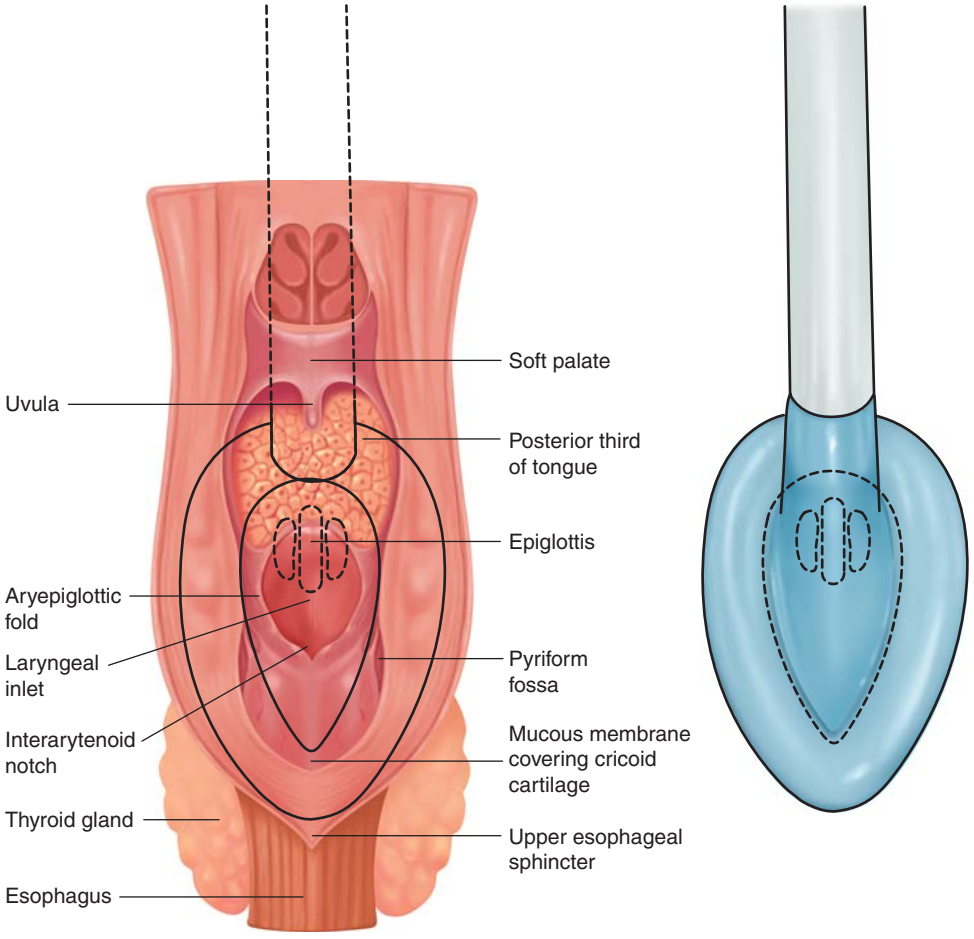

FIGURE 38-14 Dorsal view of the laryngeal mask airway (LMA) showing position relative to pharyngeal anatomy. (Image courtesy LMA North America, Inc.)

If mask ventilation remains effective, other alternate techniques to consider are video laryngoscopy, fiber-optic intubation, or laryngeal mask-facilitated intubation. If these techniques are not practical for any reason, remaining options are limited, and include a surgical airway and awakening the patient. Awakening the patient, however, is infrequently an option in the emergency setting, as discussed above.

DIFFICULT INTUBATION AND DIFFICULT FACE-MASK VENTILATION

If initial intubation attempts fail and face-mask ventilation becomes inadequate, a supraglottic airway should be used. In addition, a supraglottic airway may be placed preferentially in lieu of face-mask ventilation after initial intubation attempts in any patient exhibiting predictors of difficult mask ventilation. Several supraglottic airways are commercially available. The decision to use one or the other of these devices depends on clinical experience and availability of the devices, but at least one type of supraglottic airway should be included in difficult airway storage units. The devices have been described as either periglottic or retroglottic. Periglottic airways consist of a tube connected to an oval, somewhat pear-shaped mask with an inflatable or hydrocolloid gel-filled rim that fits into the periglottic area. The tip of the bowl of the mask, when correctly positioned, sits within the proximal end of the esophagus while the heel of the mask abuts the base of the tongue or within the vallecula (Fig. 38-14). Retroglottic airways have two inflatable cuffs: one distal designed to occlude the esophagus, and a more proximal cuff intended to seal the retropharynx. Between these two cuffs lies an opening through which air can flow (Fig. 38-15). Such devices have been used quite successfully to provide rescue ventilation in patients in whom face-mask ventilation has failed.[55] Although practice with supraglottic airways is recommended before use in an emergency, the insertion and ventilation success rate are high even in unskilled hands.[56–58]

The airway seal, that is to say, the airway pressure at which gas escapes around the cuff has a wide range depending on the device. The LMA-Classic and other similarly designed airways typically seal the airway up to pressures of 15 to 20 cm H_2O.[59] Devices such as the air-Q (Mercury

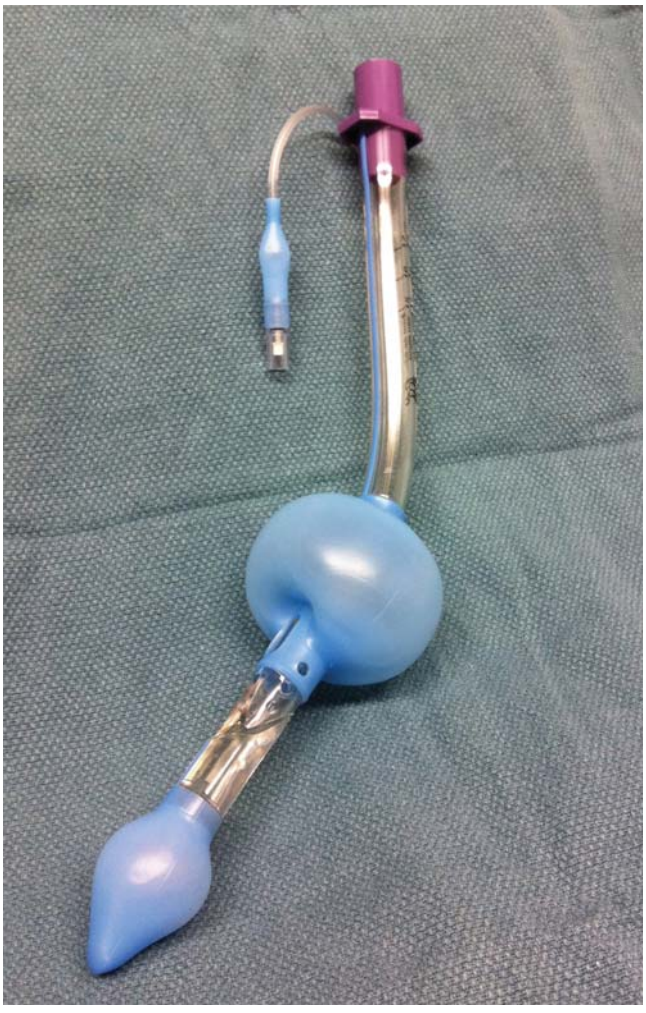

FIGURE 38-15 A retroglottic airway, the laryngeal tube. A single port inflates both the distal esophageal and more proximal pharyngeal balloons. The airway tube terminates in an opening just distal to the pharyngeal balloon. (Photograph courtesy A Joffe.)

Medical, Clearwater, FL) and the i-Gel (Intersurgical, Ltd., Berkshire, UK) supply a seal of approximately 25 cm H_2O and have the advantage of shorter, larger diameter airway tubes that allow direct passage of usual adult size tracheal tubes through them (7 to 8 mm inner diameter).[60,61] The LMA-Proseal is the most extensively studied device with the most reliable airway seal, up to pressures of 40 cm H_2O, although the reported average is approximately 30 cm H_2O.[62] It should be noted that the LMA-Classic and similar devices will not necessarily prevent aspiration of gastric contents, although this has not been a commonly reported problem during either elective use,[63] or during emergency ventilation. A number of supraglottic airways (LMA-Proseal, LMA-Supreme, i-Gel) have incorporated an esophageal vent to minimize the aspiration risk, although the benefit in this regard is contentious and there is a dearth of data supporting this claim.

Besides their simplicity, ease of insertion, and effectiveness, a major advantage of supraglottic airways is that they can provide a direct route to the larynx and trachea. When correctly seated in the supraglottis, the termination of the airway tube of the device sits directly opposite the glottic aperture. Intubation of the trachea through these devices has been described using several techniques. The most successful, however, involve the blind passage of an ETT through the device or fiber-optic bronchoscope aided techniques.[64,65] The clear advantage of the latter technique is that it allows direct visual guidance and confirmation of intratracheal placement, and reported success rates are higher for fiber-optic versus blind intubation.[45,66] The lumen of the originally designed, or "classic" size 3 LMA is only large enough to accept a 6-mm ETT, whereas the size 5 LMA will accept a 7-mm ETT. For this reason, difficult airways supplies for use in the intensive care unit may include newer supraglottic airways as detailed above so as to avoid this limitation.

An LMA specifically designed for intubation, the LMA-Fastrack, is modified to include a lumen large enough to accept an 8-mm ETT, a rigid structure to allow easier tube placement, and a bar to lift the epiglottis away from the laryngeal aperture. Like the classic LMA, placement and ventilation success rates are high with the intubating LMA, even for novice users.[67,68] Intubation can be done blindly or using fiber-optic guidance; although blind intubation is usually successful, multiple attempts may be necessary.[68] Fiber-optic guidance results in a higher success rate on the first attempt.

FAILED INTUBATION AND VENTILATION: CRICOTHYROTOMY

If intubation has been unsuccessful and ventilation via face mask and supraglottic airway is compromised, particularly if hypoxemia is present, more invasive airway management techniques must be employed. An important skill in airway management is the ability to recognize the need for a surgical airway *before* the development of injury-inducing, severe hypoxemia. The trachea can be accessed either percutaneously or surgically via the cricothyroid membrane; the approach used depends on the skill of the airway practitioner, and surgeon and equipment availability. Percutaneous placement of a large bore needle or catheter (13 to 16 gauge) permits transtracheal jet ventilation, which generally will provide adequate oxygenation and ventilation before a definitive surgical tracheotomy.[69] In order to carry out transtracheal jet ventilation, however, a high-pressure oxygen source and an adjustable, high-pressure device (jet injector) must be available; attempted manual ventilation through a catheter is largely ineffective. In addition, the potential complications associated with transtracheal jet ventilation are severe, particularly if the catheter is inadvertently positioned outside the trachea, and include barotrauma, arterial perforation, and gas trapping because of airway obstruction or insufficient expiratory time.[70]

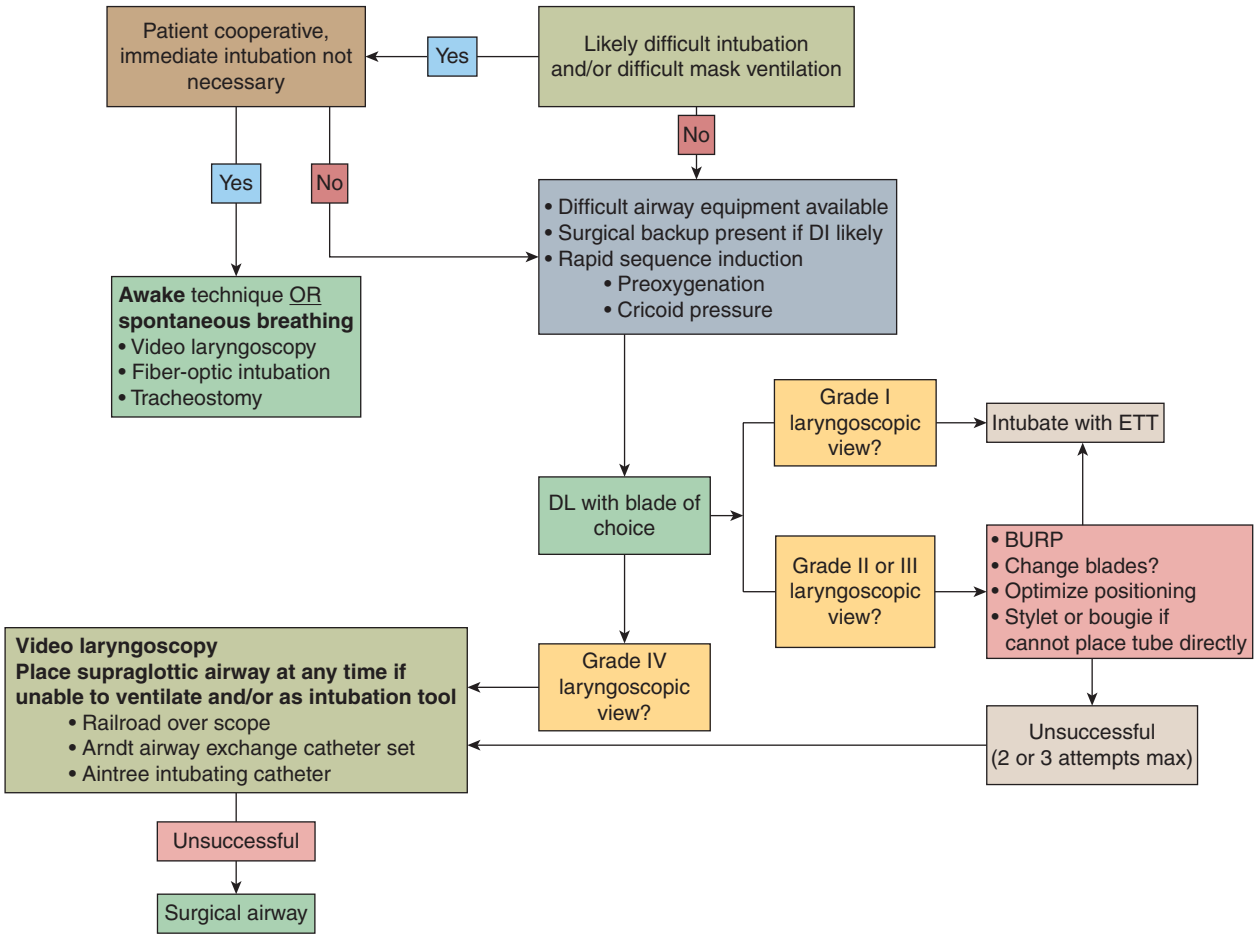

FIGURE 38-16 Airway management algorithm for emergent tracheal intubations. Additional help should be sought at the first indication of a difficult airway situation. It is critical that movement to the next step in the algorithm not be prolonged by repeated attempts at direct laryngoscopy that may traumatize the airway and lead to failed ventilation and oxygenation. Confirmation of intratracheal placement should always use CO_2 detection combined with clinical findings. *DI,* difficult intubation; *ETT,* endotracheal tube.

The correct position of the cannula should be verified by syringe aspiration of air before initiating ventilation, and care must be taken to avoid kinking of the catheter at the insertion site. For these reasons, transtracheal jet ventilation is becoming an increasingly uncommon recommendation in these situations and the necessary equipment has largely been relegated to the operating room.

Surgical cricothyrotomy is an effective and relatively safe and rapid way to secure the airway in experienced hands.[71,72] The standard surgical cricothyrotomy technique utilizes a #11 scalpel to penetrate the skin, subcutaneous tissue, and cricothyroid membrane, followed by hemostat-aided dilation of the cricothyroid space before tube insertion. The "rapid four-step technique" uses a #20 scalpel to penetrate the cricothyroid membrane in one move, followed by caudal retraction of the cricoid cartilage and introduction of the tracheal tube.[73] The latter technique appears to be faster with a comparable complication rate. Ideally, these techniques should be reviewed and practiced on a model before use in the emergency setting.

Figure 38-16 is a difficult airway algorithm for emergency intubation situations.

Verification of Intratracheal Tube Placement and Position

A disastrous complication of endotracheal intubation is the unrecognized placement of the ETT in the esophagus.[74] Placement of the tube into a main stem bronchus is less likely to result in death or severe neurologic injury, but is still a risk for significant morbidity. Although misplacement might seem simple to avoid or to detect, even experienced clinicians are sometime fooled, especially following a difficult intubation (Fig. 38-17). At one time, airway management failures including unrecognized esophageal intubation were a small but significant cause of intraoperative mortality, morbidity, and liability claims. Minimum standards for monitoring established by the American Society of Anesthesiologists in 1986 included a directive that all

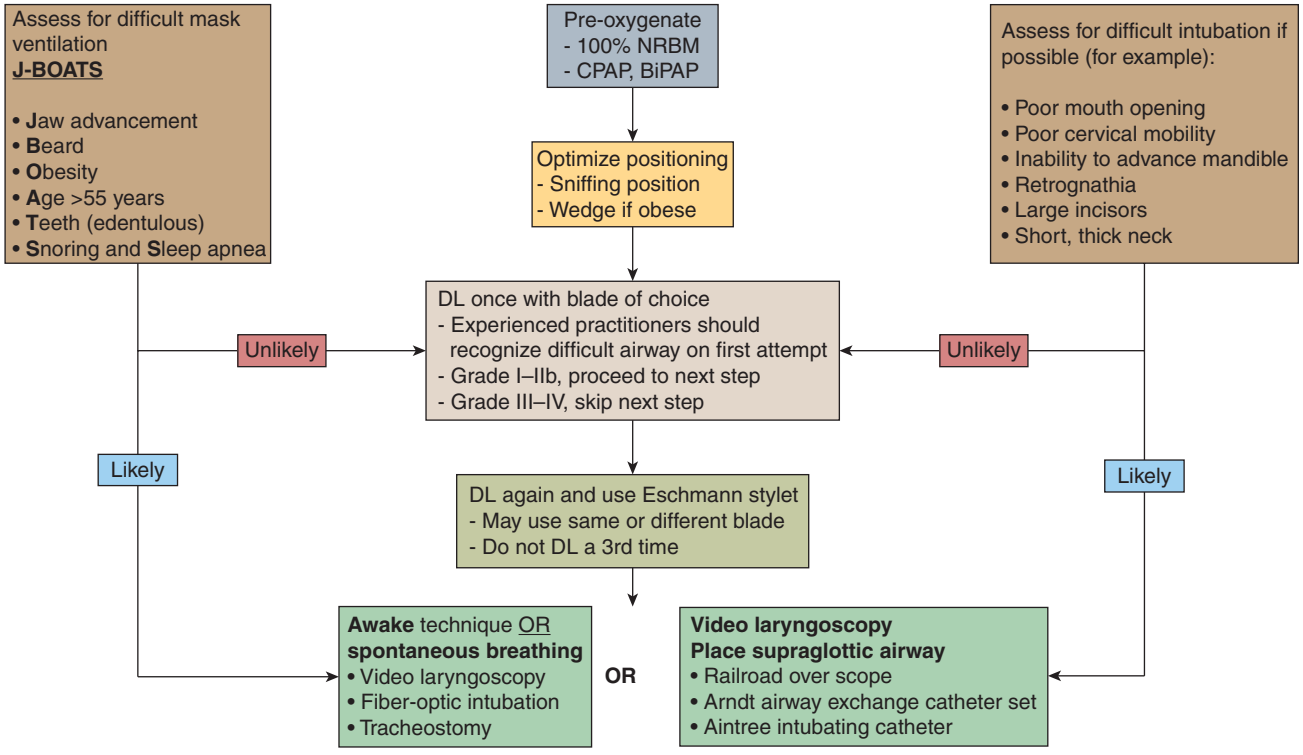

FIGURE 38-17 Incorporation of considerations for difficult ventilation and intubation. Help and airway equipment should be summoned early. When a "cannot intubate, cannot ventilate" situation occurs, or there is an inability to intubate by the means listed, the algorithm culminates in a surgical airway.

tracheal intubations be confirmed by the measurement of carbon dioxide in the exhaled gas (capnometry). This standard, likely complemented by the additional standard that ventilation be continuously monitored by capnometry during general anesthesia, has been associated with a reduction in the incidence of respiratory-related anesthesiology legal claims, and a greater than 50% relative reduction in claims related to esophageal intubation.[75] It is assumed that the incidence of esophageal intubation has also decreased, although this is not directly proven.

CONFIRMATION OF INTRATRACHEAL PLACEMENT

Clinical signs of intratracheal placement include direct observation of the tube entering the glottis, condensation in the ETT with exhalation, and observation and auscultation of the chest. Unfortunately, all clinical methods can and have failed. Inflation of the stomach results in some movement of the chest wall, creating sounds of air movement and some return of gas during the expiratory phase. Experimentally, placing a tube in the esophagus and attempting positive pressure ventilation actually results in some gas exchange because of diaphragmatic movement with consequent lung ventilation. This mechanism is thought to account for cases in which a patient survives for many minutes following an intubation that eventually proves to be esophageal. This is clearly the exception, however, and esophageal intubation that is unrecognized for more than a few minutes generally leads to adverse consequences.

Although observation of the tube entering the glottis would seem a fail-safe test, there are numerous reported cases of esophageal intubation in which the clinician stated that the cords were seen. This may occur because the tube itself obscures the view during placement and the tube may then enter the esophagus.

Multiple methods should be used to confirm intratracheal tube placement for each intubation attempt. These methods should include capnometry, which is now considered the "gold standard" for confirmation of intratracheal placement. Capnometry may fail to detect esophageal intubation if intubation follows a period of mask ventilation because of exhaled gas that has entered the stomach,[76–78] or if carbonated beverages are ingested shortly before intubation.[79] In these instances, however, the "exhaled" CO_2 levels will decrease to near zero as the gastric gas becomes diluted, whereas CO_2 will persist if the ETT is in the trachea. False negatives can occur if there is no CO_2 production or pulmonary blood flow, for example during cardiac arrest or after massive pulmonary embolism,[80] or after marked hyperventilation.[81]

Capnography, which refers to the graphical description of the exhaled CO_2 waveform, has become standard in operating rooms in the United States and much of the rest of the world. Portability and cost has limited the use of capnography in

areas where tracheal intubation is performed less frequently. Alternatives to capnography include portable capnometry using hand-held devices, or colorimetric CO_2 detectors. The latter contain an indicator (metacresol purple) that changes color from purple to yellow when it is exposed to CO_2. Colorimetric capnometry is comparable to capnography in differentiating tracheal from esophageal intubation.[82,83]

An alternative to exhaled CO_2 detection is to apply gentle suction to the in situ tube; if the tube is in the esophagus, the suction causes the pliable esophageal tissue to occlude the tube and no air can be aspirated. If the tube is in trachea, however, the semirigid walls prevent tube occlusion when suction is applied, and air can be obtained. Suction can be applied manually with a syringe, or more commonly with a self-inflating bulb ("bulb syringe"). This technique has good sensitivity for detection of esophageal intubation in elective and emergency settings,[84–88] but failures have been reported, particularly in pregnant subjects.[89] In addition, this technique has a relatively low specificity in detecting esophageal intubation compared to CO_2 detection, and incorrect identification of correct tube placement (bulb does not reinflate or air cannot be aspirated) has been reported in patients with morbid obesity, obstructive lung disease, copious secretions, and endobronchial intubation.[86,90,91] Thus, this technique cannot be advocated as a replacement for CO_2 detection, although it appears to have particular value in patients where CO_2 detection may fail, particularly during cardiac arrest.[86]

ASSESSING DEPTH OF INTRATRACHEAL PLACEMENT

The ETT tube can move as much as 5 cm during maximal cervical range of motion from flexion through extension; the tube moves cephalad as the neck extends.[92] The average distance from larynx to tracheal carina is 12 to 14 cm, and the top of the cuff of tracheal tubes in common use begins approximately 6 cm above the tip of the tube. Thus, the ETT should ideally be placed 5 ± 2 cm above the carina to ensure that the tip does not migrate endobronchially during neck flexion, or that the cuff does not herniate through the glottis with cervical extension.[92]

Endobronchial placement can result in atelectasis and hypoxemia,[93] and inadequate depth of placement has several possible adverse consequences. If the cuff is between the cords the seal will be inadequate risking both aspiration and inadequate ventilation. Adding more air to the cuff usually will not improve the seal as the cuff has a circular profile and the pentagonal shape of the glottic opening leaves the corners open. Inadequate depth of placement also may lead to serious long-term problems with subglottic stenosis. If the cuff is overinflated in the immediate subglottic region, mucosal ischemia may result. As this heals, scarring will lead to narrowing in the region of the cricoid. This problem is extremely difficult and is not readily surgically correctible.

Although auscultation of breath sounds is a reasonable adjunctive test for confirmation of ETT depth, the incidence of missed endobronchial intubation using auscultation alone may approach 10%.[93] In addition, auscultation does not detect ETTs that are either dangerously close to the carina, or positioned too high in the trachea.

The risk of endobronchial intubation can be minimized by: (a) observation of the ETT as it passes through the glottis; insertion of the tube no more than 3 to 4 cm after the upper end of the ETT cuff passes the glottis; (b) insertion of the tube no deeper than 20 cm at the teeth in adult females and 22 cm in adult males;[94] (c) palpation of the ETT cuff in the sternal notch.[95] These benchmarks will result in good placement in a high proportion of adults, but may fail at the extremes of stature, and are more likely to fail in women.[96]

Other methods for detecting endobronchial placement include chest radiography and fiber-optic bronchoscopy. Chest radiography confirms the position of the tube relative to the carina. Even if the carina is not visible, a tube tip overlying the third or fourth thoracic vertebral body with the head in the neutral position means the tube is in good position.[92] Fiber-optic bronchoscopy is as reliable as chest radiography and may be less expensive, but is not readily available at all intubation sites. Chest radiography has the added advantage of providing information about the lung fields as well.

PHARMACOLOGIC ADJUNCTS TO TRACHEAL INTUBATION

Except in cases of cardiac arrest, coma, or extreme neuromuscular weakness, tracheal intubation is facilitated by administration of pharmacologic agents, particularly if direct laryngoscopy is used. The goals of the administered drugs are threefold: (a) to provide optimal intubating conditions by minimizing muscular tone; (b) to ensure patient comfort during the procedure; and (c) to minimize physiologic responses to intubation, as follows.

The upper airway is richly innervated, resulting in a series of physiologic responses during intubation, including activation of both the sympathetic and parasympathetic nervous systems.[97] Bradycardia occasionally results, most commonly in children. In unanesthetized adults, blood pressure following intubation may reach levels as high as 250/150 mm Hg and the pulse will frequently rise to near maximal heart rates. Appropriate anesthesia will generally prevent these responses.

Direct laryngoscopy in the unanesthetized patient stimulates a strong gag reflex, and likewise insertion of a tube in the trachea will stimulate coughing. These reflexes are not only noxious for the patient, but can make tracheal intubation more challenging. Normal subjects develop a mild, clinically insignificant increase in lower-airway resistance following tracheal intubation,[98] and patients with reactive airways may develop marked bronchoconstriction. Bronchospasm following induction of general anesthesia accounts for a small but significant proportion of perioperative morbidity; notably, many cases of severe intraoperative

bronchospasm occur in patients without previously diagnosed reactive airways disease.[74,99–101] Ideally, tracheal intubation of patients with known asthma or other reactive airways disease should be preceded by administration of inhaled bronchodilators, in addition to anesthetic drugs with bronchodilating properties (e.g., propofol or ketamine, as discussed below).

Direct laryngoscopy causes mechanical obstruction of cerebral venous flow, and increases cerebral blood flow related to increased cerebral metabolic rate and transient increases in P_{CO_2}.[102,103] In the presence of preexisting intracranial pathology, these factors can lead to a rapid rise in intracranial pressure and carry a risk of herniation of brain contents. The increase in intracranial pressure can be blunted by the prior administration of anesthetic agents.

In addition to topical anesthetics (discussed earlier), the typical drugs administered to facilitate tracheal intubation are sedative-hypnotics, intravenous lidocaine, and neuromuscular blocking drugs ("muscle relaxants").

Sedative-Hypnotics

The most common sedative/hypnotics used as adjuncts to tracheal intubation are the short-acting barbiturates, propofol, etomidate, ketamine, and the benzodiazepines. With the exception of ketamine, these drugs are all γ-amino butyrate receptor agonists. They all have dose-dependent cardiovascular and/or respiratory depressant effects of varying degrees, and will result in loss of airway control at higher doses. Barbiturates, propofol, and etomidate are all very effective at reducing intracranial pressure; benzodiazepines are less potent in this regard, and ketamine can increase intracranial pressure.

SHORT-ACTING BARBITURATES

Sodium thiopental, the prototypical intravenous induction agent, is highly lipid soluble and thus rapidly enters the brain to produce unconsciousness. The return of consciousness is also rapid because of rapid redistribution of the drug. There is marked respiratory depression following injection with transient apnea the rule. Barbiturates cause vasodilation and myocardial depression, making them a poor choice for the hypovolemic patient. The typical induction dose of sodium thiopental is 3 to 5 mg/kg intravenously, with reduced doses given in the presence of cardiovascular instability, hypovolemia, and advanced age. Higher doses may be necessary if there is a history of heavy alcohol or tranquilizer use.

PROPOFOL

Propofol produces rapid loss of consciousness after bolus intravenous administration, with recovery beginning within 1 to 2 minutes. Propofol has cardiovascular depressant effects that are similar in magnitude to those seen with barbiturates, and its potency appears to be increased during hemorrhagic shock.[104] Thus, large doses of propofol should be avoided in patients with hypovolemia or significant cardiovascular depression for any reason. Propofol profoundly suppresses respiratory drive and airway reflexes, and has bronchodilating properties; thus, it is a useful agent for intubation of patients without concomitant administration of a neuromuscular blocking drug, or for intubation of patients with bronchospasm or reactive airways.[105] Propofol rarely causes myoclonus after bolus administration. Propofol is mixed in a lipid-based solution that supports bacterial growth; thus, propofol-containing syringes must be handled carefully and administered within a few hours of opening. Typical induction doses of propofol are 1 to 2.5 mg/kg intravenously, depending on age and cardiovascular stability.

ETOMIDATE

Etomidate has a rapid onset of action and a rapid recovery, has little effect on myocardial function, and has mild respiratory depressant effects. In addition, it has mild α_{2b}-adrenergic receptor agonist activity, which contributes to its lack of hypotensive effects compared to other induction agents.[106] Because of these favorable properties, etomidate has long been favored as an adjunct to tracheal intubation. Etomidate, however, can transiently suppress adrenal function by reversibly inhibiting 11β-hydroxylase, and prolonged infusions of etomidate in critically ill patients have been associated with severe suppression of adrenal cortical function and increased mortality.[107] Moreover, recent data suggest that even single doses of etomidate can result in prolonged adrenal suppression in critically ill patients, particularly those with sepsis.[108–110] This observation has generated considerable concern and debate about the advisability of using etomidate as an adjunct to tracheal intubation in critically ill patients, with some experts calling for caution if not complete abandonment of the use of etomidate in this patient population.[111,112] It remains unclear, however, if etomidate exerts an independent effect on mortality,[113] and a randomized, controlled trial comparing etomidate to ketamine for rapid sequence induction in acutely ill patients revealed no mortality difference between the two groups.[114] Further study of this issue will be necessary to definitively determine if etomidate should continue to be used as an intubation adjunct in critically ill patients; in the interim, it is reasonable to consider the use of alternative agents where feasible.

Etomidate also causes self-limited myoclonus relatively frequently. The latter may not be seen if etomidate is given in conjunction with a neuromuscular blocking drug. In addition, etomidate has proemetic effects and can causing a burning sensation when injected through a peripheral venous catheter, and these latter effects limit its use as an elective induction agent. The typical induction dose is 0.1 to 0.3 mg/kg intravenously; doses of 4 to 8 mg in an adult patient will typically produce deep sedation with maintenance of spontaneous ventilation.

KETAMINE

Ketamine is an *N*-methyl-D-aspartate-receptor antagonist, which gives it a different sedation and side effect profile in comparison with the other agents discussed here. Ketamine produces rapid loss of consciousness, although patients often appear awake because their eyes often remain open. Recovery from an intravenous dose of 2 mg/kg may take 10 to 15 minutes. Ketamine is a direct myocardial depressant[115,116] but clinically produces cardiovascular stimulation via release of catecholamines.[117] This sympathomimetic effect also gives ketamine bronchodilating properties.[118,119] Ketamine's major adverse effects include the potential for myocardial ischemia resulting from cardiovascular stimulation, increased intracranial pressure, and unpleasant dreams or hallucinations during the recovery phase. As noted above, ketamine appears to be equivalent if not superior to etomidate in safety when used for rapid sequence induction in acutely ill patients.[114] The typical induction dose of ketamine is 0.5 to 1 mg/kg, intravenously.

BENZODIAZEPINES

Midazolam is the benzodiazepine most widely used for hypnosis during intubation because of its rapid onset and short duration of action. It and the other benzodiazepines are more suited as sedative agents rather than for full induction of anesthesia, as the large doses of these drugs necessary to produce loss of consciousness result in prolonged sedation. In critically ill patients, however, smaller doses can result in loss of the airway, respiratory depression, and apnea; thus, titrated and closely monitored administration is recommended. Typical doses of midazolam for sedation during awake intubation are 0.5 to 2 mg intravenously.

Intravenous Lidocaine

High-dose intravenous lidocaine has general anesthetic effects, including a reduction of cerebral metabolic rate and a blunting of the hemodynamic response to intubation. Lidocaine 1.5 mg/kg given intravenously (before laryngoscopy) blunts the increase in intracranial pressure typically seen during intubation of patients with intracranial pathology.[120] Intravenous lidocaine also suppresses cough and bronchoconstriction during laryngoscopy, but only when given at doses of 1.5 mg/kg or greater and approximately 3 minutes before intubation.[121]

Neuromuscular Blocking Drugs

Although there are a wide variety of neuromuscular blocking drugs available, only two, succinylcholine and rocuronium, are sufficiently rapid in onset to be of value for emergency tracheal intubation. Succinylcholine's pharmacokinetic profile makes it the ideal drug for emergency tracheal intubation. Succinylcholine binds to the nicotinic receptor at the neuromuscular junction to cause depolarization of the end plate and, eventually, of surrounding fibers. This effect persists for several minutes, thus causing the muscle membrane to remain depolarized and refractory to further impulses. The diffuse depolarization of the muscles can be seen as generalized fasciculations. The usual intubating dose of 1 mg/kg of succinylcholine results in adequate intubating conditions in 90% of patients at 1 minute. The termination of drug action results from the metabolism of circulating succinylcholine by pseudocholinesterase with return of muscle strength in 3 to 5 minutes in most patients. Pseudocholinesterase deficiency occurs rarely, and results in prolonged action of succinylcholine.

Succinylcholine has a number of side effects, some of which are potentially lethal. Succinylcholine is a trigger agent for malignant hyperthermia, and should not be administered to malignant hyperthermia-susceptible patients. Administration of succinylcholine results in an efflux of intracellular potassium resulting in a clinically insignificant transient rise in serum potassium in most patients. In patients with central neurologic deficits, however, such as stroke, traumatic brain injury, encephalopathy, or spinal cord injury, or after peripheral denervation, succinylcholine can lead to massive potassium release and potassium levels over 10 mEq/L.[122,123] Similar responses are seen in burn patients beginning several days after the burn, in patients with myopathies, rhabdomyolysis, and after crush injuries.[122] The mechanism of hyperkalemia is in part related to extrajunctional proliferation of nicotinic receptors, but may also be related to direct muscle membrane damage during critical illness. The reported mortality with succinylcholine-induced hyperkalemia is more than 10%.[122] Succinylcholine is thus absolutely contraindicated more than several days to a week following a burn or new neurologic deficit. In addition, given the high incidence of critical illness-induced myopathy and neuropathy, succinylcholine should be avoided in patients who have been critically ill for a week or more.[124] Given the potential lethality of the hyperkalemic response after succinylcholine, an alternate agent should be used if there is any potential contraindication to succinylcholine.

Succinylcholine may also result in a transient increase in intracranial pressure, although this is probably not clinically significant and should not countermand the use of succinylcholine if rapid control of the airway is necessary.[125]

Rocuronium is a competitive antagonist of acetylcholine at the neuromuscular junction. Rocuronium is "nondepolarizing," does not result in muscle fasciculation or potassium release, and does not act as a trigger for malignant hyperthermia. Rocuronium at an intubating dose of approximately 1 mg/kg results in acceptable intubating conditions at 1 minute after administration, although intubation conditions are generally inferior to those achieved after succinylcholine.[126] Because rocuronium does not cause muscle fasciculation, which, in turn, can increase oxygen consumption, it may allow a longer apneic period before oxyhemoglobin desaturation compared

to succinylcholine.[127] Rocuronium's major drawback is that its duration of action is determined by hepatic and renal clearance, and has a variable range of 30 to 90 minutes. This makes rocuronium less than ideal for patients with difficult airways, as the option of allowing return of spontaneous ventilation should intubation and face-mask ventilation fail is not available, as it is for succinylcholine. Nonetheless, rocuronium is a reasonable alternative to succinylcholine for rapid sequence induction, particularly in patients who are at risk for complications from the latter agent.

COMPLICATIONS OF TRANSLARYNGEAL INTUBATION

John L. Stauffer

The term *endotracheal intubation,* or *tracheal intubation,* broadly refers to the insertion of a definitive artificial airway into the trachea by either the translaryngeal or transtracheal route. *Translaryngeal intubation* (TLI), a more specific term, is transoral or transnasal intubation of the airway through the larynx. The term *endotracheal tube* (ETT), as opposed to *tracheostomy tube,* refers to a tube passed via the mouth or nose into the trachea.

Macewen is usually given credit for the first successful translaryngeal intubation. In a landmark paper in 1880, he described TLI in four patients for as long as 35 hours and reported complications, including cough, discomfort, tracheal mucosal congestion, and thickening of the vocal cords and posterior rim of the glottis.[1] The modern era of TLI began in the 1950s when it was used to manage respiratory failure from drug overdose[2,3] and polio,[4] and to provide an alternative to immediate tracheotomy when patients required prolonged ventilator support. As experience with TLI grew, so did knowledge of its complications and limitations. Comprehensive reviews of this subject appeared first in 1950[5] and frequently thereafter.[6–14]

TABLE 39-1: CLASSIFICATION OF COMPLICATIONS OF TRANSLARYNGEAL INTUBATION

- Temporal classification
  - Complications during endotracheal tube (ETT) placement

TABLE 39-2: EARLY COMPLICATIONS OF TRANSLARYNGEAL INTUBATION AFTER 226 INTUBATIONS IN 143 ADULTS

Clinical Problem	No.	Percentage
Excessive cuff pressure to achieve seal by minimal occluding pressure technique[a]	42	19
Self-extubation	29	13
Inability to seal airway[b]	24	11
Right main-stem bronchus intubation	21	9
Aspiration[c]	17	8
Lip ulceration or cellulitis	16	7
Pharyngeal injury or bleeding	15	7
Mechanical problems with the ETT[d]	14	6
Difficulty suctioning via the ETT	12	5
Pain in nose, mouth, pharynx, or chest related to the ETT	8	4
Glottic edema	5	2
Oral mucous membrane injury	5	2
Tooth avulsion	4	2
Laryngospasm at the time of extubation	3	1
Pneumothorax	2	1
Esophageal intubation	2	1
Miscellaneous[e]	49	22
Total number of complications observed: 268		

[a]Defined arbitrarily as >25 mm Hg.

[b]Defined as leakage of air around the cuff because of a defect in the cuff or inadequate seal with cuff pressure <60 mm Hg.

[c]Defined as aspiration apparent clinically as an immediate result of the intubation attempt or after successful intubation.

[d]Includes partial dislodgment of the tube, length too short or too long, cuff laceration, and biting and occluding the tube.

[e]Includes nasal bleeding, which was recorded twenty-two times.

This chapter provides a practical review of complications of TLI in critically ill adult patients, helps the reader understand the mechanisms underlying these adverse events, and illustrates how awareness of these complications may lead to their prevention, earlier recognition, and successful management. The chapter reviews important complications and consequences of TLI with standard ETTs that are encountered in the practice of adult critical care medicine. They are arranged according to the outline in Table 39-1. Complications of anesthetic intubations are occasionally cited to add awareness of complications that may also be seen in the critical care setting.

FREQUENCY OF COMPLICATIONS

The complication rate of TLI varies with the setting, the urgency of the procedure, the skill of the intubator, patient anatomy, and other factors. In the prehospital setting, the rate of complications of TLI ranges from 9.5[15] to 22.7%.[16] In the emergency department, 8%[17] to 38%[18] of patients undergoing TLI experience one or more complications.

In a prospective study in the adult critical care setting, Stauffer et al observed that 62% of all TLIs had one or more associated adverse events either during intubation or while the ETT was in place.[19] The mean number of complications per patient was 1.2. The most common early clinical problems were, in descending order of frequency, excessive cuff pressure required to seal the airway, self-extubation, inability to seal the airway, right main-stem bronchus intubation, and aspiration (Table 39-2). Other prospective studies have reported that 28% [20] to 39%[21] of TLIs in the intensive care units (ICUs) of academic centers were associated with one or more complications, many of which were life-threatening. The complication rate of emergency TLI by anesthesia residents in ICUs and wards of large tertiary academic health centers ranges from 4.2%[22] to 16.1%,[23] with endobronchial intubation, airway trauma, aspiration, and esophageal intubation leading the list of observed complications.

Little is known about the impact of TLI complications on utilization of health care resources. One report found a significant increase in health care costs and hospital length of stay resulting from tracheal injury from ETTs.[24]

COMPLICATIONS DURING ENDOTRACHEAL TUBE PLACEMENT

Nasal and Paranasal

Nasal intubation may inflict trauma to the nose, especially when it is performed urgently or without adequate premedication. A retrospective study of 105 nasotracheal intubations in the emergency department revealed a 26% rate of immediate complications, including epistaxis, emesis, and main-stem

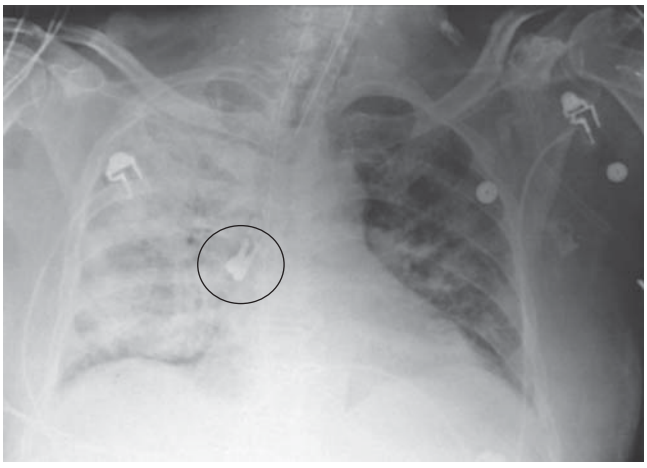

FIGURE 39-1 Chest radiograph showing an aspirated molar tooth in the right main bronchus of an intubated patient. Pneumonia in the right lung was also observed. (Reproduced, with permission, from Ostrinsky Y, Cohen Z. Tooth aspiration. *N Engl J Med.* 2006;354:e25. Copyright © Massachusetts Medical Society.)

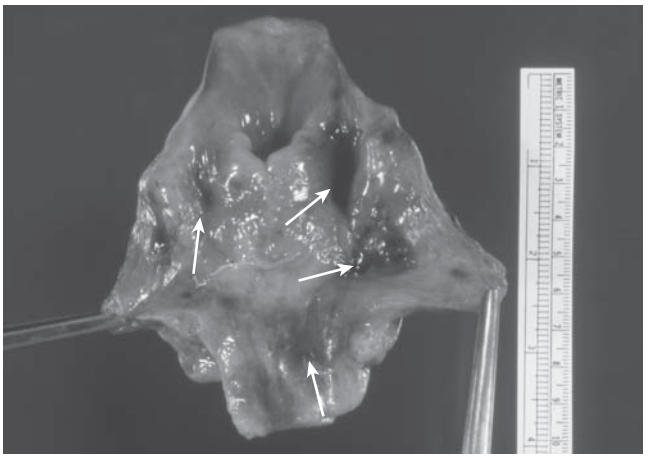

FIGURE 39-2 Autopsy specimen of larynx, hypopharynx, and upper esophagus opened posteriorly. The patient was an older man with chronic obstructive pulmonary disease (COPD) and acute respiratory failure in whom repeated forceful attempts at oral intubation by an inexperienced physician were not successful. The tip of the ETT traumatized the airway. Multiple areas of submucosal hemorrhage in the piriform sinuses and hypopharynx are evident (*arrows*).

bronchus intubation, and a 23% rate of late complications such as pneumonia, sinusitis, and sepsis.[25] Nasal bleeding complicated 54% of attempts at nasal intubation in an adult ICU.[19] Dislodgment of nasal turbinates[26] and nasal polyps[27] is rare. Intracranial placement of nasotracheal tubes, particularly in the setting of facial trauma, has also been reported.[28]

Oral

Overall, dental injury from TLI is uncommon, occurring in approximately 0.9% of prehospital TLIs,[29] 0.04%[30] to 0.13%[31] of anesthesia TLIs, and 0.2% of emergent nonoperating room TLIs.[22] In anesthetic intubations, loosening, luxation, or avulsion of teeth, damage to crowns and bridges, and crown or root fracture were the most commonly observed dental injuries in two large series.[30,31] Dental injury is the most common reason for anesthesia-related malpractice claims.[31] Avulsed teeth and dental appliances may be aspirated into the trachea or bronchi.[32] Figure 39-1 illustrates aspiration of a tooth in the setting of endotracheal intubation.[32] Difficult intubation, poor dentition, and inexperience of the intubator predispose to dental injury.[30] Oral mucous membrane injury has been observed in 1% to 2% of attempts at oral intubation.[19] Lip injury occasionally occurs from pressure exerted by the laryngoscope blade. Temporomandibular joint dislocation is a very rare complication of anesthetic orotracheal intubation.[33]

Pharyngeal

Lacerations, bleeding, contusions, excoriations, submucosal hemorrhage, and edema may result from intubation trauma to the nasopharynx, oropharynx, or hypopharynx. Oropharyngeal and hypopharyngeal injuries occur from trauma by the laryngoscope blade, ETT, stylet, or dislodged dental appliances.

Perforation of the posterior pharyngeal wall or hypopharynx is a particularly serious complication. It may result in mediastinal and subcutaneous emphysema, hematoma, upper airway obstruction, abscess formation,[34,35] mediastinitis, pneumothorax, pneumomediastinum,[36] pneumoperitoneum,[37] and even cardiac arrest.[8,38,39]

Hypopharyngeal injury from TLI has been the subject of a number of reports in both adults[8,37–42] and children.[43] Like oral injury, pharyngeal trauma from TLI occurs mainly in emergency settings and in the hands of inexperienced intubators, but it may occur in the anesthetic setting as well.[44] Piriform sinus laceration by forceful blind intubation may result in severe barotrauma with bilateral pneumothorax, pneumomediastinum, mediastinal abscess, and cardiac arrest.[40] Figure 39-2 illustrates hypopharyngeal contusions from repeated unsuccessful attempts at oral intubation by an inexperienced intubator.

Laryngeal

Reports of laryngeal complications that occur during ETT placement come mainly from the anesthesia literature. The larynx is the most common site of airway injury in anesthesia claims analysis.[45] Laryngeal injuries during ETT placement include glottic contusion, vocal cord hematoma and laceration, vocal process avulsion,[46] and arytenoid cartilage dislocation.[46,47] Vocal cord hematomas are reported to be more common on the left true vocal cord,[48] a finding that has been attributed to the fact that most intubators are right-handed.[10] Epiglottic hematoma from TLI is considered very rare.[49,50] Arytenoid dislocation from traumatic intubation occurs in up to 1.7%[47] of anesthetic intubations, leading to complications such as hoarseness and aspiration[47] and acute

respiratory failure.[51] Colice et al observed no cases of this complication in critical care intubations.[52]

Tracheal

Tracheal tears, reported variously as perforation,[53] laceration,[54] and rupture,[55–59] are rare complications of TLI. The large majority of cases occur in women and in patients older than 50 years of age,[60] and involve the posterior membranous portion of the trachea at or near the carina.[61] Causes of tracheal tears include emergency intubation, damage to the posterior membranous trachea by a stylet,[56] overinflation of the cuff,[43,56] excessive coughing or movement during intubation, and preexisting abnormalities of the trachea such as tracheomalacia.[55,60,61] Subcutaneous emphysema, pneumomediastinum, and respiratory distress are commonly seen after this type of tracheal injury.[55,56]

Malpositioning of the ETT in the trachea is a frequent consequence of emergency TLI in both the prehospital and the intensive care settings. In one report of prehospital airway management in a large urban region, malposition of the ETT was detected in 5.2% of 846 patients with attempted TLI in the field who were transported to a hospital.[62] In a prospective series of 271 emergency TLIs in critically ill adults, Schwartz et al observed nine (3.3%) cases in which the ETT tip was too high (>6 cm above the carina) and twenty-three (8.5%) cases in which it was too low (<2 cm from the carina), in addition to ten cases (3.7%) of right main-stem bronchus intubation.[63] Malpositioning of the ETT was significantly more common in women than in men.

Bronchial

Intubation of a main-stem bronchus is a potentially serious complication of intubation.[19,64,65] Right main-stem bronchus intubation has been reported in 10.7%[66] and 15.2%[67] of prehospital TLIs and in 3.7%[63] and 9.6%[64] of cases in prospective series of critical care intubations. In contrast, only 1.6% of anesthetic TLIs are complicated by endobronchial intubation.[68] Left main-stem bronchus intubation is very rare.[69] Potential complications of right main-stem bronchus intubation include hyperinflation of the right lung, right pneumothorax, atelectasis of part or the entire left lung, and impaired gas exchange. Figure 39-3 illustrates right main-stem bronchus intubation with the complication of atelectasis of the left lung.

Pulmonary

Pulmonary aspiration, which is usually defined as the appearance of new infiltrates on the chest radiograph immediately after intubation, has been observed in 2% to approximately 6% of emergent intubation procedures.[20–22,29,70] The prospective investigation of 297 TLIs in critically ill adults reported by Schwartz et al revealed twelve cases (4%) of new unexplained lung infiltrates attributed to aspiration and two cases

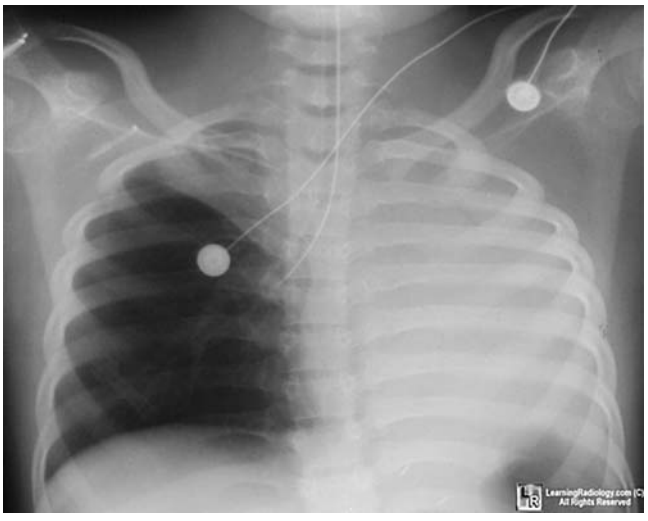

FIGURE 39-3 Chest radiograph showing the tip of the endotracheal tube in the right main-stem bronchus. This case of right endobronchial intubation is complicated by left lung atelectasis. (Reproduced, with permission, from William Herring MD, www.learningradiology.com. Published with permission from LearningRadiology.com.)

of pneumothorax (1%).[70] Aspiration of gastric contents was second only to failed intubation among all major complications of anesthetic airway management in a recent national survey in the United Kingdom.[71] Besides pneumothorax, other types of barotrauma may occasionally be seen. Failed intubation attempts may lead to worsening gas exchange, including severe hypoxemia.[72] Hypoxemia (oxyhemoglobin saturation <90%) has been reported in 18%[72] to 21%[73] of emergency TLIs. Hypoxemia was observed in 10.5% of TLIs when two or fewer intubation attempts were made, compared with 70% of TLIs requiring three or more attempts.[72] Bronchospasm was reported in three (0.8%) of 358 prehospital TLIs.[29] The bronchospasm response to TLI is rarely severe. Patients with asthma are at the highest risk.

Miscellaneous

GENERAL

Without adequate premedication, critically ill patients may experience pain in the upper airway, generalized discomfort, and anxiety during intubation. These important complications are difficult to assess objectively and are usually overlooked in large case reviews in the literature.

Bacteremia is an overlooked but potentially important consequence of both orotracheal and nasotracheal intubation.[74,75] Staphylococci and streptococci are the most common bacterial isolates.[75] The frequency of transient bacteremia following orotracheal intubation ranged from 3.2%[74] in elective TLI for anesthesia to 9% in urgent TLI performed in ICU patients.[76] In the latter series, only *Streptococcus* species were isolated immediately after TLI, and no patient had streptococcal bacteremia before or 1 hour after TLI. Bacteremia has been detected following 5.5%[77] to 16%[78] of nasotracheal intubations.

ESOPHAGEAL

An analysis of claims for airway injury from anesthesia showed that the esophagus was the third most common site of injury, and esophageal injuries were more severe than all other types of airway injury combined.[45] Inadvertent perforation of the posterior wall of the esophagus or pharynx by the ETT tip or rigid stylet is a rare but serious complication of TLI. Risk factors for this injury include inexperience of the operator, anatomic abnormalities, and difficult intubation, especially in the setting of cardiopulmonary resuscitation. The literature describing this complication is limited to single case reports[79,80] and small series. O'Neill et al described two cases of esophageal and pharyngeal perforation from elective anesthetic intubation, noting that this severe complication is not always limited to emergency or difficult intubations.[41] The potential consequences of esophageal perforation include subcutaneous emphysema, pneumomediastinum, pneumothorax, mediastinitis, and mediastinal abscess. Anterior esophageal perforation from TLI has not been reported.

Esophageal intubation is a common complication of TLI, particularly in emergency settings, and it has potentially severe consequences, including hypoxemia, regurgitation and aspiration of gastric contents, cardiac arrest, and irreversible hypoxic brain injury.[81–83] Esophageal intubation occurred in ten (6.7%) of 149 patients intubated in the prehospital setting in Germany [66] and in thirty-seven (5.4%) of 691 patients intubated in the prehospital setting in France.[29] It was reported in thirty-three (5.5%) of 603 patients intubated in an emergency department.[17] In tertiary care centers the frequency of esophageal intubation complicating emergency TLI ranges from 1.3% to 9.7%.[22,67,70,72]

GASTRIC

Gastric distension may result from esophageal intubation. Swallowing of foreign objects such as teeth and dental fixtures may also occur.[84] TLI may stimulate the gag reflex, leading to vomiting.

MUSCULOSKELETAL

Musculoskeletal complications during intubation are uncommon. Injuries to the cervical spine and cervical spinal cord during orotracheal intubation have been reported.[85]

NEUROLOGIC

Hypoxic brain injury may result from ineffective ventilation, oxygenation, or circulation as a result of failed intubation or mishaps such as esophageal intubation. Cervical spinal cord injury is reportedly a rare complication of anesthetic TLI.[86] Neck hyperextension during direct laryngoscopy to facilitate TLI in patients with restricted neck mobility or preexisting cervical spine instability has been proposed as a risk factor for cord injury,[87] but proof of this relationship has been difficult to establish.[88] Transient increases in intracranial pressure occur with TLI, particularly with endotracheal suctioning,[89] putting patients with head injury at risk for secondary brain injury.[90]

PHYSIOLOGIC

Cardiovascular. The cardiovascular pressor response to laryngoscopy and TLI includes transient and variable increases in heart rate and both systolic and diastolic blood pressure as a result of pharyngeal stimulation. The magnitude of these responses varies with the route and ease of TLI,[91] the use of anesthetic agents, concurrent medications, underlying cardiovascular status, and many other factors. In healthy individuals these cardiovascular responses are usually inconsequential, but complications may result when they are exaggerated[92] or occur in patients with hypertension, cardiac disease, or cerebrovascular disease.[93] Some, but not all, studies document a rise in plasma epinephrine and norepinephrine levels with TLI.[94–97]

The hypertensive response to nasotracheal intubation is greater than that to orotracheal intubation.[96] The hemodynamic response to orotracheal intubation is greater than that to insertion of the laryngeal-mask airway (LMA North America, San Diego, CA),[94] but less than that to insertion of the esophageal-tracheal Combitube™ (Covidien, Mansfield, MA).[94]

Hypotension may also occur during TLI. In the setting of rapid sequence intubation for general anesthesia, Istvan observed hypotension in 27% of 248 patients undergoing appendectomy.[98] Franklin et al observed that twenty-four (29%) of eighty-four patients requiring TLI in an emergency department developed life-threatening hypotension, which was significantly associated with the presence of chronic obstructive pulmonary disease, hypercapnia, and hypoxemic respiratory failure, but not with the administration of sedatives or paralyzing medications.[99] Griesdale et al observed severe hypotension in thirteen (9.6%) of 136 patients requiring TLI in an academic ICU.[21]

MacKenzie et al reported cardiac arrhythmias in 58% and 32% of nasal and oral anesthetic intubations, respectively.[100] Bradycardia was observed in 1.6% of emergency intubations in a large tertiary hospital when two or fewer intubation attempts were required versus 18.5% of intubations requiring three or more attempts.[72] Most cases with bradycardia were associated with severe hypoxemia (arterial oxyhemoglobin saturation [SpO_2] <70%) and half culminated in cardiac arrest.[72]

Other. TLI causes transient but significant increases in intraocular pressure.[101,102]

Cardiac Arrest and Mortality Rate of Translaryngeal Intubation

Cardiac arrest from emergency TLI is common. Mort reported cardiac arrest in sixty (2%) of 3035 critical care patients during emergency TLI in a tertiary care institution. Inadvertent esophageal intubation with profound

hypoxemia, regurgitation, aspiration, and bradycardia were highly associated risk factors for cardiac arrest.[103] Adnet described cardiac arrest as a complication of TLI in four (1.1%) of 358 patients with initial conditions other than cardiac arrest who required intubation in the prehospital setting.[29]

Schwartz et al reported a mortality rate of 0.85% during or within 30 minutes of emergency TLI in critical care patients without preexisting hypotension.[70] Biboulet et al prospectively recorded eleven anesthesia-related cardiac arrests in a series of 101,769 anesthetics performed from 1989 to 1995 (frequency: 1.1 per 10,000), and the mortality rate was 0.6 per 10,000.[104] All the cardiac arrests were considered avoidable.

COMPLICATIONS WHILE THE ENDOTRACHEAL TUBE IS IN PLACE

Nasal and Paranasal

NASAL COMPLICATIONS

In a prospective series of 379 patients with nasotracheal intubation, Holdgaard et al found inflammation and ulceration of the nostrils or nasal septum in 110 patients (29%) within 5 days of extubation.[105] Nasal bleeding occurred in 19% of patients and conchae fractures in 11%. Necrosis of the nasal alae may occur at the site of constant pressure on the nose by an upturned nasotracheal tube (Fig. 39-4).[106] This injury was seen in 4% of nasotracheal intubations,[107] and it may be accompanied by bacterial invasion with cellulitis.[108] Nasal septal ulceration is uncommonly seen.[19]

PARANASAL COMPLICATIONS

Sinus Effusions. Nasotracheal intubation for more than a few days commonly results in accumulation of fluid in the paranasal sinuses.[108–110] Fassoulaki and Pamouktsoglou found computed tomographic (CT) scan evidence of paranasal sinus fluid accumulation, opacification, or mucosal thickening in all of sixteen adult patients studied prospectively by the eighth day of nasotracheal intubation.[109] The maxillary and sphenoid sinuses each were affected in 87% of cases, followed by the ethmoid (50%) and frontal (12.5%) sinuses. Sinus effusions were unilateral and on the same side as the nasotracheal tube. Involvement of more than one sinus at a time was common.[109] Ultrasound evaluation has demonstrated sinus effusions in 30% of patients with nasotracheal intubation[108] and 63% of patients with orotracheal intubation.[110]

FIGURE 39-4 Hemorrhagic ulceration of the left ala nasi (*arrow*) as a result of pressure exerted by a previously upturned nasotracheal tube. This type of injury can be prevented by positioning the endotracheal tube so that its proximal end points straight down from the anterior naris. (Modified, with permission, from Zwillich and Pierson.[106])

Sinusitis. In 1982, Knodel and Beekman called attention to nasotracheal intubation as a cause of maxillary sinusitis with fever in mechanically ventilated patients.[111] Sinusitis has subsequently been recognized as a common and potentially serious complication of TLI, particularly nasotracheal intubation (see Chapter 47).[109,110,112–114] Sinusitis may also complicate orotracheal intubation[115] and the use of nasogastric tubes.

Severe complications of TLI-associated sinusitis include fever, bacteremia, pneumonia, sepsis, and meningitis. Van Zanten et al reported that sinusitis was discovered as the sole cause of fever in fifty-seven (16.2%) of 351 critically ill patients with orotracheal intubation who were evaluated for fever of unknown origin.[115] Gram-negative bacteria such as *Klebsiella* and *Enterobacter* species are commonly isolated from sinus aspirates in patients with sinusitis complicating nasotracheal intubation. Gram-positive bacteria, particularly *Staphylococcus aureus,* and fungi are also frequently isolated. Anaerobic infection, particularly with *Bacteroides* species, also occurs. Polymicrobial infections are common.

Middle Ear Effusions and Otitis. Middle ear effusion is an underrecognized but common complication of prolonged TLI, occurring in as many as half of patients.[116,117] Cavaliere et al observed that twenty-eight (80%) of thirty-five unconscious ICU patients had middle ear effusion, and there was a significant association with TLI and mechanical ventilation.[118] Lucks et al found middle ear effusions in twenty-three (29%) of seventy-eight adults with prolonged TLI, most of whom were intubated orally.[119] Tympanocentesis revealed organisms in 22% of patients with middle ear effusion, particularly *Pseudomonas aeruginosa, Klebsiella oxytoca,* and *Enterobacter cloacae,* typical of the gram-negative organisms colonizing the airway in patients with TLI.[118]

Oral

Ulceration or cellulitis of the lips was noted in 7% of TLIs in critically ill adults.[19] Lip edema, bleeding, and hemorrhagic crusts are very common during TLI as a result of pressure injury and abrasion by the orotracheal tube, oropharyngeal airway, tape, orogastric tube, or ETT holder.[19,120] Figure 39-5 illustrates lip injury from prolonged orotracheal intubation.[120]

FIGURE 39-5 Ulceration of the right side of the upper and lower lip in a patient with prolonged orotracheal intubation. This type of injury can be prevented by proper securing of the endotracheal tube (ETT), minimizing the direct pressure transmitted to the mouth from the ETT and ventilator tubing, and regular oral examination during the period of translaryngeal intubation. (Modified, with permission, from Stauffer.[120])

Hanley et al reported reactivation of herpes simplex virus infections in 53% of patients with oral TLI longer than 48 hours, but clinical findings were noted in only half of these cases.[121] Figure 39-6 demonstrates herpes simplex virus type 1 complicating orotracheal intubation.[122] Dental injury, stomatitis, erosion of the hard palate, and soft-tissue injury to the tongue and oral mucosa may develop during TLI, and in some cases these complications are severe (Fig. 39-7).[19,123] They are reported to be more likely to occur in patients with concurrent use of oropharyngeal airways or those with rigid contracture of the jaw or propulsive movements of the tongue.[123]

FIGURE 39-6 Severe hemorrhagic lesions on the lips of a patient with an oral endotracheal tube (ETT) in place. Herpes simplex virus type 1 (HSV-1) was identified by culture and polymerase chain reaction assay. Reactivation of HSV-1 was considered to be related to immunosuppression of critical illness and friction trauma of the lips by the ETT. (Reproduced, with permission, from Tang JW, Chan PKS. Herpes labialis. *N Engl J Med.* 2007;357:1855. Copyright © Massachusetts Medical Society.)

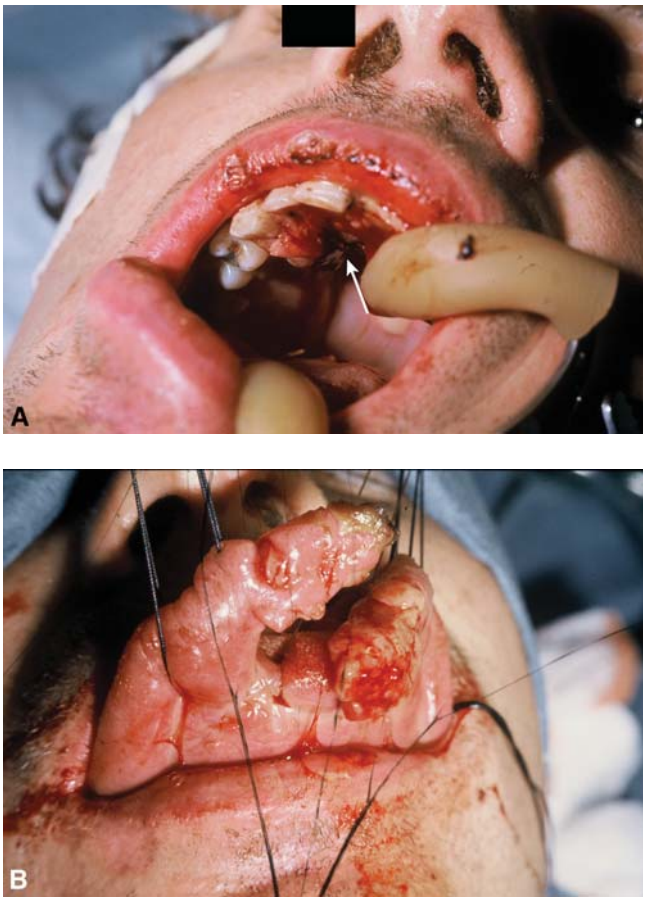

FIGURE 39-7 Severe injury to the mouth may occur during translaryngeal intubation because of pressure-induced necrosis. This patient was a young man who was intubated because of status epilepticus and need to control the airway. Rigid contracture of the jaw occurred repeatedly while an oral pharyngeal airway was in place to prevent occlusion of the endotracheal tube by biting. Evidence of oral injury included erosion of the hard palate (*arrow*) by the oropharyngeal airway (**A**), and complete transection of the tongue, photographed at the time of surgical repair (**B**). (Modified, with permission, from Stauffer and Petty.[123])

Pharyngeal

Pharyngeal complications while an ETT is in place are uncommon.

Laryngeal

Laryngeal injury is the most common and potentially the most severe complication of TLI,[52,124–134] and fear of late laryngeal complications of TLI is cited as the primary reason for performing tracheotomy for long-term airway maintenance. The most common postmortem findings in the larynx after prolonged TLI are mucosal ulceration, edema, and submucosal hemorrhage (Table 39-3).[19,135] Figure 39-8 presents a schematic and illustrations of common TLI-induced laryngotracheal lesions. Figure 39-9 presents endoscopic views of

selected cases of glottic injury from TLI in Lindholm's comprehensive study.[130]

Experience with prolonged TLI in the 1970s showed moderate to severe laryngeal injury in 4.2%[136] to 7.2%[137] of cases. Kambic and Radsel found severe laryngeal injury in sixty-two (6.2%) of 1000 patients after anesthetic intubations, indicating that TLI for short periods and in a controlled setting was not without risk.[124] Most prospective studies reveal that serious permanent laryngeal injury from TLI is very uncommon.[19,129,138] All but a few TLI-induced laryngeal injuries tend to heal within 6 to 8 weeks and leave no permanent sequelae.[52,128,138,139]

SUPRAGLOTTIC INJURY

Mucosal ulceration, significant inflammation or edema, and submucosal hemorrhage at autopsy have been noted in 12%, 7%, and 5%, respectively, of patients with prolonged TLI (see Table 39-3).[19] Astrachan et al found severe supraglottic edema in 1% of TLIs.[107]

FIGURE 39-10 Autopsy specimens of larynx from two patients showing typical translaryngeal intubation-induced ulcers on the posterior true vocal cords. *Left:* Superficial hemorrhagic ulcers (*arrows*). Focal mucosal hemorrhage is also seen. *Right:* Deeper ulcers to the level of cartilage (*arrows*).

GLOTTIC INJURY

Laryngeal Ulceration. Ulceration of the posterior aspect of the true vocal cords and arytenoids has been reported in 51%[19] to 79%[130] of TLIs. This injury represents the most common significant complication of TLI.[47,108,131–134,136,139,140] Investigators first reported posterior laryngeal ulcers from TLI in the early 1950s.[141,142] Lindholm observed postmortem macroscopic ulceration or necrosis in the interarytenoid area, the medial side of the arytenoids, and the inner posterolateral area of the cricoid cartilage in 9%, 79%, and 68% of adults, respectively.[130] Laryngeal ulcers from TLI are symmetrical, triangular-shaped erosions of the posterior and medial aspects of the vocal processes (Fig. 39-10) and arytenoids and the posterolateral area of the cricoid cartilages.[47] They are typically 4 to 12 mm in diameter and 1 to 5 mm in depth, and they may penetrate into the cartilage[131] and the cricoarytenoid joints. The areas most vulnerable to ulceration by pressure from the shaft of the ETT are the posterior endolarynx, the arytenoids, the cricoarytenoid joints, and the interarytenoid space.[126] Using telelaryngoscopy, Deeb et al examined 142 adults who required tracheotomy because of failed extubation.[143] They observed that mucosal erosions and ulcerations, often with exposed cartilage, were common, and the most severe ulcers affected the intercartilaginous glottis and posterior subglottis, often with extensive granulation tissue. In some cases, the paired posterior ulcers may be large enough to join each other, producing a "horseshoe lesion."[108]

Glottic Edema and Inflammation. Varying degrees of hyperemia, edema, and inflammation of the glottic mucosa occur in practically all patients during TLI.[19,52,125,130,139,140] Stauffer et al found severe edema and inflammation at autopsy in 29% of patients following TLI, particularly in the posterior commissure area.[19] Figure 39-11 illustrates an example of intubation-related laryngeal edema.[144]

Vocal Cord Paresis and Paralysis. This complication during TLI presents after extubation and is discussed (see the section Early Complications After Extubation/Laryngeal/Vocal Cord Paresis and Paralysis).

Glottic Hemorrhage. The incidence of glottic hemorrhage developing after intubation is not known. Stauffer et al found evidence of submucosal hemorrhage in the glottis in 12% of TLI cases at autopsy (see Table 39-3).[19]

Granuloma Formation. The term *vocal fold granuloma* refers to growths of granulation tissue at the site of mucosal injury as a result of abnormal tissue healing. These lesions typically appear at the site of laryngeal ulceration and vary in size from 2 to 3 mm to more than 1 cm in diameter. They may be unilateral or bilateral.[130] Figures 39-9B and C and 39-12

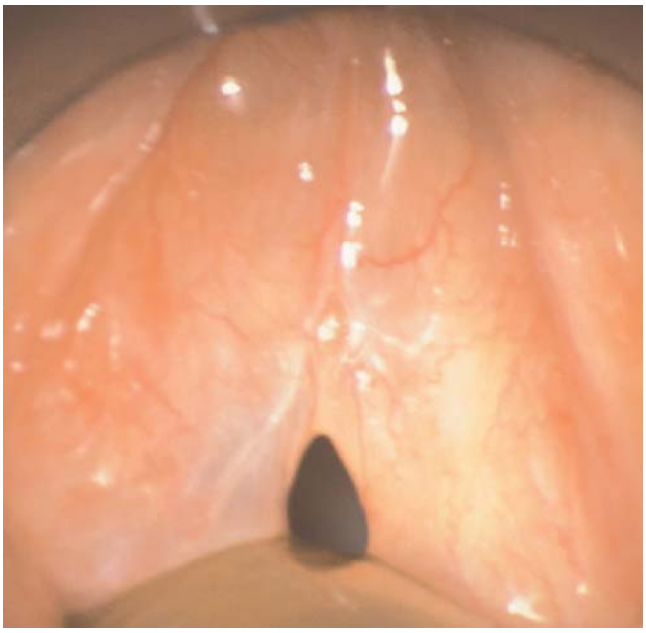

FIGURE 39-11 Laryngoscopic view of edema of the vocal folds following translaryngeal intubation. Some patients with this complication, which presents as postextubation stridor, may require reintubation. (Used, with permission, fromWittekamp.[144])

Tracheobronchitis
Carina irritation, leading to cough and bucking
Suctioning complications

from the series of Lindholm et al,[130] present endoscopic views of small and large laryngeal granulomas following extubation. Laryngeal granulomas during TLI have been observed in up to 16%[128] of patients during TLI. Although usually associated with prolonged TLI, laryngeal granulomas may also occur after short-term intubation.[145,146] This topic is discussed below in "Late Complications After Extubation."

SUBGLOTTIC INJURY

Cricoid cartilage abscess results from bacterial invasion of the cricoid cartilage after pressure ulceration by the ETT.[10,108] Cricoid cartilage abscess may appear as long as 8 weeks after extubation and predispose to posterior glottic stenosis.[10]

Tracheal

Tracheal injury during TLI (Table 39-4) may occur at the site of the inflated cuff, at the level of the tip of the tracheal tube, and at the site of injury by suction catheters. Cuff-site injuries are the most common.[19]

EDEMA AND INFLAMMATION

Fiberoptic bronchoscopy during TLI often reveals varying degrees of tracheal inflammation and edema below the tip of the ETT. Mucosal edema or inflammation is found at autopsy in 39% of TLI patients at the cuff site and in 49% at other levels of the trachea (see Table 39-3).[19] Infiltrates of neutrophils and mononuclear cells are found in the mucosa and submucosa at the cuff site.[147]

TRACHEAL ULCERATION

The use of high-volume, low-pressure cuffs on ETTs has greatly reduced the frequency of cuff-site ulceration. Figure 39-8 (*right panel*) illustrates a small cuff-site ulcer with exposed cartilage on the anterior tracheal wall. Severe cuff-site ulcers that were common in the era of hard-cuff ETTs[148,149] are now rarely seen. Modern soft-cuff ETTs, however, do not completely protect the mucosa from injury. Stauffer et al reported tracheal mucosal ulceration at autopsy in 15% of patients with prolonged TLI with soft-cuff ETTs at the cuff site and in 5% at other tracheal sites (see Table 39-3).[19] Soft cuffs apply lateral pressure over a longer segment than hard cuffs, and pressure from overlapping folds of the fabric of soft cuffs may create channels in the tracheal mucosa.[150]

GRANULOMA FORMATION

Granulomas in the trachea are much less common than in the larynx following prolonged TLI, because tracheal ulceration is now much less common than laryngeal ulceration. All of the laryngotracheal granulomas observed by Lindholm were in the larynx.[130] Astrachan et al found tracheal granulomas in only 1% of patients.[107]

SUBMUCOSAL HEMORRHAGE

Submucosal hemorrhage was found at autopsy in 7% of patients at both the cuff and other tracheal sites (see Table 39-3).[19]

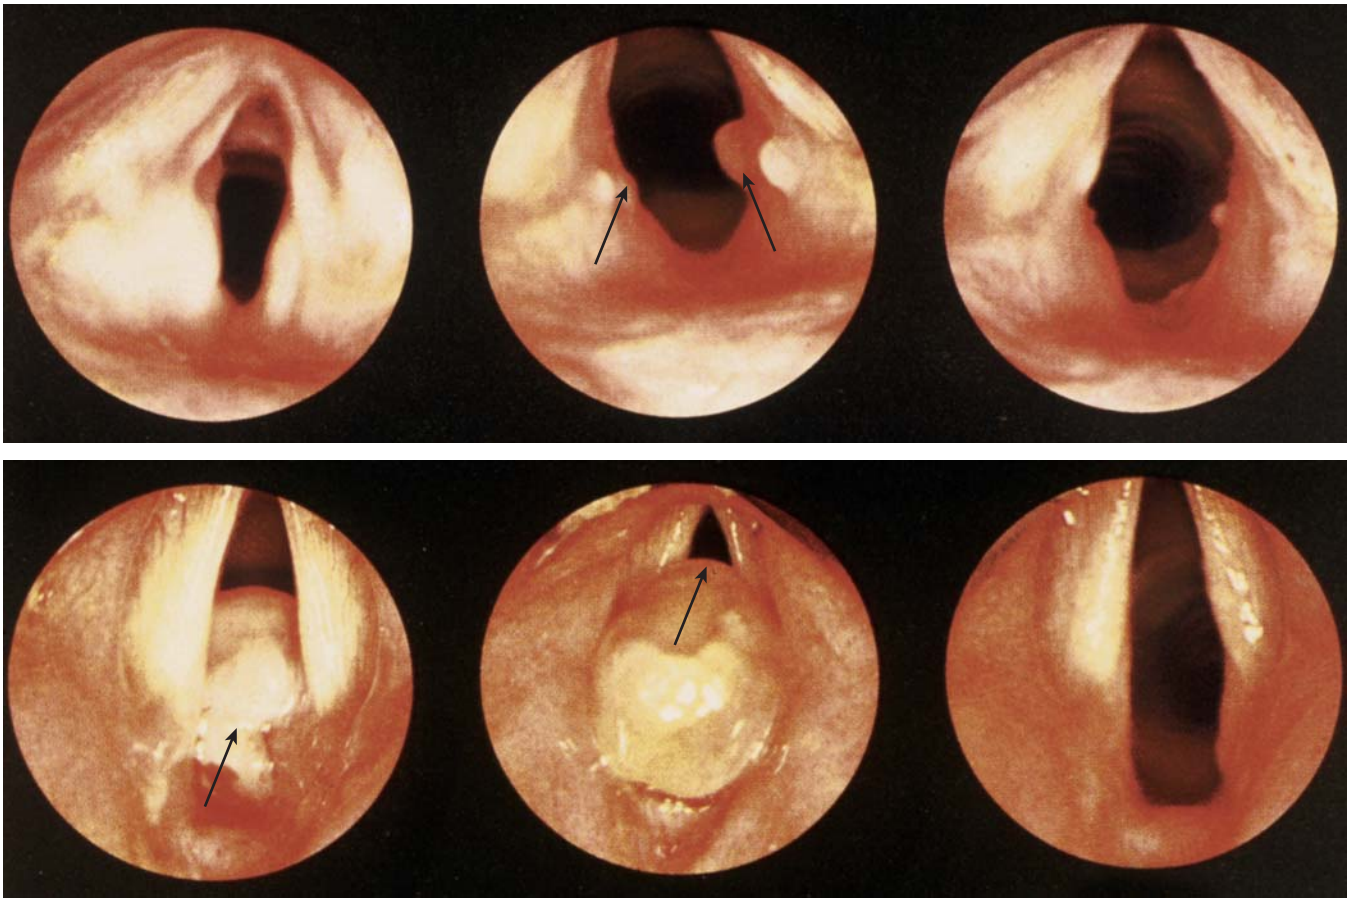

FIGURE 39-12 Laryngeal granulomas are growths of granulation tissue that may result from abnormal wound healing at the site of laryngeal ulcers. The *top panel* shows endoscopic views of the larynx 24 hours after extubation (*left view*), 20 days after extubation (*middle view*), and 34 days after extubation (*right view*). Small laryngeal granulomas (one on the left vocal fold and two on the right vocal fold) are evident in the middle view, and marked spontaneous improvement is observed 14 days later (*right view*). The *bottom panel* shows a very large polypoid laryngeal granuloma 5 months following short-term intubation (*left* and *middle views*) that caused respiratory difficulty and required surgical removal. Healing was achieved following surgery (*right view*). (Used, with permission, from Lindholm.[130])

TRACHEAL NECROSIS

Abbey et al reported a case of massive tracheal necrosis and suppuration after 10 days of TLI.[151] Possible risk factors include sepsis, hypotension, and elevated cuff pressures.

DESTRUCTION OF TRACHEAL CARTILAGE

Ulceration and eventual destruction of the C-shaped cartilaginous tracheal rings may occur as a result of sustained elevation of cuff pressure,[152] resulting in tracheal dilation, tracheomalacia, and injury to the adjacent great vessels and esophagus.

TRACHEAL RUPTURE AND TRACHEAL LACERATION

Tracheal laceration and tracheal rupture are rare complications of TLI during the period when the ETT is in place.

TRACHEAL DILATION

Dilation of the trachea, a sign of severe tracheal wall damage,[152] may appear even with soft-cuff ETTs during TLI or after extubation (See the section Late Complications After Extubation/Tracheal/Tracheal Dilation),[153] although this complication is mainly related to tracheotomy.[154] When tracheotomy is performed following long-term TLI, it may be difficult to determine whether the cuffed ETT or the cuffed tracheostomy tube was primarily responsible for the injury.[155]

TRACHEOMALACIA

Although tracheomalacia has been reported in patients with tracheotomy following TLI,[156] tracheomalacia after TLI alone is very rare when ETTs with high-volume, low-pressure cuffs are used.

TRACHEOESOPHAGEAL FISTULA

Cuff pressure–induced necrosis and erosion of the posterior membranous portion of the trachea and anterior wall of the

esophagus may result in tracheoesophageal fistula.[132,157,158] This rare complication of artificial airways has been mainly associated with tracheotomy,[132,159,160] but TLI, even with soft-cuff ETTs, is also a risk factor.[161] The concurrent use of a nasogastric tube could conceivably enhance the risk. Tracheoesophageal fistula may be silent or present with the appearance of gastric contents in tracheal secretions or with massive gastric distension.[162] After cuff deflation or extubation, it may present with cough following ingestion of food.[161]

TRACHEOARTERIAL FISTULA

Tracheoarterial fistula is a very rare complication associated with long-term tracheotomy. This usually fatal event has been attributed to high cuff inflation pressure leading to tracheal necrosis and erosion of the wall of the innominate artery. Only a few cases of tracheoarterial fistula during prolonged TLI have been reported.[163–165] In one of these cases, erosion into the innominate artery occurred at the level of the tip of the ETT, leading to fatal exsanguination on the fortieth day of TLI.[165] There is one report of tracheoinnominate artery fistula complicating short-term anesthetic orotracheal intubation.[166]

EPITHELIAL DAMAGE

Contact of the tracheal surface with an inflated cuff, ETT tip, or suction catheter results in loss of columnar tracheal epithelium cells and distortion of their cilia.[167–169] Regeneration of the ciliated surface and restoration of ciliary structure and function occurs within 2 weeks after extubation[167,168]

SQUAMOUS METAPLASIA OF THE TRACHEAL EPITHELIUM

Squamous metaplasia of the tracheal mucosa has been observed in dog models of intubation and in humans[147,170,171] and is attributed to abrasion of the mucosa by the inflated cuff or suction catheter. It may involve both surface and glandular epithelium adjacent to necrotic tracheal ulcers following prolonged TLI.[172]

REDUCTION IN MUCOCILIARY CLEARANCE

Tracheal injury at the cuff site depresses mucociliary clearance in both experimental animals and humans. Cuff inflation,[168] squamous metaplasia,[173] and loss of cilia[169] all contribute to impaired mucociliary transport during TLI.

AIRWAY COLONIZATION WITH BACTERIA

Colonization of the trachea with bacteria occurs in nearly all patients during TLI,[174–176] mainly from aspiration of secretions above the inflated ETT cuff and from infected ETT biofilm.[177] Gram-negative bacteria, particularly *Pseudomonas* species, have a particular tropism for the tracheobronchial mucosa. Bacterial colonization of the trachea during TLI is a risk factor for ventilator-associated pneumonia (VAP; see Chapter 46).[177,178] Ventilator-associated tracheobronchitis in intubated patients (fever, purulent lower airway secretions, positive sputum cultures, and absence of new or progressive lung infiltrates) is also increasingly recognized as an important clinical infection in the ICU.[179,180]

PSEUDOMEMBRANOUS TRACHEITIS

Pseudomembranous tracheitis, a rare and little known complication of TLI that has been attributed to ischemic cuff-site injury, was first reported in 1969.[131] Lins et al reported five cases and reviewed a total of twenty-four cases.[181] Tracheal epithelial injury from aspiration of gastric contents during TLI has been also cited as a cause of tracheal pseudomembrane formation.[182] Harbison et al reported a patient who presented with acute stridor from a fibrinous tracheal membrane 3 days after TLI lasting 48 hours.[183] Removal of the membrane by rigid bronchoscopy was curative. Deslee et al described one fatal case of fibrinous tracheal pseudomembrane from TLI.[184]

MISCELLANEOUS

Tracheobronchitis, protracted coughing, and consequences of ETT suctioning,[89,185] such as chest pain, hypoxemia, and cardiac arrhythmias, are sometimes observed.

Bronchial

Main-stem bronchus intubation (see Fig. 39-3) is mainly a complication during ETT placement, but it may also occur after intubation. In a retrospective series of 278 adult ICU patients with TLI, Kollef et al found that seven (2.5%) had inadvertent endobronchial ETT placement.[186]

Pulmonary

Pulmonary complications during TLI include aspiration, pneumonia, retained secretions, and atelectasis.

ASPIRATION

Aspiration of oropharyngeal secretions or gastric contents can be a serious complication while the ETT is in place.[35,177,187–189] Leakage of contaminated subglottic secretions around the ETT cuff into the lower airway increases the risk of VAP.[177] Estimates of the frequency of clinically significant aspiration during TLI range as high as 20%.[188] Aspiration of gastric contents during TLI may be less common than aspiration of oral and pharyngeal secretions, but data are sparse.

PNEUMONIA

VAP (see Chapter 46) is a common and serious threat to patients with artificial airways who require mechanical ventilation.[35,177,178,190] VAP occurs in as many as 28% of patients during the course of mechanical ventilation.[190] A large, retrospective, matched cohort study showed that VAP

developed in 9.3% of adult patients receiving mechanical ventilation for more than 24 hours.[191] The mortality rate of VAP ranges from 24% to 50%.[190] Mechanisms of pneumonia related to TLI are discussed (see the section Pathogenesis of Complications of Translaryngeal Intubation/Complications While the Endotracheal Tube Is in Place/Clinical Influences in Pulmonary Complications/Pneumonia and Tracheobronchitis).

RETAINED SECRETIONS

TLI may promote retention of bronchopulmonary secretions in the lung because of impaired cough performance.[192]

ATELECTASIS

Atelectasis may complicate TLI as a result of retained bronchopulmonary secretions, migration of the ETT into a main-stem bronchus, and other factors operative during mechanical ventilation.

Miscellaneous

GENERAL

Pain, Discomfort, and Psychological Impact. Certainly all who have cared for intubated patients recognize that anxiety, depression, feelings of isolation and withdrawal, and frustration with impaired communication are major psychological detriments related to TLI. The immediate and long-term psychological impact of TLI, however, has been the subject of only a few investigations. The psychological health of intubated patients is influenced not only by TLI, but also by noise, light, sleep deprivation, stresses of underlying illness, and other adverse influences in the ICU.[193] In a study that was not entirely limited to TLI patients, Swaiss and Badran recorded the following distressing complaints in interviews of adult patients 1 day after discharge from the ICU: anxiety (68%), discomfort from the ETT (60%), fear (54%), pain (52%), discomfort from the nasogastric tube (48%), difficulty in communicating (33%), dreams and hallucinations (31%), discomfort from physiotherapy (24%), noise (15%), insomnia (13%), and thirst (10%).[194]

Unplanned Extubation. "Unplanned extubation" is a broad categorical term that includes self-extubations and other extubations that are variously called "accidental," "deliberate," and "inadvertent" in the literature.[19,64,107,195–197] The overall frequency of unplanned extubations in critically ill adults is 8.6%.[197] In a prospective epidemiologic study of more than 5000 critically ill adults with TLI, self-extubation was the most common accident related to TLI.[198] Unplanned extubation is more likely to occur with oral than with nasal TLI.[199,200] In a large case series, Chevron et al reported that unplanned extubation was usually deliberate (87% of patients) and associated with insufficient sedation.[200] Unplanned extubation may occur from forces applied to the ETT by ventilator tubing, bedrails, patient motion, bucking, coughing, and forcing the tube forward with the tongue.

Coppolo and May reported a 12-month experience with self-extubation in adult ICU patients and noted self-extubation in 11%, cardiorespiratory sequelae of self-extubation in 31%, and need for reintubation in 31% of cases.[195] Others have documented reintubation rates following self-extubation as high as 74%.[201] Not surprisingly, the need for reintubation is much lower when self-extubation occurs during weaning from mechanical ventilation than during the period of full ventilator support.[202] Besides the need for reintubation, sequelae of unplanned extubation include longer ICU and hospital stays,[199,203,204] prolongation of mechanical ventilation,[203] and complications of TLI.[204]

Mechanical Complications. Various mechanical problems with ETTs occur in approximately 6% of intubations (Table 39-5),[19] and they may place patients at risk for serious complications and need for reintubation. Beckmann and Gillies examined a large database of voluntary incident reports from ICUs in Australia and New Zealand to determine the frequency of reintubations not related to accidental or self-extubation.[205] Among 143 such incidents, the reasons for reintubation included the following mechanical complications: tube malposition (twenty-five [17%]), tube securing or taping problems (twenty-four [16%]), pilot tube or cuff problem (twenty-three [16%]), and blocked or kinked

airway (twenty [14%]), in addition to failed extubation (nineteen [14%]), inadequate preparation for extubation (eight [6%]), and other events (twenty-four [17%]).[205]

Dislocation or misplacement of an ETT may result in endobronchial intubation (see Fig. 39-3), carinal irritation by the ETT tip, high placement at the level of the upper trachea or hypopharynx, and self-extubation. Potential complications of high tube placement include injury to the larynx and adjacent structures including the recurrent laryngeal nerves, inability to seal the airway, leading to aspiration and inadequate ventilation, and subglottic stenosis. Kollef et al reported that twenty-two (8%) of 278 adult ICU patients had at least one significant ETT dislocation, with complications such as anoxic encephalopathy, hypoxemia, gastric aspiration, atelectasis, and pneumothorax.[186] An earlier prospective study revealed ETT malposition in five (8.2%) of sixty-one patients with prolonged TLI.[35]

If an ETT is positioned too low in the trachea, flexion of the neck may allow it to migrate into a main-stem bronchus, and conversely, if an ETT is positioned too high in the trachea, extension of the neck may allow it to migrate into the pharynx, potentially leading to unplanned extubation.[206] Conrardy et al showed that flexion of the neck moved the tip of the ETT an average of 1.9 cm toward the carina (range: 0 to 3.1 cm), and extension of the neck moved the ETT a similar distance away from the carina (range: 0.2 to 5.2 cm).[206] The route of intubation (nasal vs. oral) and cuff inflation or deflation did not affect tube movement.

The ETT may become partially or completely obstructed during placement or while it is in place by patient biting, retained secretions, blood or blood clots, foreign bodies, tumor, or other material. Obstruction from tube kinking or external compression by cuff overinflation is very rare. The tip of the ETT may impact on the tracheal mucosa leading to tube obstruction if the tube lacks a Murphy eye.[207]

ETT cuff problems during TLI include leak, rupture, and inability to seal the airway. Rashkin and Davis noted leaky cuffs during TLI in fifteen (25%) of their sixty-one patients.[35] Cuff rupture is now rarely observed. Inability to seal the airway by inflating or overinflating the cuff was the most common early clinical problem following TLI in one series.[19] Vyas et al checked cuff pressures in thirty-two patients intubated with ETTs with high-volume, low-pressure cuffs and found that 62% had elevated cuff pressures, some as high as 100 cm H_2O.[208] They performed a telephone survey that revealed that cuff pressure was checked regularly in only 17% of ICUs.

A wide variety of other mechanical problems have been encountered while the ETT is in place, including malfunction of the one-way inflation valve, inadvertent severance of the inflation tube or pilot balloon, disconnection from the ventilator, and difficulty passing a suction catheter through the ETT.

Malnutrition. TLI precludes effective swallowing and necessitates feeding by way of enteric tubes or intravenous lines. Chapter 41 discusses malnutrition in patients with TLI.

ESOPHAGEAL

Tracheoesophageal fistula may develop during TLI (see the section Complications While the Endotracheal Tube Is in Place/Tracheal/Tracheoesophageal Fistula).

GASTRIC

Gastric distension may occur if a tracheoesophageal fistula develops during TLI.[162]

MUSCULOSKELETAL AND NEUROLOGIC

Musculoskeletal and neurologic complications directly related to TLI while the ETT is in place have not been reported.

PHYSIOLOGIC

Compared with a normal upper airway, an ETT increases the resistance to airflow. Gal and Suratt demonstrated that TLI in healthy men increased total airways resistance from 0.99 cm H_2O/L/s to 2.25 cm H_2O/L/s, an increase of 178%.[209,210] Approximately half of this increase was attributed to the ETT itself, and the remainder to reflex bronchoconstriction.[209,210] TLI increases lower airway resistance slightly in normals without reactive airways disease by stimulation of irritant receptors, provoking bronchoconstriction,[211] and prophylactic treatment with bronchodilators has a protective effect.[212]

Airflow resistance during TLI increases as the length of the ETT increases or its diameter decreases.[213] Because they increase airflow resistance, ETTs increase the patient's work of breathing.[214] The work of breathing increases as the patient's minute ventilation increases and as the diameter of the ETT decreases.[214–216] At minute ventilation rates at or below 8 L/min, an ETT has little impact on the work of breathing.[215] Although the extra work of breathing imposed by an ETT is not clinically important in most patients, it may be clinically significant in patients with poor ventilatory function.

COMPLICATIONS DURING AND AFTER EXTUBATION

Complications During Extubation

Oral, nasal, pharyngeal, and laryngeal complications that developed while the ETT was in place may, of course, first be detected at extubation. Table 39-6 lists complications of TLI that Stauffer et al observed immediately after extubation in the ICU.[19] Hoarseness and sore throat are the most common symptoms at extubation. New complications occurring in the brief period of extubation are transient and uncommonly reported. They include discomfort, pain, and anxiety.[193] Significant increases in heart rate, blood pressure, and plasma catecholamine levels occur at extubation.[94] Nasal

TABLE 39-6: CLINICAL FINDINGS AT EXTUBATION IN A SERIES OF 81 PATIENTS

	No.	Percent (%)
History (obtained in sixty-nine patients)

bleeding and dental injuries may occur during extubation, but such events are rarely reported.

Partial laryngeal obstruction at extubation is most often related to laryngeal edema (see the section Early Complications After Extubation/Laryngeal/Edema). Laryngeal injury and other complications during self-extubation of an ETT with an inflated cuff have not been adequately studied. Surprisingly, few patients appear to develop laryngeal complications following self-extubation. Pulmonary aspiration may occur if extubation and suctioning techniques are faulty. The requirement for reintubation soon after extubation is usually caused by laryngeal edema or respiratory failure. Difficult extubation should be anticipated in patients whose intubation was difficult.[217]

Early Complications After Extubation

This section discusses those complications of TLI that appear during roughly the first week after extubation. This period is dominated by symptoms of pharyngeal and laryngeal injury from TLI, including hoarseness, dysphonia, sore throat, cough, dysphagia, and odynophagia.

NASAL, PARANASAL, AND ORAL

There are no specific new complications that develop in this time interval, but complications that began earlier may of course be observed.

PHARYNGEAL

Postextubation sore throat has been reported in up to 42%[19] of ICU patients, similar to the frequency observed in patients who required TLI for general anesthesia.[218,219] Persistent and severe dysphagia after extubation following prolonged TLI should alert the clinician to the possibility of active infection in the posterior larynx.

There may be a temporary loss of the gag reflex after extubation. This was observed in 24% of patients who had direct laryngoscopy within 24 hours of extubation, supporting the notion that some patients have a sensory denervation of the pharynx and larynx from TLI.[52] Loss of upper airway reflexes increases the risk of aspiration.[52] We found pharyngeal bleeding or ulceration in 9% of patients at extubation (see Table 39-6),[19] although Colice et al did not report this complication after prolonged TLI.[52]

LARYNGEAL

Prospective studies using fiber-optic laryngoscopy within 24 hours of extubation in the ICU setting have revealed laryngeal injury in 73% to 94% of patients.[52,220,221] Colice et al performed direct fiber-optic laryngoscopy within 24 hours of extubation in eighty-two patients who had been intubated for 4 or more days (mean: 9.7 ± 0.6 days).[52] Seventy-seven (94%) of their patients had laryngeal injury (42% mild, 29% moderate, and 23% severe). Nearly all patients had posterior true vocal cord ulceration. Laryngeal edema was present in the patients with moderate to severe damage. Two patients had such large ulcers that the vocal cords could not be adducted, permitting free aspiration into the trachea.[52] Most patients who displayed initial laryngeal damage had complete resolution of laryngeal findings on laryngoscopy within 4 weeks after extubation.[52] Kastanos et al reported the following early laryngeal lesions in nineteen patients after extubation: true vocal cord granulomas in eight (42%), true vocal cord ulcerations in seven (37%), true vocal cord paresis in one (5%), and subglottic edema in one (5%).[128] Thomas et al performed fiber-optic endoscopy through the ETT just before extubation and found visible laryngeal pathology in 131 (88%) of 150 patients.[222] Table 39-7 summarizes the important laryngeal complications after TLI.

Hoarseness. In fifty-four adult male patients followed closely by Colice et al after TLI, thirty (56%) had significant hoarseness.[52] Holdgaard et al observed hoarseness in 42% of ICU patients following nasotracheal intubation.[105] Hoarseness following TLI usually resolves within a few days in most patients as laryngeal edema and inflammation subside and normal vocal cord adduction is restored.[125] In

some cases, transient postextubation hoarseness requires 7 to 10 days to resolve. Hoarseness persisting beyond 10 to 14 days suggests serious laryngeal injury such as granuloma formulation, vocal cord paresis or paralysis, or cricoarytenoid joint dysfunction, and requires the attention of an otolaryngologist–head and neck surgeon.

Edema. Postextubation laryngeal edema (see Fig. 39-11), an important complication of TLI, may occur at the supraglottic, glottic, or subglottic levels.[8] It presents with postextubation stridor and dyspnea and commonly precipitates the need for reintubation. Laryngeal edema is observed immediately after extubation in approximately 40% of patients after anesthetic intubation and in a roughly a third[223] to half of critical care patients.[52]

Laryngospasm. Postextubation laryngospasm in the recovery from general anesthesia is a well-known phenomenon. Although postextubation stridor in the ICU is sometimes attributed to laryngospasm, this complication after extubation of ICU patients is not well documented. Colice et al reported true laryngospasm in only one of eighty-two ICU patients within 24 hours of extubation.[52] True laryngospasm following extubation of the critically ill patient should be distinguished from laryngeal edema and other more common causes of postextubation stridor.

Stridor. A literature review by Wittekamp et al reported postextubation stridor in up to 30.2% of critically ill adults.[144] Many studies have investigated postextubation stridor.[19,52,224–226] Stridor occurring after extubation is usually inspiratory, indicating variable extrathoracic airway obstruction. Mackenzie et al observed severe stridor after prolonged TLI in 0.1% to 0.6% of patients.[224] This complication was found to be caused by vocal cord edema or subglottic stenosis, not laryngospasm. Symptoms of stridor appeared from 5 minutes to 4 hours after extubation.[224] Repeated intubations or tracheotomy were required in the majority of patients. Postextubation stridor should always indicate the possibility of subglottic stenosis at the level of the cricoid cartilage, a level that is particularly vulnerable to airway narrowing in children.

Muscle Dysfunction. Laryngeal incompetence is common after extubation and has been attributed to a sensory impairment or mechanical dysfunction of the larynx.[227] The frequency of aspiration secondary to laryngeal incompetence in postoperative patients ranges from 22% to 35%.[227,228] Inability of the vocal cords to adduct increases the risk of aspiration.[52,125]

Vocal Cord Paresis and Paralysis. Unilateral vocal cord paresis or paralysis is a serious but uncommon complication of TLI.[47,125,229,230] It presents in the early postextubation period as persistent hoarseness. Santos et al reported vocal cord immobility in sixteen (20%) of ninety-seven patients after extubation, and in half of these cases, a delayed presentation over a period of 1 to 10 weeks following extubation was observed.[139] Others have reported vocal cord paralysis in less than 1% of cases.[47] True bilateral vocal cord paralysis after TLI, which presents as severe stridor, is very rare.

Whited evaluated sixteen patients with vocal cord paresis or paralysis after TLI of 5 days or longer.[125] Common features in these patients were symmetry of vocal cord paresis or paralysis, edema and erythema of the arytenoids and posterior commissure, median or paramedian vocal cord positioning, late return of vocal cord abduction, a tendency for aspiration to occur, and spontaneous recovery in nearly all patients within 4 weeks.[125] Postextubation vocal cord paresis or paralysis may result from traumatic dislocation of the arytenoids,[231,232] cricoarytenoid joint arthritis, cuff inflation immediately below the vocal cords resulting in compression of the anterior branch of the recurrent laryngeal nerves,[233] or the mechanical effects of laryngeal edema and inflammation.[108] Bilateral vocal cord paralysis from intubation injury may present with hoarseness and recurrent aspiration[233] or with upper airway obstruction requiring immediate tracheotomy.

Vocal Cord Hematoma. Hematomas of the vocal cords that occur during placement of an ETT apparently resolve by the time of extubation. They were not seen after extubation in eighty-two patients studied by Colice et al.[52]

Posterior Glottic Infection and Cricoid Cartilage Abscess. Severe odynophagia or odynophonia after extubation should suggest the possibility of posterior glottic infection or cricoid cartilage abscess.[108] Posterior glottic infection may result in destruction of laryngeal cartilage and predispose to posterior glottic stenosis.[108]

TRACHEAL

In a prospective study of nineteen patients, Kastanos et al reported finding tracheal granulomas in six patients (31%) and cuff-site tracheitis in three (16%).[128] Tracheal

pseudomembranes leading to airway obstruction in the first few days after extubation have been the subject of individual case reports.[181,182]

BRONCHIAL

Specific bronchial complications of TLI in this time period have not been reported.

PULMONARY

Pulmonary aspiration may occur with laryngeal incompetence after extubation.[52,125,227] Pulmonary aspiration was observed after extubation in two (2.4%) of eighty-two patients after prolonged TLI in the series of Colice et al.[52] This finding was attributed to vocal cord dysfunction and temporary loss of sensorimotor function of the larynx and pharynx.[52] Burgess et al observed aspiration of swallowed contrast material in 33% of surgical patients immediately after extubation.[227] Endoscopic evaluation of swallowing after prolonged TLI has revealed aspiration in 14%[234] to 45%[235] of patients.

Postextubation negative pressure pulmonary edema secondary to laryngeal or tracheal obstruction following TLI and prolonged forceful inspiration has been described in small case series or individual case reports.[236,237]

MISCELLANEOUS

There are no significant miscellaneous complications of TLI in the early postextubation period.

Late Complications After Extubation

Late complications of TLI, those appearing in the weeks to months after extubation, are usually the result of abnormal airway mucosal healing with fibrosis or granuloma formation. Laryngeal stenosis is the most serious of these events (see discussion below).

NASAL AND PARANASAL

Nasal stricture and nasal septal perforation following prolonged nasotracheal intubation are rare.

ORAL

The only late oral complications of TLI are those related to initial dental or oral trauma.

PHARYNGEAL

In some patients, dysphagia may persist for several weeks. Residual problems related to pharyngeal perforation during ETT placement may persist late after extubation.

LARYNGEAL

Fortunately, late laryngeal complications of TLI (see Table 39-7) are uncommon because of the normal healing of laryngeal ulcers and other laryngeal injuries discussed above. Healing of laryngeal mucosal injury after extubation is usually complete within 8 to 12 weeks.[138] Nevertheless, abnormal healing may result in serious late laryngeal complications of TLI. Hoarseness that fails to improve for many weeks after extubation suggests abnormal healing with structural deformity of the larynx.[130]

Laryngeal Stenosis. Laryngeal stenosis following TLI may be supraglottic, glottic, or subglottic in location. Supraglottic stenosis is unusual. Glottic or subglottic stenosis is a serious but fortunately uncommon late complication of TLI. Although rarely severe, it represents the most notorious complication of TLI and has received extensive attention in the literature.[52,108,125–127,130,238–242] TLI is the most common cause of posterior glottic laryngeal stenosis.[242]

Most prospective studies of TLI document a very low rate of laryngeal stenosis.[19,128,130,138,243] The reported frequency of this complication ranges from 0% to 12%. When the results of seven prospective studies are combined, the overall incidence of laryngeal stenosis is 1.3% to 2.9% (Table 39-8), depending on whether the disproportionately higher number of cases in the Whited analysis is included. Colice found no cases of laryngeal stenosis in fifty-four prospectively studied survivors of prolonged TLI.[138] Elliott et al found that three (10%) of thirty survivors of the acute respiratory distress syndrome had laryngeal stenosis.[240] Laryngeal stenosis following TLI for general anesthesia is very rare.

Whited found posterior commissure fibrosis with stenosis in two (12.5%) of sixteen patients with TLI of 5 days or longer who were referred for evaluation of vocal cord paralysis or paresis.[125] Later, he reported frequencies of laryngeal stenosis of 6% in 200 patients with prolonged TLI[126] and 14% in fifty patients intubated for 11 days or longer.[127] This rate

TABLE 39-8: RATES OF LARYNGEAL STENOSIS AFTER PROLONGED TRANSLARYNGEAL INTUBATION IN PROSPECTIVE STUDIES

Year	Reference	Frequency of Laryngeal Stenosis
1969	Lindholm[130]	1/206 (0.5%)
1981	Stauffer et al[19]	2/27 (7.4%)
1982	Pecora and Seinige[243]	0/21 (0%)
1983	Kastanos et al[128]	2/19 (10.5%)
1983	Whited[126]	12/200 (6.0%)
1989	Colice[138]	0/54 (0%)
1994	Santos et al[139]	0/62 (0%)
	Total	17/589 (2.9%)[a]

[a]With the exception of the study by Whited, the rate of laryngeal stenosis is five of 389 (1.3%).

of laryngeal stenosis is higher than the rates in other prospective studies (see Table 39-8). In Whited's study, duration of TLI was the only independent variable assessed, and other potential risk factors for laryngeal stenosis were not evaluated.[126,127]

Lindholm noted only one case of laryngeal stenosis (subglottic) in 206 adult patients after TLI,[130] but patients in his series had a relatively short duration of intubation (mean: 32 hours). Stauffer et al found that two (7%) of twenty-seven patients evaluated for airway stenosis with tomograms after extubation had subglottic stenosis, defined as a 10% or greater reduction in transverse diameter of the trachea at the cricoid level.[19] Subglottic stenosis in adults following prolonged TLI appears to be much less common than in neonates and children, in whom this complication occurs with a frequency as high as 8%.[244]

Laryngeal Granuloma Formation. Granuloma formation is an important late complication of TLI, typically presenting as persistent hoarseness. Granulomas occur primarily in the larynx,[19,130,139,245] but rarely may occur in the trachea. Laryngeal granulomas (see Figs. 39-9 *B* and *C* and 39-12) are usually a few millimeters in diameter and rarely grow large enough to compromise the airway lumen. They may be sessile or pedunculated. As a manifestation of the healing process, albeit abnormal, granulomas may not appear until weeks after extubation. Laryngeal granulomas usually appear at the edges of posterior glottic ulcers, particularly those on the vocal processes and arytenoids. They usually resolve spontaneously, but surgical excision is sometimes required because of persistent hoarseness or airway compromise.[138]

The reported frequency of laryngeal granulomas after TLI is highly variable. After anesthetic intubation, they are extremely rare.[245] Colice et al found laryngeal granulomas in four (7%) of fifty-four patients carefully examined after TLI.[52] In that series, all patients with persistent hoarseness after TLI had laryngeal granulomas. Lindholm found postintubation granulomas in approximately one-third of adults after TLI, but not in any infants or children.[130] In the Lindholm series, only seven (2.6%) of 265 patients followed after extubation required surgical excision of laryngeal granulomas. The report of Santos et al of ninety-seven patients with prolonged TLI described laryngeal granulomas in 44%, and in 57% of these cases, the granulomas developed an average of 4 weeks after extubation.[139]

Synechia Formation. Synechia (membrane or web) formation at the glottis occurs in less than 1% of TLIs.[130,246] Synechia formation may "weld" the vocal cords together, leading to aphonia and airway obstruction.[8]

TRACHEAL

Tracheal Stenosis. Tracheal stenosis is an uncommon complication of TLI alone. Figure 39-13 illustrates endoscopic and clinical features of tracheal stenosis in a patient with dyspnea following TLI.[247] Stenosis of the trachea in adults surviving prolonged periods of mechanical ventilation is usually attributed to tracheotomy rather than TLI.[248] Severe tracheal stenosis following TLI alone is fortunately rare.[249] Santos et al prospectively observed no cases of tracheal stenosis in sixty-two adults surviving long-term TLI.[139] A retrospective review of laryngotracheal stenosis following TLI, tracheotomy, or both in 315 neurologic patients reported by Richard et al found tracheal stenosis in only one patient in the group of 172 patients (0.6%) with TLI only (mean duration: 17 days).[241] In contrast, twenty-five (19%) of 131 patients with TLI followed by tracheotomy had tracheal stenosis. Tracheal stenosis following tracheotomy usually occurs at the site of the tracheal stoma,[250] whereas this lesion is observed at the site of the inflated cuff when it follows TLI alone. Spiral computed tomography with multiplanar reconstruction and virtual bronchoscopy are highly accurate in diagnosing tracheal stenosis.[251]

Tracheal Dilation. Persistent tracheal dilation is caused by cartilaginous injury at the cuff site.[152–154] This complication was reported in 2% to 5% of patients following use of hard-cuff tracheostomy tubes,[153] and it is rarely seen following TLI with soft-cuff ETTs.

Tracheal Granuloma Formation. Tracheal granulomas occur mainly at the site of tracheal cuff-site ulcers. These are extremely rare in the era of soft-cuff ETTs.

BRONCHIAL

There are no late bronchial complications of TLI.

PULMONARY

There are no late primary pulmonary complications of TLI.

MISCELLANEOUS

There are no important late miscellaneous complications of TLI other than residual problems related to tracheoesophageal fistula.

PATHOGENESIS OF COMPLICATIONS OF TRANSLARYNGEAL INTUBATION

This section reviews the causes and mechanisms of selected complications of TLI. Most of the investigation of mechanisms of complications of TLI has focused on laryngeal injury and tracheal cuff-site injury.

Complications During Endotracheal Tube Placement

Complications during placement of an ETT often occur as a result of suboptimal technique stemming from poor judgment or inexperience. Failure to prepare the patient for

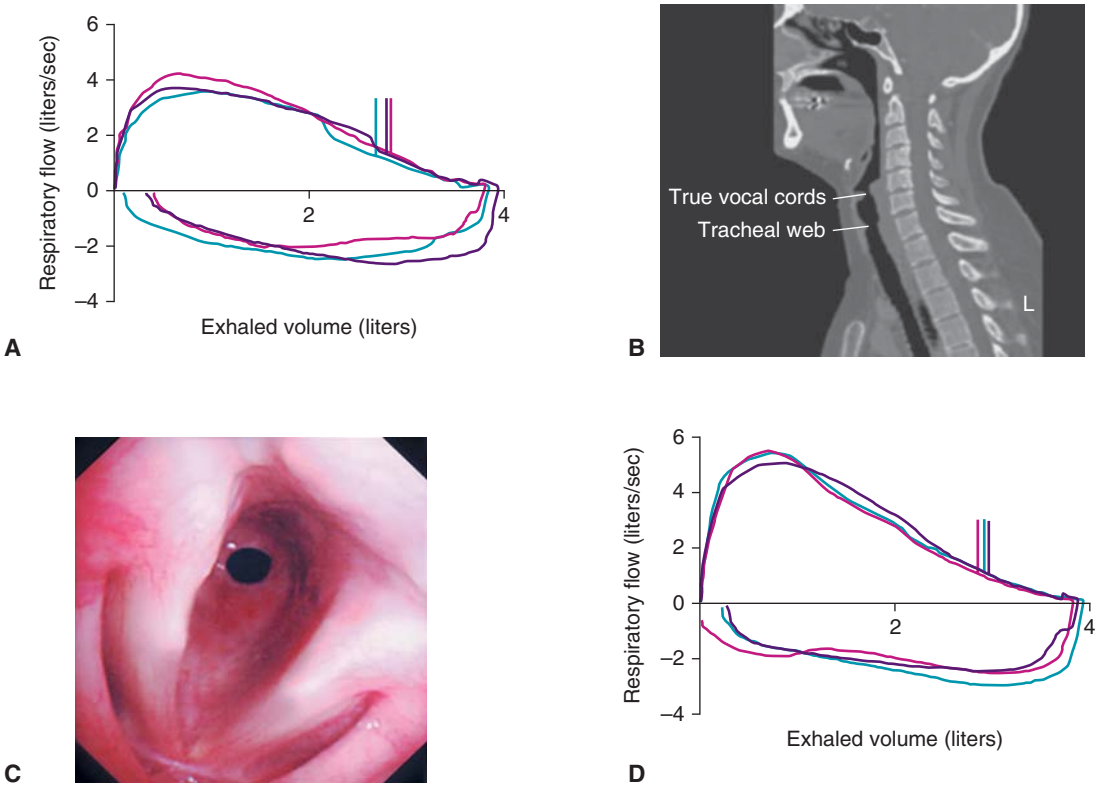

FIGURE 39-13 Tracheal stenosis is an important but uncommon complication of endotracheal intubation. Panel **C** illustrates subglottic tracheal stenosis in a 45-year-old woman with dyspnea who had required prolonged endotracheal intubation 8 years earlier. Computed tomography demonstrated tracheal narrowing 2.8 cm below the vocal cords (**B**), and a flow-volume loop revealed attenuated expiratory/inspiratory flow rates (**A**). Marked improvement in symptoms and stridor and improvement in flow rates (**D**) were reported after resection of the stenotic segment and tracheal dilation. (Reproduced, with permission, from Datta A, Cale A. Postoperative tracheal stenosis. *N Engl J Med.* 2010;362:e5, January 14, 2010. Copyright © Massachusetts Medical Society.)

intubation and equipment malfunction may also lead to complications. For example, during nasal intubation attempts, failure to prepare the nasal mucosa with a topical anesthetic or vasoconstrictor or failure to select the more patent side of the nose for intubation may result in nasal mucosal laceration or turbinate injury.

It is generally taught that complications of intubation are more likely to occur in emergency situations than in elective, controlled intubations, but there are few data to establish this with certainty. Wang et al found that failure of prehospital intubation attempts was significantly associated with a number of covariates by multivariate logistic regression, including the presence of clenched jaw/trismus, inability to pass the ETT past the vocal cords, intact gag reflex, and increased body weight.[252] Adnet et al found significant associations between the number of intubation attempts and the rate of mechanical and general complications of emergency prehospital TLI,[29] but Schwartz et al did not find this association in critical care intubation.[70] Supervision of TLI in teaching hospitals by senior physicians is associated with a lower rate of complications.[20]

Incorrect use of the laryngoscope may cause dental injury or pharyngeal laceration. Blind jamming of the ETT into the hypopharynx may cause serious soft-tissue injury. Failure to oxygenate and ventilate the patient before intubation may result in hypoxic brain injury. Deep insertion of the ETT far beyond the vocal cords may result in right main-stem bronchus intubation. These are only a few examples of how faulty intubation technique, inexperience, and poor judgment may lead to intubation complications.

Complications While the Endotracheal Tube Is in Place

Complications of TLI during this time interval depend upon anatomic, physiologic, ETT, and clinical influences.

ANATOMIC AND PHYSIOLOGIC INFLUENCES

Nasal and Paranasal Complications. Necrosis of the nasal alae and ulceration and perforation of the nasal septum result from ischemic necrosis secondary to pressure on these structures from the nasotracheal tube. Sinus effusions and sinusitis are caused by obstruction of the sinus ostia by the adjacent nasotracheal or nasogastric tube, edema, inflammation, or mucus plugging. Otitis and middle ear effusions are related to obstruction of the eustachian tube by the same influences.

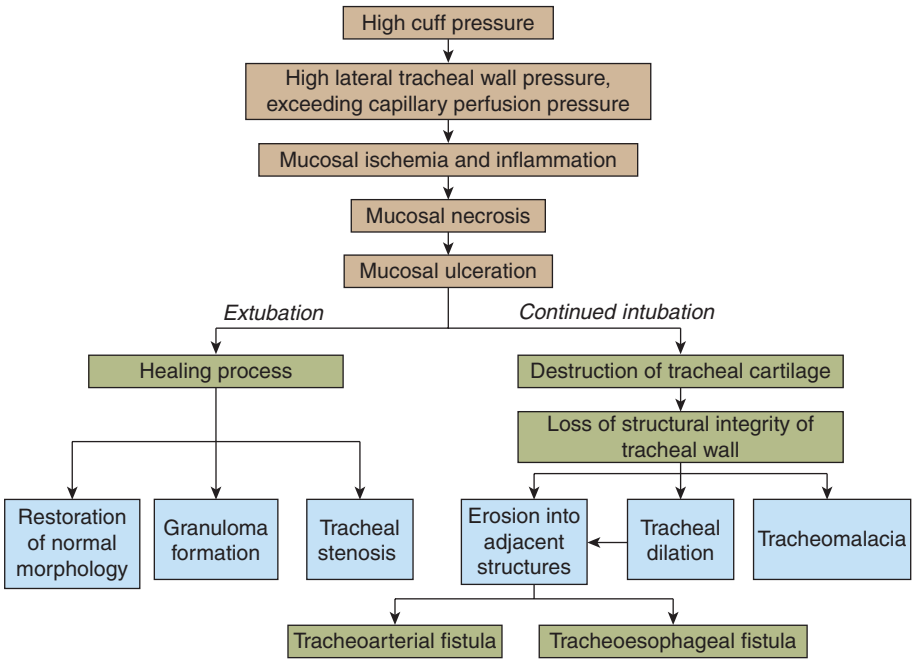

FIGURE 39-14 Outline of pathogenesis of tracheal injury at the site of the air-inflated cuff.

Laryngeal and Tracheal Complications. Serious laryngeal and tracheal injury during TLI is generally attributed to ischemic injury of the mucosal surface and deeper tissues by pressure exerted at vulnerable anatomic sites.[253] For example, ischemia occurs when the pressure exerted on the posterolateral wall of the larynx by the ETT or on the tracheal wall by the inflated cuff exceeds the capillary perfusion pressure in these areas. Necrosis, sloughing of the mucosa, and ulceration follow. Microscopically, inflammatory cell infiltrates and bacterial invasion are seen in the devitalized mucosal tissues. Eventually, destruction of soft tissues and cartilage in the wall of the larynx and trachea occur. In severe cases, there is loss of structural integrity of the tracheal wall, producing dilation or softening. If the patient survives, the healing process begins with one of three eventual outcomes: restoration of normal morphology, development of granulation tissue, or fibrosis. In the larynx, fibrosis results in glottic or subglottic stenosis, synechia formation, or cricoarytenoid joint fixation. In the trachea, fibrosis results in segmental stenosis.

The concept of tracheal mucosal injury by an air-filled cuff was established by studies performed in the 1960s and 1970s. It is outlined in Figure 39-14. Tracheal mucosal perfusion pressure is a critically important determinant of ischemic injury at the tracheal cuff site.[254–260] In humans, the tracheal capillary perfusion pressure is estimated to be 25 mm Hg (range: 22 to 32 mm Hg) or 34 cm H_2O (range: 30 to 44 cm H_2O).[258,259] The role of capillary perfusion pressure in the pathogenesis of tracheal cuff-site injury is discussed (see the section Clinical Influences in Tracheal Cuff-Site Injury).

Laryngeal and tracheal structures that are vulnerable to ETT pressure are the arytenoids, the posterior rim of the glottis, the subglottis, the cuff site, and the site of the tip of the ETT.[261] The posterior rim of the glottis is a contact point or fulcrum where the ETT abrades and applies constant pressure to the mucosa, leading to the risk of mucosal ischemia and ulceration.[47,239] Quartararo and Bishop have described the geometric shape of the glottis as a pentagon, which of course does not resemble the circular shape of the ETT.[48] This geometric mismatch creates several points of contact where ulceration is most likely to occur (Fig. 39-15).[48] An experimental ETT was once designed to fit the natural shape of the glottis.[262]

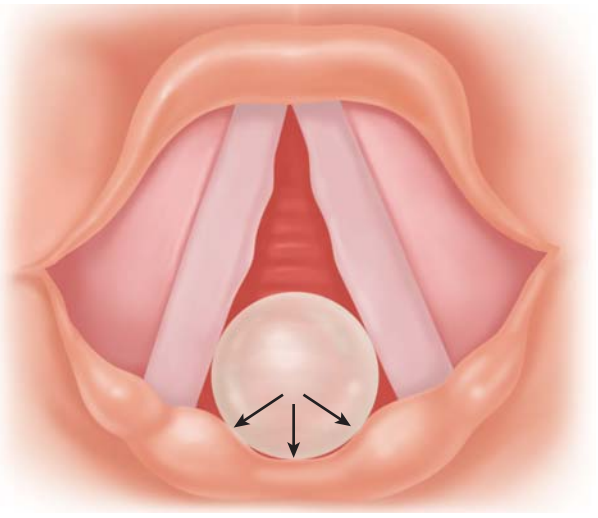

FIGURE 39-15 Schematic of an endotracheal tube (ETT) in the glottis, showing the circular shape of the ETT and the pentagonal shape of the glottis. The *arrows* indicate the points of maximum pressure on the posterior wall of the glottic opening. (This article was published in Semin Anesth, Vol. 9, Quartararo C, Bishop MJ. Complications of tracheal intubation: prevention and treatment, pages 19–27, Copyright © Elsevier.)

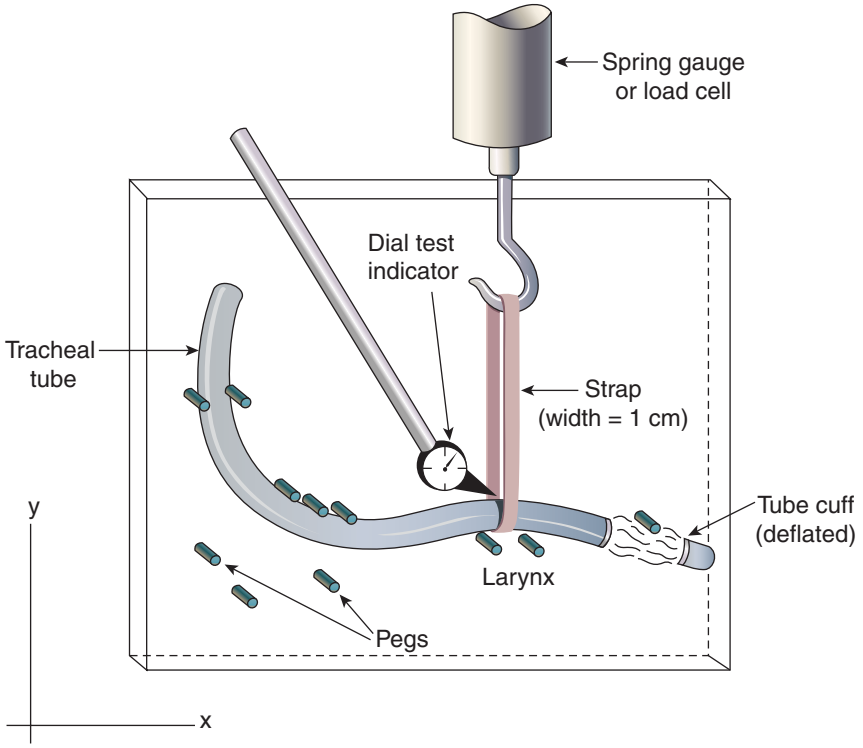

FIGURE 39-16 Method of estimating forces exerted on the posterior larynx by endotracheal tubes (ETTs). A pegboard is used to simulate the shape of the ETT in vivo. A gauge measures the force needed to barely lift the tube at the level of the larynx, thereby estimating pressure on the larynx. Modern polyvinyl chloride and silicone rubber tubes under simulated in vivo conditions exert forces on the larynx in the range of 162 to 265 g. (Modified, with permission, from Steen et al.[263])

The essential curvature of the ETT necessitates that force be directed posteriorly and laterally at the posterior glottic rim and cricoid ring.[253] Furthermore, the tongue muscles force the ETT posteriorly. Glottic pressure by the ETT has been estimated in both in vitro[263] (Fig. 39-16) and animal[264] studies to range as high as 200 to 400 mm Hg. In vitro studies of a variety of ETTs indicate that deforming forces from 230 to 1000 g are applied to the posterior laryngeal wall.[265] Pressure-induced ischemic injury of the posterior cricoid lamina and vocal processes of the arytenoids is accompanied by cricoid and arytenoid perichondritis and chondritis, which may heal with eventual fibrosis and scar contracture.[242]

Cricoarytenoid joint injury may occur while the ETT is in place but be recognized only after extubation. Postextubation symptoms of hoarseness and odynophagia along with the findings of malposition and no movement of the arytenoids suggest cricoarytenoid joint dysfunction. Paulsen et al reported that laxity of the cricoarytenoid joint capsule and large synovial folds are predisposing factors for cricoarytenoid joint trauma from TLI, including hemarthrosis.[266]

The cricoid ring, a completely circumferential ring that encircles the lower part of the larynx, is an important contact point with an ETT. Inflammation and edema of the laryngeal mucosa at the level of the cricoid ring narrow the airway lumen, making the subglottic area vulnerable to acute stenosis. Postextubation stridor is a manifestation of this phenomenon.[224] Experiments in dogs have demonstrated clearly that the posterior third of the cricoid cartilage is a major site of deep ulceration from pressure and abrasion by the ETT.[263] Ischemic necrosis in this area may be followed by bacterial invasion and abscess formation.[108] Simultaneous use of a nasogastric tube with an ETT could conceivably increase the risk of this complication.

Whited observed that the anterior wall of the trachea is a vulnerable site for tracheal injury from an ETT because of positioning of the cuff and tip of the tube.[261] Surprisingly few complications of TLI, however, are noted in the anterior wall of the trachea in these locations in the modern era of soft-cuff tubes.

ENDOTRACHEAL TUBE INFLUENCES

Physical Characteristics of an Endotracheal Tube. Technical standards for modern ETTs[267–269] establish the shape, size, and stiffness of an ETT, all of which influence TLI-induced airway injury. As previously discussed, the curved shape of an ETT invites pressure injury at the contact points with the airway, including the posterior larynx, cricoid cartilage, and tracheal cuff and tip sites.[130,270] The cross-sectional round shape of an ETT is also poorly suited for the shape of the glottis as noted above.[48,271] Large ETTs are more likely than small ones to cause pressure injury to the larynx[130,261,264] and the trachea. Large ETTs also cause more postextubation sore throat and hoarseness than do smaller tubes.[272] Modern

ETTs vary considerably in their stiffness and thermolability (ability to become less stiff at body temperature).[273]

Surface Characteristics. A slimy coating or *biofilm* may accumulate on the walls of the ETT during use, promoting the adherence of oral microorganisms and placing the patient at risk for VAP.[274,275] Use of silver-coated ETTs to suppress biofilm formation and bacterial colonization reduces the risk of VAP.[276]

Chemical Composition. The manufacture of modern ETTs follows strict guidelines set by Committee F29 on Anesthetic and Respiratory Equipment of the American Society for Testing and Materials.[267] Modern ETTs are composed of polyvinyl chloride, which is nontoxic, but chemical additives such as stabilizers, plasticizers, fillers, and pigments may incite inflammatory reactions in tissue.[268]

Cuff Characteristics. The value of cuffs on ETTs to seal the airway became apparent in the 1930s, but in the following decade investigators observed that high cuff inflation pressures could cause ischemia and sloughing of the tracheal mucosa.[277] Animal studies in the 1960s clarified the mechanisms of cuff-site tracheal injury,[148,278,279] and several groups of investigators described the critical role of high cuff inflation pressures in producing ischemic necrosis of the tracheal mucosa (see the section Clinical Influences in Tracheal Cuff-Site Injury/Cuff Pressure). Others later implicated high cuff inflation pressures in mucosal inflammation, tracheal dilation, destruction of tracheal cartilage leading to tracheal stenosis and tracheoesophageal fistula, and erosion of the tracheal mucosa and submucosa with loss of submucosal glands.[147] By the early 1970s, investigators established clearly that inflating the ETT cuff to pressures that exceeded tracheal capillary perfusion pressure could cause mucosal ischemia. Studies of the microcirculation of the rabbit trachea by Nordin et al revealed that the mucosa overlying the cartilaginous tracheal rings would become ischemic if hard cuffs were inflated to the point where lateral tracheal wall pressure exceeded 30 mm Hg.[257]

Besides intracuff pressures, other cuff characteristics may contribute to airway injury. Overlapping folds of cuff fabric may create channels that permit migration of fluid into the lung. This aspiration process is promoted by larger tubes, larger cuff diameters, stiffer cuff fabrics, and spontaneous breathing.[280] Bernhard et al demonstrated that modern ETTs display considerable variability in cuff characteristics such as diameter, thickness, compliance, shape, resting volume, and just-seal volume.[273,281] These various factors, as well as the size and shape of the trachea,[282] may affect the pressure–volume relationship of a given ETT cuff in vivo.[206,281]

CLINICAL INFLUENCES IN LARYNGEAL INJURY

Multiple factors may be important in the pathogenesis of laryngeal and tracheal cuff-site injury during TLI. Clinical investigation of the pathogenesis of airway injury from TLI has been complicated by difficulty in controlling these many factors while examining the effect of one variable on airway injury. Accordingly, the role of most of the specific clinical influences on laryngeal or tracheal injury discussed below remains unsettled.

Tube Size Relative to Laryngeal Size. The relationship of ETT size to laryngeal injury is controversial. Several prospective studies of critical care TLI have observed no relationship of laryngeal injury with ETT size.[19,52,283] Lindholm, however, concluded that large ETT size with respect to laryngeal size is an important determinant of laryngeal injury,[130] and Santos et al observed that laryngeal erythema, ulceration, and delayed true vocal cord immobility were related to ETT size.[139]

Laryngeal Abrasion. Abrasion of the laryngeal mucosa by movement at the interface between the ETT and the surface of the larynx would intuitively seem to be of great importance in the pathogenesis of laryngeal ulceration. This concept, however, has been difficult to prove. Some degree of abrasion of the laryngeal mucosa likely occurs whenever there is movement of the ETT or movement of the larynx. Breathing, swallowing, coughing, yawning, hiccupping, attempting phonation, and head and neck movements[206] are all plausible contributors to the abrasive action of the ETT on the laryngeal surface. ETT movement with cycling of the ventilator, suctioning the airway, and nursing care interventions may further contribute to mucosal abrasion.[126]

The role of laryngeal mucosal abrasion by movement of the ETT has been considered by a number of investigators.[19,52,126,129,130,283,284] The findings of El-Naggar et al suggested that friction between the ETT and laryngeal mucosa is an important factor in the pathogenesis of laryngeal injury.[129] Colice et al reported that the severity of laryngeal injury following extubation was significantly associated with neuromotor activity while the ETT was in place.[52] Patients with flaccid paralysis had milder degrees of injury.[52] Dunham and LaMonica found more laryngotracheal injury in patients with head and neck rigidity than in those with a nonrigid posture.[284]

Duration of Intubation. Since the early 1950s, clinicians and investigators have speculated, and often assumed, that duration of TLI is an important determinant of complications of TLI. This relationship obviously has an important influence on decisions about performing tracheotomy for long-term airway maintenance. It would seem obvious that a longer duration of TLI increases the risk of laryngeal (or tracheal) injury, but this relationship remains controversial because of conflicting data from a number of studies.

Early reports suggested that duration of TLI is important in the pathogenesis of laryngeal injury in critical care intubation.[131,285–287] Donnelly observed that the severity of histopathologic injury to the larynx at autopsy was related to the duration of TLI.[131] A retrospective study by Hedden et al came to the same conclusion.[285] Later observations by Whited[126,127] and by Supance et al[244] suggested that longer

periods of TLI increased the risk of laryngeal stenosis. Santos et al found significant relationships between duration of TLI and aspiration, laryngeal granulomas, and vocal cord immobility, but not laryngeal ulceration.[139] Two prospective studies reported a significant relationship between duration of TLI and postextubation stridor or requirement for reintubation.[225,288]

A number of prospective studies, however, have not been able to establish that duration of TLI is an important determinant of overall laryngeal injury.[19,35,52,128,138,283,284] Rashkin and Davis found no correlation between acute laryngotracheal injury and duration of TLI in sixty-one adult patients intubated for more than 3 days,[35] and Kastanos et al found no such relationship in nineteen patients intubated longer than 1 day.[128] In a prospective study of trauma patients, Dunham and LaMonica found no difference in laryngotracheal pathology between those patients undergoing early tracheotomy and those with 2 weeks of TLI.[284] Colice et al noted that serious laryngeal injuries could develop after only 1 to 3 days of TLI.[52] In fifty-four patients surviving after TLI, they found no relationship between the frequency of nonstenotic laryngeal complications and the duration of intubation.[52] Subsequently, Colice reported that prolonged TLI (>10 days) did not influence the rate of resolution of laryngeal injury.[138]

Some animal studies support the absence of a relationship between duration of TLI and laryngeal complications. Bishop et al[289] and Weymuller[290] reported that length of intubation was not related to the severity of laryngeal injury in dogs. In the dog model used by these investigators, TLI caused mucosal inflammation and erythema by 24 hours and loss of mucosal architecture within 1 week, but laryngeal damage remained relatively stable after 1 week.[289]

It can be concluded that studies in both animals and humans fail to provide convincing evidence of an association between duration of TLI and laryngeal complications. Most prospective clinical studies have not been able to prove that duration of TLI by itself is an important determinant of laryngeal injury.

Age. Clinical and autopsy findings in prospective studies suggest that age is not a significant determinant of overall laryngeal injury from TLI.[19,52,139]

Gender. The role of gender in laryngeal injury from TLI is unclear. Hedden et al reported in a retrospective study that laryngeal injury at autopsy following TLI was more severe in women than in men.[285] Postmortem observations in separate studies could not confirm this relationship.[19,131] Clinical studies have suggested that laryngeal stenosis following TLI is more common in women than in men.[242,270] Lindholm interpreted his observations to suggest that tube size relative to laryngeal size is an important determinant of laryngeal injury,[130] but Colice et al reported contrasting results.[52]

Hypotension. The pivotal role of laryngeal and tracheal capillary perfusion pressure in the pathogenesis of ETT-induced airway injury has led investigators to speculate that hypotension is an important risk factor for laryngeal injury during TLI. There are no convincing data, however, to support this concept.[52]

Route of Intubation. Two studies suggest that posterior laryngeal ulcers are more common with oral intubation than nasal intubation.[19,134] Possible reasons for this observation are that nasotracheal tubes are generally smaller than orotracheal tubes, they move less because they are stabilized by the walls of the nasal cavity, and they enter the glottis at a straighter angle of entry, thereby decreasing pressure on the posterior glottis. Another study, however, did not find less laryngeal injury with nasal intubation than oral intubation.[243]

Miscellaneous Factors. Underlying disease state, infection, corticosteroid therapy, head position, state of consciousness, gastric acid reflux, and many other factors have all been considered as possible determinants of laryngeal injury during TLI, but none of these factors have proven to have a contributing role. Several studies have suggested that laryngeal injury following TLI is more common in patients with diabetes mellitus.[143,270] Bacterial invasion of subglottic tissue injured by TLI may have a role in the pathogenesis of subglottic stenosis. In a rabbit model of subglottic ischemic injury from ETT cuff overinflation, Kil et al observed diffuse mucosal and submucosal inflammation, necrosis, and loss of surface epithelium.[291] Treatment with high-dose dexamethasone 1 hour before extubation and 6 hours after extubation had no effect on the histologic pattern of injury.

Posterior glottic stenosis may be more likely if TLI is followed by tracheotomy.[127,242] This association might occur because tracheotomy results in nonuse of the larynx, which might promote the formation of adhesions across ulcerated laryngeal surfaces.[242] Whited found a high statistical association between posterior laryngeal stenosis after TLI and subsequent tracheotomy, but cautioned that this might reflect selection bias rather than a true cause-and-effect relationship.[126,127] Colice et al also reported in their prospective study that the severity of laryngeal injury after TLI was associated with subsequent tracheotomy.[52]

In summary, it is likely that many factors contribute to laryngeal injury from TLI. Available data suggest that the mechanical force applied to the posterior larynx by the ETT is the most important risk factor for laryngeal injury. It is intuitive that abrasion of the laryngeal mucosa by movement at the interface with the ETT is an important risk factor, but supportive data are limited. Duration of TLI by itself has an uncertain role in the pathogenesis of laryngeal injury.

CLINICAL INFLUENCES IN LARYNGEAL GRANULOMA FORMATION

The prospective study of ninety-seven patients by Santos et al found significant associations between the early appearance of true vocal cord granulomas after extubation

and (a) duration of TLI, (b) subsequent tracheotomy, (c) use of a larger ETT in those patients who required tracheotomy, and (d) use of a nasogastric tube.[139] The delayed appearance of true vocal cord granulomas 2 to 10 weeks after extubation was significantly associated with subsequent tracheotomy and with use of a nasogastric tube. Lindholm also found a positive correlation between ETT diameter and the subsequent development of laryngeal granulomas.[130]

CLINICAL INFLUENCES IN TRACHEAL CUFF-SITE INJURY

Cuff Pressure. The important role of high cuff inflation pressures in the pathogenesis of tracheal cuff-site injury is now well established, based on studies of both TLI and tracheotomy.[148–150,254,256,258,260,278,279,292–296] The pioneering studies of Cooper and Grillo,[148,278,279] Grillo et al,[149] Ching and Nealon,[292] Ching et al,[293] and Nordin et al[257,259,294] established conclusively in both animal models and in humans that hard cuffs were more injurious to the tracheal mucosa than soft cuffs. These observations were confirmed by other investigators.[254,256,260] Figure 39-17 shows the critical role of cuff pressure in causing tracheal cuff-site injury in animal experiments performed by Cooper and Grillo.[148]

Intracuff pressure is transmitted laterally against the wall of the trachea (see Fig. 39-14). The intracuff pressure exceeds the pressure exerted against the tracheal wall (the lateral tracheal wall pressure) by a small amount in soft cuffs and by a greater amount in hard cuffs. Ischemia and eventual necrosis occur when the lateral tracheal wall pressure exceeds the capillary perfusion pressure of about 25 mm Hg,[258–260,294,295] as illustrated in Figure 39-18. Ischemia of the tracheal mucosa occurs in rabbits when the cuff inflation pressure exceeds 30 mm Hg.[257] Necrosis of the tracheal mucosa leads to sloughing and ulceration of the mucous membrane, exposing tracheal cartilage. Continued ischemia may be followed by partial or complete destruction of cartilaginous tracheal rings and loss of the structural integrity of the affected tracheal segment, leading to tracheal dilation (see Fig. 39-14).[153,154] Healing of the injured tracheal segment during any stage of this process may lead to a tight fibrous stricture (tracheal stenosis).

Modern soft-cuff ETTs transmit intracuff pressure to the tracheal wall, but not to the extent that hard-cuff ETTs do. Overinflation of soft cuffs, however, may cause high lateral tracheal wall pressures to develop, even to the point at which capillary perfusion pressure is exceeded.[258] In the clinical setting, it is important to note that variations in ETT cuff pressure are commonly observed after the ETT pressure is set to a safe level, so high pressures may develop periodically.[297] The amount of lateral tracheal wall pressure appears to be more important than the duration of intubation in producing tracheal damage.[259,296]

Cuff Design and Shape. The geometric shape of the cuff relative to the shape of the tracheal lumen has been implicated in tracheal cuff-site damage.[293,298] Asymmetric inflation of cuffs, leading to focal tracheal mucosal injury, was occasionally reported when hard-cuff ETTs were used, but with soft-cuff tubes that inflate evenly, this phenomenon is no longer observed. Because modern soft-cuff tubes do have quite variable physical characteristics, including inflation diameter, fabric thickness, compliance, and geometric shape,

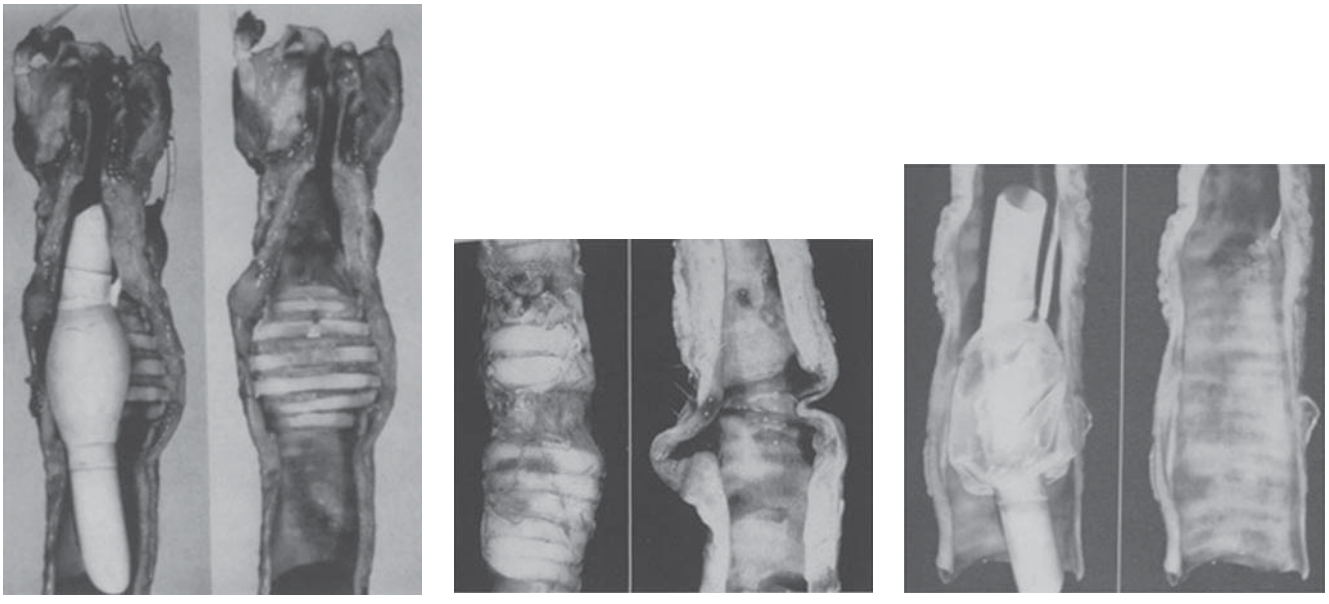

FIGURE 39-17 An experiment in dogs indicated the critical role of high cuff-inflation pressure in causing severe tracheal cuff-site injury. Shown here are severe tracheal ulceration with exposed tracheal cartilage (*left*) and tracheomalacia (*center*) from prolonged intubation with endotracheal tubes (ETTs) with low-volume, high-pressure cuffs. The panel on the *right* shows a normal tracheal surface after prolonged intubation with an ETT with a high-volume, low-pressure cuff. (Modified, with permission, from Cooper and Grillo.[148])

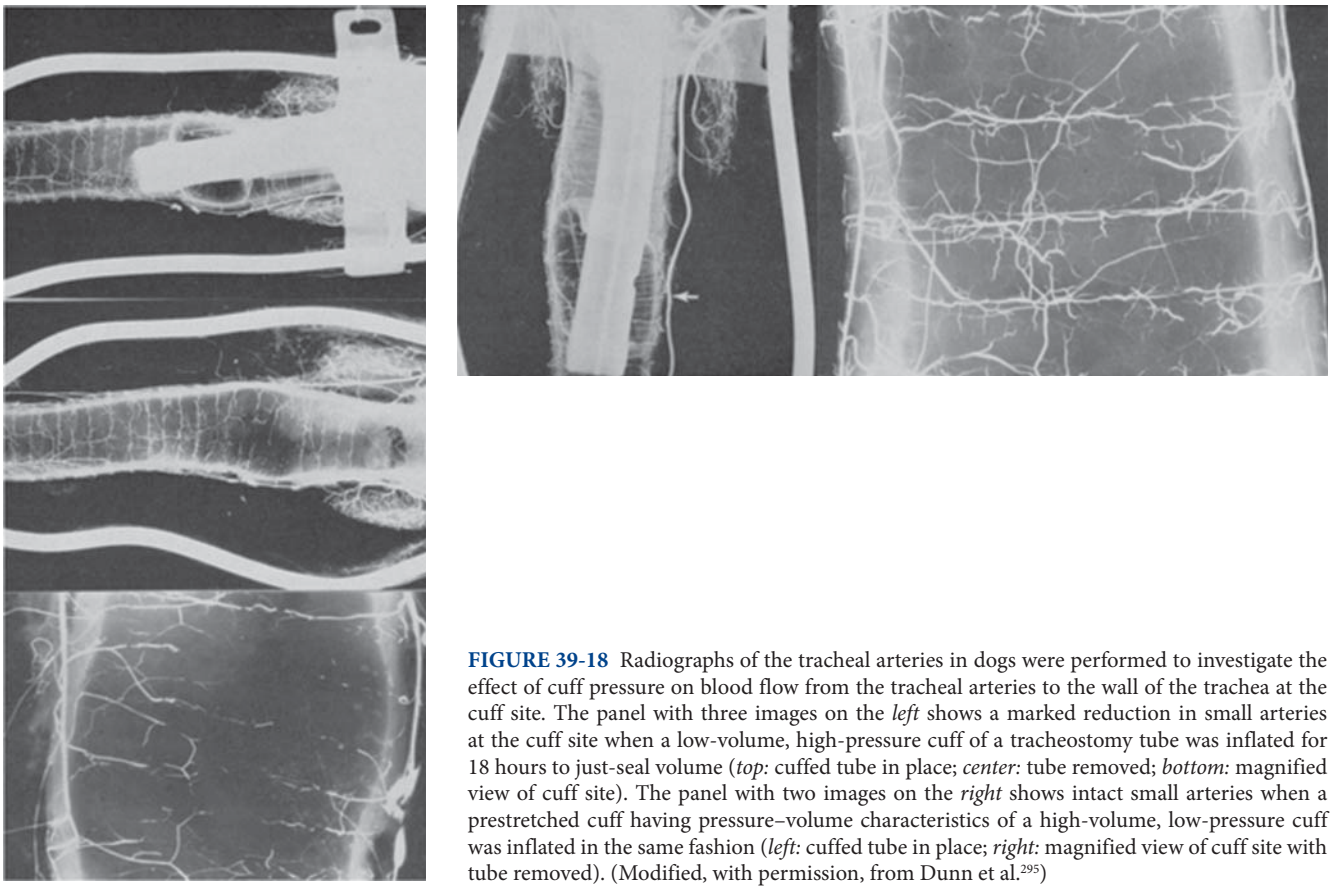

FIGURE 39-18 Radiographs of the tracheal arteries in dogs were performed to investigate the effect of cuff pressure on blood flow from the tracheal arteries to the wall of the trachea at the cuff site. The panel with three images on the *left* shows a marked reduction in small arteries at the cuff site when a low-volume, high-pressure cuff of a tracheostomy tube was inflated for 18 hours to just-seal volume (*top:* cuffed tube in place; *center:* tube removed; *bottom:* magnified view of cuff site). The panel with two images on the *right* shows intact small arteries when a prestretched cuff having pressure–volume characteristics of a high-volume, low-pressure cuff was inflated in the same fashion (*left:* cuffed tube in place; *right:* magnified view of cuff site with tube removed). (Modified, with permission, from Dunn et al.[295])

all are not the same in their pressure–volume relationship and potential for mucosal injury.[254,273,281]

Age. Prospective studies that have examined the influence of age on tracheal cuff-site injury have not found a conclusive relationship.[19,128,129]

Gender. The role of gender in cuff-site tracheal injury from TLI is controversial, as prospective studies have found conflicting results.[19,128,129]

Duration of Translaryngeal Intubation. The relationship between duration of TLI and tracheal cuff-site injury is controversial, probably because observational clinical studies have not been able to control for confounding variables such as cuff pressure, tube movement, and ETT size. We found no statistical association between tracheal cuff-site injury at autopsy and duration of TLI or duration of TLI and tracheotomy together.[19] Other studies have also failed to find a significant relationship between duration of tracheotomy and cuff-site injury.[129,299,300] Only one prospective study found that tracheal cuff-site injury was significantly associated with the duration of TLI.[128]

Hypotension. Few studies have examined the relationship between hypotension and tracheal cuff-site injury in humans. We found no relationship between hypotension and tracheal cuff-site injury at autopsy.[19] In an experimental study of dogs with cuffed tracheostomy tubes, Dunn et al found that intercurrent periods of hypotension did not affect the extent of tracheal injury from tracheostomy tube cuffs.[295]

Corticosteroid Therapy. Two prospective studies reported no association between corticosteroid therapy and tracheal cuff-site injury from TLI.[19,128]

Airway Infection. Nordin reported that bacterial invasion of tracheal mucosa damaged by high cuff inflation pressures begins to occur about 4 hours after the onset of cuff inflation.[259] There is, however, no convincing evidence from clinical or experimental studies that airway infection increases the risk of cuff-site complications.[129,278]

Miscellaneous Factors. Kastanos found a statistically significant association between tracheal injury from TLI and the use of positive end-expiratory pressure.[128] Excessive motion between the inflated cuff and the trachea was implicated in tracheal injury by the studies of Lindholm.[130]

Siobal et al reported a case of tracheoinnominate artery fistula in a burn patient who was intubated for 40 days with an 8-mm internal diameter ETT, which was equipped with a subglottic suction port and held in position by a wire suture

to a molar tooth.[165] Erosion of the left anterior wall of the trachea by the tube tip was attributed to the prolonged period of intubation, fixed position of the tube, and decreased flexibility of the tube as a result of the suction channel feature.

CLINICAL INFLUENCES IN PULMONARY COMPLICATIONS

Pneumonia and Tracheobronchitis. This topic is discussed in Chapter 46. Myriad factors predispose to VAP and ventilator-associated tracheobronchitis while an ETT is in place,[177,179,180,190,301] including the underlying disease(s); impaired host defenses; antibiotic exposure; aspiration; enteral feeding tubes; sinusitis; impaired mucociliary function; ineffective cough; respiratory equipment; hospital transport out of the ICU; ETT biofilm; and increased binding of bacteria to the tracheobronchial epithelium. During intubation, the lower airways of ICU patients are heavily colonized with a variety of organisms. Those isolated most frequently as pathogens in VAP are aerobic gram-negative bacilli (especially *P. aeruginosa, Enterobacteriaceae,* and *Acinetobacter* species) and *S. aureus.*[190] Polymicrobial infections in VAP are common. Anaerobic organisms may also be isolated in cultures of lower respiratory tract secretions in patients with VAP,[302] but their significance in the pathophysiology of VAP remains controversial.[303]

An indwelling ETT is by itself a risk factor for VAP and ventilator-associated tracheobronchitis, because it is a foreign body and it bypasses protective upper airway defenses. Aspiration of contaminated upper airway secretions and leakage of bacteria-laden fluid that pools above the inflated ETT cuff are important mechanisms of entry of pathogens into the lung.[177,304,305] The ETT biofilm also serves as a reservoir for microorganisms, increasing the risk for VAP and ventilator-associated tracheobronchitis.[274,306] Reintubation may be a separate important risk factor for VAP.[307]

Aspiration. Aspiration of gastric and upper airway secretions into the lower airway while an ETT is in place may occur for a variety of reasons.[189] TLI per se invites aspiration of secretions because of stenting of the larynx in an open position, prevention of glottic closure, esophageal compression by the inflated cuff, pooling of secretions above the cuff, creation of channels along folds of cuff fabric,[280] and desensitization of protective upper airway reflexes. Elpern et al, in a prospective study of aspiration in intubated adults, observed that cuff inflation to occlusion does not prevent aspiration, nor does a head-up position in bed.[189] They also noted that nasogastric tubes increased the risk of aspiration, whereas level of consciousness and feeding status did not.

Complications During and After Extubation

In a prospective study of critically ill adults, Jaber et al found that postextubation stridor was associated with traumatic or difficult intubation, prior self-extubation, and increased cuff pressure at the time of ICU admission.[225] They also observed that postextubation stridor increased with duration of TLI,[225] a finding that was also observed by Tadie et al.[221] Efferen and Elsakr reported that postextubation stridor was associated with cuff pressure, corticosteroid therapy at the time of extubation, and a neurologic disorder necessitating TLI.[226] Megarbane et al observed that female gender and intubation time were predictive of postextubation laryngeal injuries in acutely poisoned patients.[220]

The pathogenesis of laryngeal and tracheal stenosis following TLI is related to the healing process of airway injury incurred during TLI. Why some ulcerative lesions heal normally, others with granuloma formation, and others with cicatrix or scar formation is obscure. Table 39-9 summarizes important or potentially important mechanisms of laryngotracheal injury from TLI.

TABLE 39-9: IMPORTANT MECHANISMS OF LARYNGOTRACHEAL INJURY FROM TRANSLARYNGEAL INTUBATION

- Laryngeal ulceration
  - High pressure on the posterior endolarynx
    - Curvature of the endotracheal tube (ETT)
    - Round shape of the ETT
    - Stiffness of the ETT
  - Abrasion (excessive movement at the tube-mucosa interface)
  - Large diameter of the ETT
  - Female gender
  - Oral route of intubation
- Laryngeal granuloma formation
  - Laryngeal ulceration
  - Nasogastric tube
  - Large diameter of the ETT
  - Increasing age
- Laryngeal stenosis
  - Laryngeal ulceration
  - Subsequent tracheotomy
    - Laryngeal inactivity
    - Bacterial invasion
- Tracheal cuff-site ulceration
  - High lateral tracheal wall pressure

IMPORTANT PROSPECTIVE STUDIES OF COMPLICATIONS OF TRANSLARYNGEAL INTUBATION

Because the literature on complications of artificial airways is largely based on retrospective and anecdotal observations, study of this topic is especially prone to potential bias and faulty conclusions. Few techniques of airway management satisfy the criteria of evidence-based medicine. Fortunately, however, a growing number of prospective studies of complications of TLI, tracheotomy, or both

are now available. Large prospective studies of complications of TLI are difficult to perform but they do provide valuable insights.

A growing number of studies comparing complications of TLI with those of tracheotomy or complications of delayed versus early tracheotomy have employed a randomized design.[129,284,308–313] Prospective studies attempting to randomize patients to early tracheotomy have been difficult to perform. Only a few prospective studies have attempted to directly compare complications of TLI alone with those of tracheotomy.[19,129,130,284] A growing number of prospective studies have evaluated airway complications of early versus delayed tracheotomy,[308,309,311–315] but the complications that can be attributed to TLI alone in these studies are difficult to assess.

Rumbak et al randomized 120 adult medical ICU patients to early percutaneous tracheotomy within 48 hours or delayed tracheotomy after 10 to 14 days of TLI.[309] The early tracheotomy group experienced significantly lower mortality, less-frequent pneumonia, fewer days in the ICU, fewer days of mechanical ventilation, and fewer days of sedation. Sugerman et al, however, using a similar study design, found no significant differences between the early and the delayed tracheotomy groups with regard to mortality rate, days in the ICU, or frequency of pneumonia.[308] This section reviews selected prospective clinical studies of laryngeal or tracheal complications of TLI in adults (Table 39-10).

Lindholm's study represents the most comprehensive study of complications of TLI ever performed.[130] He investigated 457 patients for acute and late complications of intubation. Very few late, severe complications and no deaths were attributed to TLI. Large ETT size, ETT stiffness, and excessive laryngeal motion were identified as important risk factors for laryngeal injury. Because, however, the patients were intubated in large part with red rubber and latex tubes with hard cuffs, and the duration of intubation was less than 3 days, the results of the study are not entirely applicable to modern critical care.

TABLE 39-10: SELECTED PROSPECTIVE STUDIES OF COMPLICATIONS OF TRANSLARYNGEAL INTUBATION

Year	References	No. of Patients
1969	Lindholm[130]	457
1981	Stauffer et al[19]	150
1984	Whited[127]	200
1989	Colice et al[52]	82
1994	Santos et al[139]	97
1995	Schwartz et al[70]	238
2004	Bouderka et al[310]	62
2006	Jaber et al[20]	220
2007	Benedetto et al[317]	150
2008	Griesdale et al[21]	136

Stauffer et al compared complications of TLI with those of tracheotomy in 150 critically ill adults in two large teaching hospitals.[19] Survivors were studied for late complications and nonsurvivors were evaluated at autopsy. An attempt to randomize patients into early tracheotomy and prolonged TLI groups was only partially successful. Approximately two-thirds of TLI and two-thirds of tracheotomies had one or more complications, but the complications were judged to be more severe in the tracheotomy group. Laryngotracheal injury at autopsy did not correlate with the duration of TLI. A few patients appeared to tolerate TLI well for up to 3 weeks.

Whited described his personal experience as an otolaryngologist–head and neck surgeon with 200 patients from the critical care units of two teaching hospitals who had TLI from 2 to 24 days.[127] Mirror or fiber-optic laryngoscopy tracheoscopy was performed at extubation and serially thereafter. Fifty survivors (group I) had TLI for 2 to 5 days, 100 (group II) had TLI for 6 to 10 days, and fifty (group III) had TLI for 11 to 24 days. The severity of posterior laryngotracheal injury appeared to increase with the duration of TLI, but statistical analysis was not provided. Chronic posterior commissure stenosis progressing inferiorly to the level of the cricoid ring and into the trachea occurred in 14% of group III patients. Chronic stenosis was more common in patients with TLI followed by tracheotomy than in those with TLI alone. Other variables that might have affected the outcome were not described. The author concluded that TLI for less than 7 days is safe and that TLI beyond 10 days is unacceptable as a routine policy.

Colice et al examined eighty-two adult patients intubated more than 4 days for laryngeal complications of TLI using direct fiber-optic laryngoscopy and careful follow-up.[52] Nonlaryngeal complications were not evaluated. Ulceration and edema of the posteromedial aspects of the vocal cords were observed in 94% of the patients at extubation. Neuromotor activity and performance of a tracheotomy, but not duration of TLI, were associated with increased laryngeal complications. Initial findings at laryngoscopy did not predict the late development of adverse effects.

Santos et al reported risk factors for laryngeal injury from prolonged TLI in critically ill adult men in an initial report in 1989,[316] and updated their findings with a second report in 1994.[139] The latter study described prospective observations in ninety-seven adult men with orotracheal TLI (mean duration: 9 days). Postextubation endoscopic findings in seventy-nine survivors included laryngeal erythema (94%), laryngeal ulceration (76% with resolution within 6 weeks), and laryngeal granulomas (44%). True vocal cord immobility was seen in sixteen (20%) patients and was delayed in onset in half the cases. Duration of TLI was significantly associated with true vocal cord granuloma formation and early and delayed true vocal cord immobility but not with true vocal cord ulceration. The use of a larger ETT (size 8.0-mm internal diameter as compared with size 7.5 mm) was significantly associated with true vocal cord

erythema, ulceration, granuloma formation, and delayed immobility. None of sixty-two patients with TLI alone developed laryngotracheal stenosis.

Schwartz et al prospectively studied 297 consecutive TLIs in 238 critically ill adults in medical and surgical critical care units of a large teaching hospital so as to assess immediate complications of TLI.[70] The most common indications for TLI were respiratory failure (50%), airway protection (17%), ETT change (13%), and cardiac and/or respiratory arrest (10%). Eleven percent of TLIs required three or more attempts at ETT placement. Eight percent were classified as difficult, but none of these were associated with adverse outcomes. Esophageal intubation occurred during twenty-five (8%) of the 297 intubation procedures and was not accompanied by any adverse sequelae. A new infiltrate on the postintubation chest radiograph was observed in 8% of cases, and in half of these (4%) aspiration was suspected as the cause.

Bouderka et al reported results of a prospective, randomized trial of early tracheotomy (days 5 to 6) versus prolonged TLI in sixty-two adults with severe head injury.[310] The two groups were similar in terms of age, gender, and simplified acute physiology score. Clinical symptoms of laryngotracheal complications did not differ between the two groups, but routine endoscopy to evaluate patients for these complications was unfortunately not performed. The early tracheotomy group experienced fewer days of mechanical ventilation both overall and after pneumonia was diagnosed. No differences in ICU stay, frequency of pneumonia, or mortality were observed.

Jaber et al prospectively evaluated immediate complications of 253 intubations in 220 patients in seven ICUs of two teaching hospitals.[20] Seventy-one (28%) of the intubations generated one or more severe complications, including severe hypoxemia (26%), hemodynamic collapse (25%), and cardiac arrest (2%). The presence of acute respiratory failure and shock were independent risk factors for intubation complications, and resident supervision in intubation reduced the risk of complications.

Benedetto et al performed a prospective observational study of urgent TLI in 150 patients in general hospital units at the Massachusetts General Hospital.[317] The overall rate of complications of emergent TLI was 27%, compared with a rate of 22% in elective TLIs. The most common complications observed were multiple (three or more) attempts at TLI and esophageal intubation, both occurring in 9% of cases. These event rates were strikingly similar to those observed by Schwartz et al[70] in another large teaching institution (11% for multiple attempts at TLI and 8% for esophageal intubation).

Griesdale et al examined early TLI complications in 136 patients in a prospective study in a single Canadian teaching hospital ICU.[21] Nearly all intubations were supervised, but 39% generated one or more complications. Like Jaber et al,[20] Griesdale and coworkers observed that severe hypoxemia and hypotension were the most common severe complications of TLI. All intubations were successful, but 13.2% required three or more attempts.

RECOGNITION AND MANAGEMENT OF COMPLICATIONS OF TRANSLARYNGEAL INTUBATION

Recognition of Selected Complications

COMPLICATIONS DURING ENDOTRACHEAL TUBE PLACEMENT

Right Main-Stem Bronchus Intubation. The classic physical examination findings of a patient with right main-stem bronchus intubation (see Fig. 39-3) are greater intensity of breath sounds and expansion of the right hemithorax compared with the left. Right main-stem intubation, however, may be difficult to recognize in many patients, especially those with emphysema, because of distant breath sounds on auscultation and chest hyperinflation.[318] Schwartz et al observed that neither physical examination nor referencing the centimeter markings on the ETT shaft indicated malpositioning of the ETT after emergency TLI.[63] Women are at greater risk than men for malpositioning of the ETT in critical care intubations.[63] Right main-stem bronchus intubation may lead to early hypoxemia and cyanosis, particularly if the patient has underlying lung disease.

Esophageal Intubation. Inadvertent intubation of the esophagus should be recognized immediately by capnography (see the section Prevention of Complications of Translaryngeal Intubation/Complications During Endotracheal Tube Placement/Avoiding Esophageal Intubation, and Chapter 38), although this method is not foolproof. Esophageal intubation may be recognized when manual ventilation after intubation produces poor chest expansion and gurgling sounds on auscultation over the stomach. In some cases, esophageal intubation may be very difficult to detect on physical examination. The patient with an ETT placed in the esophagus may display some degree of chest expansion, and "pseudo" breath sounds may be auscultated as gas enters the stomach. Esophageal intubation should be recognized before a postintubation chest radiograph is obtained. If a radiograph is obtained, however, it may reveal displacement of the ETT slightly away from the tracheal air column. Caution is necessary, however, because slight rotation of the patient may superimpose the tracheal air column over the ETT positioned in the esophagus.

COMPLICATIONS WHILE THE ENDOTRACHEAL TUBE IS IN PLACE

Sinusitis and Otitis. A high index of suspicion is critical to establishing the diagnosis of TLI-associated sinusitis and initiating effective therapy. Sinusitis may present as sinus pain and tenderness, or purulent nasal sinus drainage in an intubated patient, but it is important to emphasize that these findings may be minimal or absent. Sinusitis complicating nasotracheal intubation or use of nasogastric tubes typically

presents with fever, or in some patients, with bacteremia and sepsis syndrome.

Most reports have emphasized the value of CT scanning for accurate diagnosis of intubation-associated sinusitis, because physical examination is generally unreliable and standard sinus radiographs often fail to establish the diagnosis, especially when there is involvement of the ethmoid or sphenoid sinuses.[319] Radiographic maxillary sinusitis is defined as the presence on CT scanning of an air-fluid level or opacification of the maxillary sinus. Opacification of the other sinuses is common in intubated patients. Otitis is detected by routine otoscopic examination, which should also be performed in evaluation of fever of unknown origin in the intubated patient.

Nasal and Oral Injury. Nasal and oral complications during TLI are recognized by daily careful examination of the nose and mouth.

Laryngeal Injury. Recognition of laryngeal injury during TLI is rarely successful, because the ETT hides the injured areas from observation. Posterior ulceration of the larynx is hidden from view during fiber-optic endoscopy unless the ETT is removed, which is dangerous and impractical. Supraglottic and glottic edema is sometimes assessed by direct or indirect laryngoscopy during TLI. There are conflicting reports about the value of laryngoscopy in assessing laryngeal injury during TLI.[140,143] Routine endoscopy of the pharynx and larynx during TLI is not currently advised. Furthermore, endoscopic findings in the larynx during TLI do not clearly guide the timing of tracheotomy or predict long-term laryngeal sequelae of TLI.[52,246]

Tracheal Injury. Tracheal cuff-site injury cannot be detected during TLI unless fiber-optic bronchoscopy is performed while the ETT is retracted upward. This practice has no proven value, however, and is not indicated in decision making about extubation or conversion to tracheotomy. When the ratio of cuff-site diameter to tracheal transverse diameter on a chest radiograph exceeds 1.5, severe damage to the tracheal wall is present.[152] Eighteen (13.5%) of 135 intubated adult patients developed this complication as a result of cartilaginous destruction, and those who survived eventually developed tracheal stenosis or tracheoesophageal fistula.[152] Therefore, patients in whom tracheal dilation develops during TLI should be followed closely for months because of the potential for tracheal stenosis.

COMPLICATIONS DURING AND AFTER EXTUBATION

Laryngeal Injury. Persistent hoarseness, stridor, or dyspnea after extubation should always raise the question of serious laryngeal complications of TLI, including granuloma formation, laryngeal muscle paresis or paralysis, severe ulceration, laryngeal stenosis, cricoarytenoid ankylosis, or synechia formation.[125,130,242] The physician should also be aware that dyspnea, hoarseness, and stridor appearing weeks to months after extubation may indicate serious laryngeal (or tracheal) stenosis and should not be dismissed as simply being related to the underlying lung disease.[240] Glottic or subglottic stenosis may take weeks or months to develop after seemingly uneventful TLI and extubation.

The evaluation of patients with suspected serious laryngeal injury after TLI should include physical examination and laryngoscopy. Physical examination may reveal prolonged inspiratory phase, harsh tracheal sounds and palpable thrill over the larynx on inspiration, and inspiratory intercostal retractions. Upper airway stridor transmitted to the thorax should not be misinterpreted as a sign of bronchoconstriction.

Laryngoscopy is necessary in all cases. Vocal cord movement may be evaluated initially by mirror laryngoscopy. If any abnormalities are detected, direct laryngoscopy should be performed. The finding of bilateral vocal cord abduction could be related to cricoarytenoid arthritis or recurrent laryngeal nerve injury.[242] Recurrent laryngeal nerve injury is suggested by absence of vocal cord motion, while in posterior glottic stenosis there is some motion of the cords on inspiration and phonation.[242] Glottic synechiae and laryngeal granulomas are usually readily apparent at the time of direct laryngoscopy.

Imaging the larynx is very helpful in the diagnosis of TLI-induced laryngeal injury. Older imaging techniques such as soft-tissue radiographs and linear tomography have been replaced by CT scanning with multiplanar reconstruction capability to create axial, coronal, and sagittal reformatted images.[320] Magnetic resonance imaging plays a lesser role than CT imaging. Radiographic studies and fiber-optic laryngoscopy are more sensitive than the history and physical examination in detecting laryngeal injury from TLI.

The maximal expiratory-to-inspiratory flow–volume loop is sometimes performed in the evaluation of patients with suspected laryngeal (or tracheal) injury from TLI. The classic feature of unilateral vocal cord paralysis on a flow–volume loop is attenuation of inspiratory flow rates. The classic feature of bilateral vocal cord paralysis or laryngeal (or tracheal) fixed stenosis is attenuation of both inspiratory and expiratory flow rates with a "boxed-off" appearance to the flow–volume loop (see Fig. 39-13A). Classic patterns of these types of injury are not always seen, however, because the flow–volume loop is neither sensitive nor specific. A completely normal flow–volume loop, on the other hand, makes functionally significant laryngeal (or tracheal) disease unlikely.

Tracheal Stenosis. Symptomatic tracheal stenosis after extubation is very uncommon in the modern era of soft-cuff ETTs. Like laryngeal stenosis, tracheal stenosis may not become apparent for weeks, months, or even years after extubation. [321] Typical symptoms of tracheal stenosis include progressive dyspnea on exertion, cough, difficulty clearing sputum, and in some cases, stridor. Unfortunately, these findings are commonly attributed to underlying disorders such as bronchitis, asthma, chronic obstructive pulmonary disease, or resolving acute respiratory distress syndrome.[240]

The diagnosis of tracheal stenosis requires a high degree of clinical suspicion based on a history of TLI (or tracheotomy) weeks to months earlier. Initial symptoms of cough, hoarseness, and difficulty clearing lower airway secretions are followed by dyspnea and stridor. Stridor and progressive respiratory distress, however, may not occur until the tracheal diameter is reduced to approximately 5 mm or less in adults.[247] Physical examination may be normal in patients with mild to moderate degrees of tracheal stenosis. In severe cases, stridor is the key finding. Flow–volume loops demonstrate fixed airway obstruction if there is a tight fibrous ring at the stenotic segment (see Fig. 39-13A). A 50% reduction in tracheal caliber (<8-mm diameter), however, may be needed in order to produce an abnormal flow–volume relationship.[322]

Confirmation of the diagnosis of tracheal stenosis is possible with multidetector CT scanning, including axial imaging, multiplanar reconstruction, and creation of "virtual bronchoscopy" images, all of which are highly accurate in comparison with fiber-optic bronchoscopy.[251,323] Multislice three-dimensional CT imaging offers remarkably clear images of tracheal stenosis.[324] Fiber-optic or rigid bronchoscopy may be employed in some cases.

Management of Selected Complications

COMPLICATIONS WHILE THE ENDOTRACHEAL TUBE IS IN PLACE

Sinusitis. Effective management of sinusitis during TLI requires early recognition, appropriate radiographic studies (see "Complications During and After Extubation" above), and culture and sensitivity of aspirated sinus fluid. Nasotracheal and nasogastric tubes should be removed. Consultation with an otolaryngologist–head and neck surgeon is advised. Aspiration of maxillary sinus fluid yields fluid for Gram stain and cultures for bacteria (aerobic and anaerobic) and fungi, allowing selection of appropriate antimicrobial therapy. Repeated aspiration may be necessary in some patients. Sinus irrigation or lavage via an indwelling catheter is sometimes required. Treatment with nasal decongestants for short periods is commonly employed.

COMPLICATIONS DURING AND AFTER EXTUBATION

Laryngeal Complications. Laryngeal edema from mucosal trauma by the ETT may cause stridor, which appears minutes to several hours following extubation. Kriner et al prospectively observed that twenty (4.3%) of 462 patients who were intubated for more than 24 hours developed postextubation stridor.[325] Female gender, longer duration of TLI, and larger ratio of ETT diameter to laryngeal size were risk factors for postextubation stridor in this series. Fundamental elements of management of postextubation stridor include supplemental oxygen, close monitoring of vital signs and oxygen saturation, removal of secretions from the upper airway, and positioning the head and neck to maintain airway patency. The patient should be reassured and anxiety managed appropriately. Because most cases of postextubation stridor are caused by laryngeal edema, management should be directed with this in mind. Parenteral corticosteroids, aerosolized epinephrine, and inhalation of a helium–oxygen gas mixture are the mainstays of empiric therapy.[144] Helium–oxygen gas mixtures may help reduce the patient's work of breathing. Helium–oxygen mixtures with more than 40% oxygen are generally ineffective. Reintubation is commonly required if the above measures are not successful. Kriner et al noted that seven (35%) of twenty patients with postextubation stridor required reintubation.[325]

Helium–oxygen therapy has also been described for temporary relief of increased work of breathing in patients with bilateral vocal cord dysfunction complicating TLI.[230] Prevention of recurrent postextubation stridor is discussed (see the section Prevention of Complications of Translaryngeal Intubation/Complications During and After Extubation/Avoiding Stridor).

The cuff-leak test is valuable in planning for extubation, because little or no leak around the deflated cuff helps to predict the presence of laryngeal edema and postextubation stridor.[326] Jaber et al observed that a cuff-leak volume of less than 130 mL (or less than 12% of tidal volume set at 10 to 12 mL/kg) was useful in identifying critically ill adult patients at risk for stridor after extubation.[225] Others have reported that cuff leaks of less than 10%[288] or 15.5%[327] of tidal volume help to identify patients at risk for reintubation from laryngeal edema. Chung et al reported the sensitivity and specificity of the cuff-leak test to be 88.6% and 90.0%, respectively.[223] Recent reports indicate that the negative predictive value of the cuff-leak test (air leak is observed) is 96% to 97%, while the positive predictive value (air leak is not observed) ranges from 12% to 25%.[325,328,329]

As stated earlier, limited motion of the vocal cords long after extubation reflects posterior glottic fibrosis or ankylosis of the cricoarytenoid joint.[106] The goal of management is restoration of the voice, prevention of aspiration, and provision of adequate airflow. Management by an experienced otolaryngologist–head and neck surgeon is essential. Surgical and nonsurgical techniques to improve laryngeal function in patients with vocal cord paresis/paralysis are available.[106,330–332] Patients with bilateral vocal cord paralysis may require emergent tracheotomy.[106]

Treatments for laryngeal granulomas (see Figs. 39-9B and C and 39-12) are directed at their causes, which include vocal abuse and gastroesophageal reflux disease as well as TLI. Granulomas from TLI are often managed with fiber-optic laryngeal surgery[333] or surgical resection with very good results. Other therapeutic approaches for laryngeal granulomas have been described, including inhaled corticosteroids,[334] injection of corticosteroids,[106] injection of botulinum toxin,[335] and radiation.[336] Wang et al, however, observed that vocal process granulomas, regardless of etiology, may completely resolve without steroid treatment and spontaneously achieve complete remission in more than 80% of cases without excision or other intervention.[337]

Laryngeal stenosis requires surgical intervention. Surgical options depend upon the location of the stenotic lesion and include laser therapy,[338] dilation procedures, stenting, laryngofissure, resection,[339,340] keel insertion, and other reconstructive procedures.[341,342] Posterior commissure scarring is difficult to treat surgically.[238,242] Repeated surgical operations for laryngeal stenosis may be required. In many cases, permanent tracheostomy is necessary. Czigner et al treated twenty-nine patients with subglottic stenosis, which was related to TLI or tracheotomy in most cases, with resection of the stenotic segment and end-to-end anastomosis, achieving a success rate of 96%.[343] Pena et al reported very similar results.[341]

Tracheal Complications. Tracheal granulomas are managed by endoscopic removal. Small granulomas may resolve spontaneously. Management of tracheal stenosis depends upon its severity. Patients with mild degrees of tracheal stenosis (arbitrarily defined as <25% reduction in airway diameter) and no symptoms require only periodic follow-up to look for progressive stenosis. Those with greater degrees of airway narrowing and symptoms require more aggressive management. In severe cases with 50% to 75% narrowing of the trachea, emergent medical and surgical intervention is necessary.

Surgical options in patients with severe tracheal stenosis include dilation procedures,[344,345] stent placement, electrocautery, laser photoablation,[338] and resection of the stenotic segment with reanastomosis.[248,346,347] Tracheal reconstruction for tracheal stenosis is usually successful. Grillo and Donahue reported good or satisfactory results with surgery in 94% of 503 patients with postintubation tracheal stenosis.[347]

PREVENTION OF COMPLICATIONS OF TRANSLARYNGEAL INTUBATION

Most of the complications of TLI are preventable. Skilled intubation technique, seasoned clinical judgment, and meticulous care and monitoring of the intubated patient are the key elements in avoidance of TLI complications. Because intubation and reintubation put a patient at risk for airway injury, noninvasive alternatives to TLI, such as use of the laryngeal-mask airway or the esophageal-tracheal Combitube, should always be considered, particularly in difficult and emergency airway management situations.[348,349] A review of three randomized or controlled clinical trials of emergency TLI in the field demonstrated no benefit of TLI compared with bag-valve-mask ventilation techniques on survival or neurologic outcome.[350] In patients with respiratory failure from acute exacerbation of chronic obstructive pulmonary disease, noninvasive positive-pressure ventilation decreases the need for TLI and has advantages, such as decreased mortality, rate of complications, and length of hospital stay.[351] An early important step is choosing the appropriate route of TLI for each patient with awareness of the advantages and disadvantages of each.[352] Principles of airway management to prevent complications of artificial airways are described in Chapter 38 and elsewhere.[120,185,353,354]

Complications During Endotracheal Tube Placement

Most of the complications that occur during ETT placement can be prevented by assiduously following the principles and procedures of airway management described in Chapter 38. The intubator should be aware of common pitfalls in attempting to place an ETT in proper position (Table 39-11).

SELECTING THE CORRECT ENDOTRACHEAL TUBE

The ETT selected should have a high-volume, low-pressure soft cuff. All ETTs used in modern critical care should meet standards required by the F29 Committee on Anesthetic and Respiratory Equipment, American Society for Testing and Materials.[267] The ideal ETT should be compliant at body temperature to help conform to the anatomic shape of the patient's airway, thereby reducing force on the posterior larynx. It also should be kink resistant and have a soft cuff that seals the airway and prevents aspiration at minimal lateral tracheal wall pressures.[263,281]

For anesthetic intubation, Stenqvist et al have advocated the use of size 6-mm or 7-mm (i.e., the size of the internal diameter) ETTs in order to reduce pressure on the laryngeal contact points.[355] For use in the patient with respiratory failure in the ICU, however, small tubes have obvious disadvantages, including difficulty in suctioning and increased

TABLE 39-11: COMMON PITFALLS IN PERFORMING TRANSLARYNGEAL INTUBATION

Inadequate training, practice, and experience in intubation
Failure to assemble necessary intubation equipment and drugs before starting the procedure
Selection of the incorrect route of intubation
Inadequate sedation, muscle relaxation, or topical anesthesia
Failure to prepare the nose with vasoconstrictors, analgesics, and/or decongestants before nasal intubation
Failure to oxygenate and ventilate the patient with bag-and-mask ventilation before intubation
Improper positioning of the head and neck
Use of the laryngoscope blade as a lever to pry the airway open
Use of the teeth as a fulcrum to turn the laryngoscope
Failure to visualize the vocal cords
Forcing the endotracheal tube (ETT) forward against tissue resistance
Prolonged intubation attempts without regard for progressive hypoxemia and acidosis
Advancing the ETT deep into the airway after successfully passing the tube through the larynx
Equipment malfunction

airflow resistance that may increase the work of breathing and delay weaning from mechanical ventilation.[356] A size 8.0-mm to 8.5-mm tube in men or a size 7.5-mm to 8.0-mm tube in women is usually selected for oral intubation, while a tube that is 0.5-mm to 1.0-mm smaller is usually selected for nasal intubations.[185]

PREVENTING INTUBATION TRAUMA

Intubation trauma may be avoided by skilled airway management strategies (see Chapter 38). These include the initial use of bag-and-mask technique to oxygenate and ventilate the patient, thereby avoiding the necessity for "crash" intubation. The importance of adequate preoxygenation before attempting TLI cannot be overemphasized.[357,358] Attempts to visualize the glottis with the laryngoscope should be brief and limited in number. Mort reported that the relative risk of airway complications was significantly higher when three or more laryngoscopic attempts were made.[72] Eleven percent of the 297 TLIs in critically ill adults prospectively studied by Schwartz et al required this number of attempts.[70]

The value of skill and experience in intubation cannot be overstated. For example, nearly all reports of pharyngeal perforation from TLI emphasize that this complication occurs in emergency intubations performed by inexperienced intubators. Skill in intubation may be gained by mannequin or simulation training.[359–362] Bishop et al compared intubation by experienced intubators and novices, observing that novices required twice as long to intubate and had significantly higher intubation "impulses" (force of intubation multiplied by duration of effort) than experienced intubators.[359] Schmidt et al documented a lower rate of complications when anesthetic TLI was supervised by attending physicians.[23] These observations underscore the benefits of training, skill, and experience in intubation technique.

Chapter 38 discusses appropriate management strategies for the difficult intubation. Critical care providers should be familiar with current clinical practice guidelines to manage the patient with a difficult airway.[363]

Preventing Nasal Bleeding. Nasal intubation should be avoided in patients with coagulation disorders, thrombocytopenia, or platelet dysfunction. Careful examination of the nasal passage before intubation is essential, and the more patent side should be selected. Softening the nasal ETT with warm water before intubation may make it more compliant, decreasing the frequency and severity of nasal hemorrhage.[364] Application of a topical decongestant-vasoconstrictor and a topical anesthetic before nasotracheal intubation is recommended.

PREVENTING HYPOVENTILATION AND HYPOXEMIA

Monitoring of ventilation and oxygenation after intubation is critical (see Chapter 38). Unrecognized hypoventilation is among the most common preventable complications of intraoperative anesthesia. Recent guidelines emphasize the importance of preventing hypoventilation by confirming proper ETT placement (see the section Avoiding Esophageal Intubation and Avoiding Right Main-Stem Bronchus Intubation)[349] and by appropriately monitoring ventilation and oxygenation in the sedated patient.[365] Guidelines of the American Society of Anesthesiologists indicate that all patients undergoing sedation/analgesia should be monitored with pulse oximetry and with observation or auscultation of ventilatory function.[365] Monitoring of exhaled carbon dioxide should be considered for all deeply sedated patients and for moderately sedated patients whose ventilation cannot be directly observed.[365]

PREVENTING CARDIOVASCULAR REACTIONS TO TRANSLARYNGEAL INTUBATION

The tachycardic-hypertensive response and cardiac arrhythmias that may accompany laryngoscopy and TLI are potentially preventable.[92,366] The routine use of drugs to prevent these cardiovascular reactions to TLI is not advised, but prophylactic treatment should be considered in patients with hypertension, cardiac disease, or cerebrovascular disease.[366] A wide variety of drug classes and specific drugs are available for this purpose.[366]

AVOIDING ESOPHAGEAL INTUBATION

Esophageal intubation represents a misadventure in intubation with potentially disastrous consequences. A number of strategies have been described to avoid and to recognize this complication.[10,367–370] McCulloch and Bishop reviewed the efficacy of fifteen different methods to determine correct ETT placement and avoid esophageal intubation.[10] Pulse oximetry to assure adequate oxygenation and quantitative monitoring of carbon dioxide levels of expired gas are now standards of care in the operating room. No method to detect esophageal intubation is absolutely foolproof, but capnography comes closest to the mark.[367] It is superior to chest auscultation[370,371] and methods that employ a self-inflating bulb[372] or a lighted stylet.[370] Monitoring of end-tidal CO_2 levels after intubation gives a characteristic repeated waveform if the ETT is properly located in the trachea. Failure of capnography to detect esophageal intubation is very rare.[373] Although colorimetric CO_2 indicators are helpful in detecting esophageal placement of an ETT,[368,369] they still have the potential for indicating tracheal placement even though the ETT is in the esophagus.[374]

Recent international guidelines for emergency cardiovascular care call for both primary confirmation of correct tracheal placement of the ETT by physical examination and secondary confirmation by an end-tidal CO_2 detector or an esophageal detector device.[349] These steps are followed by careful chest auscultation and a chest radiograph. Use of an ETT holder to prevent subsequent dislodgment is also advised in these guidelines.[349]

AVOIDING RIGHT MAIN-STEM BRONCHUS INTUBATION

Physical examination of the chest is not reliable in determining proper positioning of the ETT.[375] Brunel et al reported that 60% of patients with main-stem bronchus intubations had equal breath sounds on chest physical examination.[318] Therefore, in general, it is always desirable to obtain a chest radiograph after intubation[318,376] unless fiber-optic bronchoscopy is performed to confirm proper positioning. By chest radiograph (or bronchoscopy) the tip of the ETT should be approximately 4 to 5 cm above the carina in adults, or at about the level of the third or fourth thoracic vertebra on the chest radiograph.[377–379] When the tip of the ETT is approximately 4 cm above the carina, the upper end of the ETT cuff is approximately 2 cm below the vocal cords.[379]

Endobronchial intubation is usually caused by intubator inexperience and is therefore preventable with proper training and supervision.[65,68,379] Intubators must resist the impulse to thrust the ETT too deeply into the trachea after the tube enters the glottis. Insertion to a depth of 21 cm in women or 23 cm in men from the upper incisor teeth or gums is a reasonable first step to avoid endobronchial intubation.[65,68] This approach will probably avoid endobronchial intubation, but in some patients it may result in positioning the ETT too high in the trachea, risking laryngeal compression or accidental extubation. Cherng et al reported that the correct oral ETT length in adults with the head in a neutral position was correlated with body height.[378] They advocated estimating the length of the tube (in centimeters) from 5 cm above the carina to the angle at the right side of the mouth with this equation: (body height in centimeters/5) – 13.[378] After a chest radiograph confirms proper positioning of an ETT, the tube should be marked with indelible ink at the level of the lip or nasal alae to avoid subsequent inadvertent tube dislocation.

Complications While the Endotracheal Tube Is in Place

A number of practices may be helpful in preventing complications during TLI (Table 39-12). A careful physical examination of the patient should be performed by the physician at least daily, including examination of the mouth, nose, ears, sinuses, neck, and chest. The entry site of the ETT should be inspected carefully after removing adhesive tape or ETT holders as necessary (Fig. 39-19).

Nasal ala ulceration (see Fig. 39-4) may be prevented by positioning the ETT so that it points downward straight out the nose, by avoiding tight taping of the tube to the nose, by selecting a nasotracheal tube that is not too large for the patient, and by other approaches.[380,381] Oral ulceration (see Fig. 39-7) may be avoided by minimizing the direct pressure transmitted to the lips and soft tissues of the oral cavity from the shaft of the ETT and ventilator tubing. Oropharyngeal airways should not be used routinely.

TABLE 39-12: SELECTED MEASURES TO REDUCE THE RISK OF COMPLICATIONS WHILE THE ENDOTRACHEAL TUBE IS IN PLACE

- Perform a careful bedside examination daily
  - Include mouth, nose, ears, and sinuses
- Avoid nasal ulceration
  - Position the nasotracheal tube so that it points downward
  - Avoid too large a nasotracheal tube
  - Avoid taping the endotracheal tube (ETT) tightly to the nose
- Avoid oral ulceration
  - Minimize direct pressure on the lips and soft tissues of the oral cavity from the shaft of the ETT
  - Support the weight of the attached ventilator tubing
  - Use oropharyngeal airways only if necessary
- Select the best ETT for the patient
  - Use high-volume low-pressure soft cuffs only
  - Avoid very large ETTs (size ≥9.0 mm) to reduce the risk of laryngeal injury
- Manage cuff inflation carefully
  - Limit intracuff pressure to ≤20 mm Hg, 25 mm Hg at the maximum
  - Consider a trial of a foam cuff ETT if higher inflation pressures are required
  - Check and record intracuff pressures every 8 hours
  - Check for high cuff pressures after general anesthesia with nitrous oxide and other anesthetic gases
  - Use the minimal occluding pressure technique for cuff inflation
  - Avoid overinflation of soft cuffs
  - Watch the chest radiograph for tracheal cuff-site dilation
- Avoid deliberate or inadvertent self-extubation
  - Use extremity restraints and sedate the patient if necessary
  - Reassure the patient to allay anxiety
  - Be certain the ETT is properly located in the trachea, with the tip approximately 4 to 5 cm above the carina (for an adult of average height)
- Suction the airway carefully
  - Avoid excessive movement of the ETT
  - Use sterile gloved technique
  - Oxygenate and ventilate the patient adequately during suctioning
  - Limit suctioning to a maximum of 10 to 15 seconds at a time
  - Suction secretions when necessary, not routinely
- Avoid transmission of mechanical forces directly to the patient
  - Use elastic connectors and swivels
  - Support the weight of ventilator tubing
  - Do not tie ventilator tubing to the bedrails
- Minimize abrasion of the laryngeal and tracheal mucosa
  - Minimize attempts to talk, swallow, and move the head and neck
  - Control coughing and aggressively treat agitation, seizures, and rigid posturing
  - Sedate the patient if necessary
- Use nasogastric tubes judiciously and only if necessary
  - Avoid large nasogastric tubes
- Attach the ETT to a source of warm, humidified gas
- Give the patient reassurance and emotional support
  - Facilitate and encourage written communication
- Remove the ETT as soon as possible

MANAGING CUFF PRESSURE

Only ETTs with low pressure cuffs should be used in adult critical care. The cuff inflation pressure should be limited to

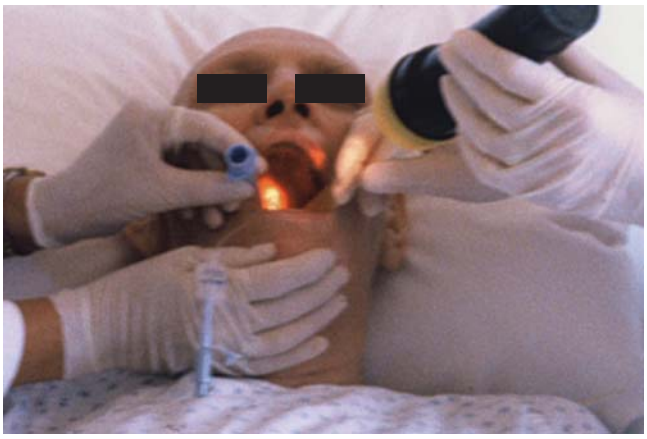

FIGURE 39-19 During translaryngeal intubation the nose and mouth should be inspected carefully every day to detect evidence of nasal or oral injury from the endotracheal tube.

less than 20 to 22 mm Hg (27 to 30 cm H_2O) if possible.[382] If higher cuff pressures are required, the cuff pressure should certainly not be allowed to exceed 25 mm Hg (34 cm H_2O). If this goal cannot be achieved, consideration should be given to replacing the ETT with a foam-cuff tube. A cuff pressure monitoring device that records the pressure in the cuff and manometer simultaneously should be used (Fig. 39-20).

Critical care practitioners should be aware that it is necessary to check the ETT cuff for excessive pressure after general anesthesia with nitrous oxide (N_2O) and other anesthetic gases, because these gases diffuse into the cuff.[383] In patients undergoing surgery with general anesthesia that included 50% N_2O, Tu et al noted that ETT soft-cuff pressures exceeded 80 cm H_2O and that cuff-site injury correlated with cuff pressure.[383] ETT cuff pressure should be checked at least every 20 to 30 minutes during and after anesthesia with N_2O.

FIGURE 39-20 The pressure in the endotracheal tube cuff should be set and checked every nursing shift to help avoid tracheal cuff-site injury. Cuff inflation pressure should be limited to less than 20 mm Hg (27 cm H_2O) if possible. The cuff pressure monitoring system shown here (Posey Cufflator Endotracheal Tube Inflator and Manometer, Posey Company, Arcadia, CA) records the pressure in the cuff and aneroid manometer simultaneously.

The "minimal occluding pressure" technique[273] is advised for maintaining cuff inflation, although some practitioners prefer the "minimal leak" technique.[384] Regardless of the technique of cuff inflation that is used, overinflation of soft cuffs should be avoided. The addition of only a few extra milliliters of air to the soft cuff may raise intracuff pressures sharply, increasing lateral tracheal wall pressure and risking tracheal mucosal injury.[258,292,293] Cuff pressures should be recorded at least every 8 hours or once every nursing shift. Routine monitoring of intracuff pressures is desirable, despite the shortcoming that it always overestimates lateral tracheal wall pressure.[385]

High cuff inflation pressures should be taken seriously. The patient should be watched carefully for signs of excessive cuff pressure, including widening of the tracheal air column on the standard chest radiograph.[152] Rising peak airway pressures during mechanical ventilation require higher cuff inflation pressures in order to prevent cuff air leak. A prospective study of fifteen patients undergoing mechanical ventilation for surgery revealed a linear relationship between peak airway pressure and minimal occluding cuff pressure, and in this series a cuff pressure of 25 mm Hg corresponded with a peak inflation pressure of 35.3 mm Hg (48 cm H_2O).[386]

AVOIDING UNPLANNED EXTUBATION

The patient should be constantly reassured to reduce anxiety. Extremity restraints should be applied if necessary and the patient sedated if it appears that self-extubation is likely. Mechanically ventilated patients who are severely agitated are significantly more likely to self-extubate than those who are not agitated.[204,387] Tung et al observed in a retrospective case-control study that ICU patients who self-extubated were more than twice as likely as controls to be agitated.[201]

Self-extubation tends to be repetitive, so constant vigilance is necessary. Staff awareness of the potential for self-extubation and the appropriate use of restraints and sedation reduce the risk of its occurrence. Proper positioning of the tip of the ETT approximately 4 to 5 cm above the carina also reduces the risk of inadvertent self-extubation such as during movement, patient transport, or extension of the head and neck.[206] Proactive nursing care aimed at avoiding excessively long periods of intubation provides a protective benefit.[388]

USING SKILLED SUCTIONING TECHNIQUES

Complications of tracheal suctioning during TLI include pain, coughing, hypoxemia, cardiac arrhythmias, bronchoconstriction, and mucosal damage. Consequently, it is important to suction the trachea carefully and never routinely.

Multiuse closed-system tracheal suction catheters save time, eliminate the need to disconnect the patient from the ventilator, and are preferable to open suctioning in patients with severe hypoxemia.[389] There is, however, no consensus that they should be used to prevent VAP.[304]

Open suctioning of the trachea should be performed with clean or sterile gloves, a sterile, single-use catheter, and sterile fluid.[304] Tracheal suctioning should ideally be performed by two attendants so as to avoid excessive movement of the ETT during suctioning and to maintain adequate oxygenation and ventilation. The patient should be adequately oxygenated and ventilated and suctioning intervals limited to a maximum of 10 to 15 seconds.

AVOIDING TRANSMISSION OF MECHANICAL FORCES FROM THE ENDOTRACHEAL TUBE DIRECTLY TO THE PATIENT

Elastic connectors and swivels between ventilator tubing and the ETT should be used. The weight of ventilator tubing should be supported by a folded towel on the patient's chest or by overhead supports. The ventilator tubing should not be tied to the bedrails. An ETT holder with integrated bite-block can help secure the position of the ETT and prevent the patient from biting and occluding the tube.

MINIMIZING ABRASION OF THE LARYNGEAL AND TRACHEAL MUCOSA

Any motion of the ETT during TLI applies shearing forces to the mucous membranes of the mouth, and more importantly, the glottis and trachea, promoting airway injury. Attempts at talking, swallowing, and moving by the patient should be discouraged. Coughing should be controlled and aggressive measures taken to manage agitation, seizures, and rigid posturing. The ventilator tubing, ETT, and patient should be thought of as one unit and moved together in order to minimize movement at the interface between the ETT and the patient's airway. Nasogastric tubes should be used only if necessary.

MISCELLANEOUS PREVENTIVE STRATEGIES

The ETT should be attached to a source of warm, fully humidified gas to promote clearing of airway secretions and to avoid desiccation of the tracheobronchial mucosa. If a heat and moisture exchanger is used, especially for prolonged periods of time, close observation of ETT patency and airway resistance is necessary because of the risk of tube occlusion. The patient should be reassured and given emotional support throughout the period of TLI. This may help avoid complications such as self-extubation and those caused by excessive motion and agitation. Because ventilated patients experience a high level of frustration and stress related to their difficulty in communication,[390] care providers need to be especially attentive to patients' communication needs. Finally, the ETT should of course be removed as quickly as possible.

MODIFYING THE DESIGN OF THE ENDOTRACHEAL TUBE

Investigators have attempted to reduce the rate of complications of TLI by modifying the design of the ETT. Such innovations have led to the introduction into clinical practice of devices such as the foam-cuff ETT and the ETT with a suctioning lumen above the cuff. The foam-cuff tube described by Kamen and Wilkinson reduces lateral tracheal wall pressure to less than 15 mm Hg.[391] Experimental innovations have included shaping the ETT to match the anatomic contour of the airway,[392] using a balloon on the shaft of the ETT,[126,261] covering the ETT shaft with foam,[316] lengthening the cuff to provide a larger contact area on the tracheal mucosa,[393] using two cuffs,[394] and adjusting the cuff design to prevent leakage of fluid into the lungs.[395] Self-regulating devices to control cuff pressure have been designed,[255] but they have not gained widespread acceptance.

Complications During and After Extubation

Respiratory care techniques to avoid complications of extubation are reviewed elsewhere.[185,396] The patient should be adequately oxygenated and ventilated before extubation. The cuff should be fully deflated before the ETT is removed, and the pool of secretions above the cuff should be suctioned from the trachea immediately upon cuff deflation. The rate of failed extubations was reduced by a quality improvement program that addressed risk factors for failed extubation.[397]

AVOIDING STRIDOR

Patients with a high risk of postextubation stridor (female gender, prolonged TLI, smaller leak volume on cuff-leak test) should be considered as candidates for prophylactic administration of corticosteroids to prevent or attenuate laryngeal edema. Older studies showed little or no benefit of single doses of corticosteroids to prevent laryngeal edema and postextubation stridor,[398,399] but several recent reviews and meta-analyses indicate a clear benefit of multiple doses of corticosteroids administered 12 to 24 hours before extubation in reducing the occurrence of stridor and the need for reintubation.[400–402]

Patients who have displayed one episode of postextubation stridor requiring reintubation represent a serious therapeutic challenge for subsequent attempts at extubation. In this situation, because no particular therapeutic regimen has been studied carefully in adults and proven to be of benefit, all measures are empiric. No matter what measures are employed, experience indicates the need for repeated intubation of such patients. In one study, such patients required a mean of 2.9 intubations.[224] A trial of parenteral corticosteroids should be considered, but no controlled studies of this approach in adults have been reported. Nebulized epinephrine and helium–oxygen gas inhalation are also reasonable approaches. Weymuller et al[108] proposed a rigorous regimen

in anticipation of a second episode of postextubation stridor, including general anesthesia in the operating room, followed by direct laryngoscopy. Deeb et al recommended immediate telelaryngoscopy for all patients who appear to require tracheotomy because of failed extubation.[143]

IMPORTANT UNKNOWNS

In spite of accumulated experience in airway management of critically ill patients spanning six decades, there is still much that is unknown about complications of TLI and their avoidance. Considering the major advances of the last few decades, it is reasonable to expect even more advances in the decades ahead. It is likely that some of the following questions will be addressed:

1. Are there better techniques to assure correct ETT placement into the trachea?
2. Can subsets of patients requiring TLI who would benefit from early tracheotomy be identified?
3. Is there an optimal size of ETT for individual patients based on gender and height?
4. Is there a better shape for the ETT to avoid posterior laryngeal injury?
5. Is abrasion of the mucosa as a result of motion between the patient and the ETT at the level of the posterior glottis an important risk factor for posterior glottis injury?
6. Would reducing ETT shaft stiffness decrease the risk of posterior glottis injury?
7. Is there a better cuff design to minimize tracheal surface injury?
8. What is the appropriate balance between cuff inflation pressure and airway peak inflation pressure, considering the competing needs of preventing tracheal mucosal ischemic injury and reducing leakage of secretions from above the cuff?
9. What is the optimal composition of the ETT shaft in relationship to its wall thickness, compliance, inner diameter, pressure-flow relationship, and biofilm accumulation?
10. What is the appropriate level of training and experience permissible to perform TLI?

THE FUTURE

Extensive experience with TLI over the last six decades has provided a huge database of ETT-related complications, mechanisms of airway injury, recommendations for management of the intubated patient, and strategies for prevention, early recognition, and treatment of the complications. Large prospective studies of complications of TLI provide special insight into the true frequency of complications and the related risk factors. Retrospective observations, individual case reports, and small case series, however, have also added to our growing knowledge about airway complications of TLI. The expanding literature has allowed us to record and classify seemingly countless examples of airway injury from TLI as well as tracheotomy. Since the development of high-volume, low-pressure ETT cuffs more than 40 years ago, however, major advances to prevent complications of TLI in critical care have not been forthcoming.

Opportunities to reduce the impact of complications of TLI include the following:

1. Performing large multicenter prospective studies of complications of TLI in critically ill adults and children to evaluate the optimal timing of tracheotomy in subsets of critically ill patients.
2. Promoting training and credentialing in advanced airway management, including management of the difficult airway, for personnel involved in critical care at all levels—paramedical personnel, emergency department staff, and critical care unit practitioners.
3. Supporting research in new design and composition of artificial airways, including research to make ETTs more compliant, especially at the level of the posterior larynx, to design new and safer cuffs, and to reduce biofilm on tube surfaces.
4. Performing further prospective studies of the use of alternatives to TLI, including the tracheoesophageal Combitube, the laryngeal-mask airway, and noninvasive positive airway pressure devices.
5. Developing clinical practice guidelines for managing TLI in critically ill patients.

SUMMARY AND CONCLUSIONS

Complications of TLI in critically ill adults are reviewed and classified according to the time period in which they occur: during ETT placement, while the ETT is in place, and during and after extubation. This chapter reviewed mechanisms of these adverse events and described steps to recognize, manage, and prevent complications of TLI. As the literature on complications of TLI expands, new insights to improve airway management of the critically ill patient continue to develop and evolve.

CARE OF THE MECHANICALLY VENTILATED PATIENT WITH A TRACHEOTOMY

John E. Heffner
David L. Hotchkin

Although Egyptian tablets depict use of tracheotomy for medical applications nearly 5600 years ago,[1] initial descriptions of the procedure in Western literature did not appear until the middle of the sixteenth century.[2] By 1718, "tracheotomy" became accepted terminology for the surgical technique that was then primarily used for relief of airway obstruction and removal of aspirated foreign bodies. Typically gruesome clinical results relegated tracheotomy to a reviled role in airway management and gained it a designation as the "scandal of surgery."[3] The diphtheria epidemics of the nineteenth century popularized tracheotomy.[4] Tracheotomy did not become widely accepted, however, until 1909, when Chevalier Jackson standardized surgical techniques and decreased the operative mortality from 25% to less than 1%.[5]

Advances in tube design during the 1960s and 1970s and improved management techniques further promoted acceptance of tracheotomy for long-term airway access for critically ill, ventilator-dependent patients. The advent of percutaneous dilational tracheotomy (PDT) further widened the application of tracheotomy by allowing the procedure to be performed in the intensive care unit (ICU) by nonsurgeons.[6] Up to 24% of patients undergoing mechanical ventilation and 6% of critically ill patients in general have a tracheotomy performed.[6–12] In North Carolina, nearly a threefold increase in the application of tracheotomy for prolonged mechanical ventilation was observed from 1993 to 2002.[9] Although only 7% of ventilated patients underwent tracheotomy in that study, they accounted for 22% of all mechanical ventilation patient charges.

Four indications exist for a tracheotomy in critically ill patients: (a) maintenance of airway patency for patients with functional or mechanical upper airway obstruction, (b) provision of airway access for suctioning retained airway secretions, (c) prevention or limitation of aspiration in patients with glottic dysfunction, and (d) management of patients who require long-term airway access for ventilator support.[13] Acceptable outcomes from tracheotomy remain dependent on the skill of the operator who performs the procedure and expertise of interdisciplinary teams charged with managing

patients from the critical care phase of their illnesses through transitions to hospital wards and long-term care facilities until successful decannulation occurs.[14,15]

TECHNIQUES OF SURGICAL AIRWAY ACCESS

Standard Surgical Tracheotomy

A *standard surgical tracheotomy* provides tracheal access through a temporary incisional tracheostoma between cartilaginous rings (Fig. 40-1). The stoma spontaneously closes after removal of the tracheotomy tube.

Standard surgical tracheotomy is a well-tolerated procedure with an operative mortality of less than 1% when performed as an elective procedure in stable, ventilator-dependent patients. In contrast, most,[16] but not all,[17] centers report a higher complication rate when surgical tracheotomy is performed as an emergency procedure. Some groups report successful emergency tracheotomy when performed on awake patients.[18] Most centers, however, have replaced emergency surgical tracheotomy with specialized endotracheal intubation techniques to secure a difficult airway,[19] emergency cricothyroidotomy,[20] and emergency percutaneous techniques.[21–27]

Percutaneous Tracheotomy

Percutaneous tracheotomy refers to several techniques that insert a standard or modified tracheal airway with a Seldinger technique below the first or second tracheal rings using a device to cut and spread the trachea[28] or a forceps or dilator technique to cannulate and dilate tracheal tissue between cartilaginous rings (see Fig. 40-1).[29–31]

Ciaglia first described percutaneous dilatational tracheotomy (PDT) wherein a Seldinger technique allowed the insertion of sequential dilators to place a tracheotomy tube.[30] The procedure has evolved from the use of sequential dilators to insertion of a single dilator that increases in caliber from tip to base where it matches the diameter of a tracheotomy tube (Ciaglia Blue Rhino, Cook Critical Care Inc., Bloomington, IN) (Fig. 40-2).[32] The single-dilator Blue Rhino technique results in faster insertion times as compared with the sequential dilator technique,[27,33,34] and a lower risk of posterior tracheal injury.[27,35,36]

Recently, the Ciaglia PDT has been further modified with use of a balloon dilator (Ciaglia Blue Dolphin, Cook Critical Care Inc., Bloomington, IN), which is placed across the anterior tracheal wall and inflated to dilate the stoma by radial force, thereby avoiding anterior–posterior compression of tracheal structures that can fracture cartilaginous rings. The procedure has not yet been established as being superior to the Blue Rhino technique.[37,38]

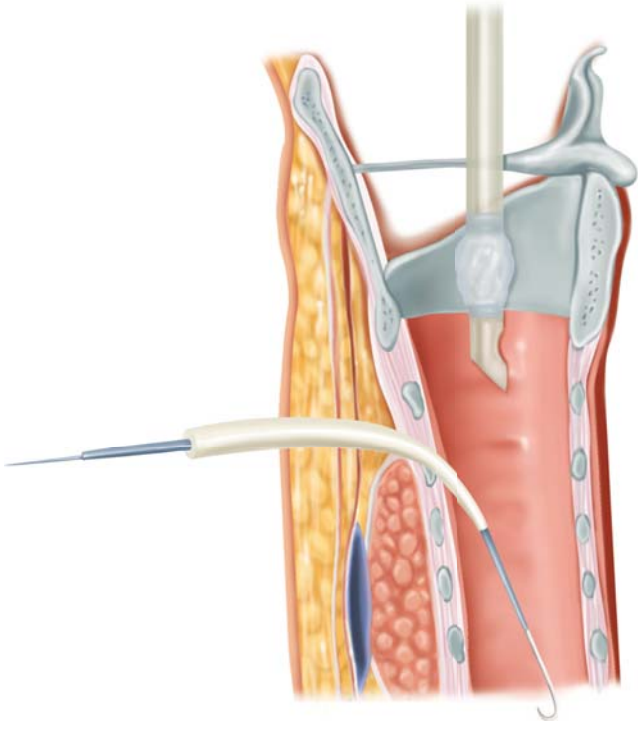

FIGURE 40-2 Insertion of a stoma dilator for percutaneous dilatational tracheotomy. (Courtesy Cook Critical Care, Bloomington, IN.)

The Ciaglia PDT technique is the most commonly performed percutaneous tracheotomy procedure in the United States and is frequently used in Europe.[39–41] Nonsurgeons can perform the procedure with low complication rates, with few patients requiring conversion to a surgical tracheotomy.[42] Controversy remains, however, among otolaryngologists, with only 29% of otolaryngology residency programs teaching PDT; however, programs that do include training in PDT use the Ciaglia Blue Rhino technique and endorse its safety.[43,44]

Other techniques for percutaneous tracheotomy include a specialized guidewire dilating forceps with a groove that allows loading of a guidewire onto forceps, which dilate the trachea, thread the wire, and insert a tracheotomy tube by Seldinger technique (Portex guidewire dilating forceps kit, Sims, Inc, Philadelphia, PA).[45] The guidewire dilating forceps technique provides quick, safe, and effective placement of a tracheotomy for critically ill patients.[46–51] Guidewire dilating forceps require the same time to completion as the Ciaglia single-dilator method.[52,53] Comparative studies have shown both higher,[54] similar,[46,52,53] and lower[50] complication rates with the guidewire dilating forceps as compared with the Ciaglia Blue Rhino technique, with each having unique complications.[55] Long-term follow-up studies demonstrate acceptable rates of tracheal stenosis and other chronic airway complications with guidewire dilating forceps,[56–59] although one study of 208 patients observed a 38% incidence of a changed voice and a 12% incidence of persistent, severe cough. Patients with short, fat necks, conditions that prevent neck extension, an enlarged thyroid isthmus, a previous tracheotomy, coagulopathy, or anticoagulation therapy have successfully undergone the guidewire dilating forceps technique.[60]

Frova et al described a single-step technique (PercuTwist, Rusch, Kernen, Germany) that threads a screw-type dilator between tracheal rings to allow insertion of a specially designed tube.[61] This technique causes less compression of the anterior tracheal wall than does the Ciaglia technique. Early experience with PercuTwist reported variable success with difficulties in learning the procedure and problems with damage to tracheal structures.[34,62–65] More recent reports using bronchoscopic guidance compared PercuTwist with other percutaneous techniques and reported similar complication rates and speed of completion of the procedures.[66–68]

Fantoni proposed translaryngeal tracheotomy for placing a tracheotomy in a reverse direction from within the airway through the tracheotomy tract.[69] The operator places a needle into the trachea between the second and third tracheal rings. With bronchoscope guidance, a guidewire is passed retrograde through the needle into a cuffed, rigid bronchoscope, which is then removed from the airway. A tracheotomy tube with a tapered proximal end is loaded onto the cephalad end of the guidewire and pulled through the airway and the needle tract. Comparative studies suggest that translaryngeal tracheotomy is equally effective and less traumatic than the Ciaglia PDT technique.[70–73]

All percutaneous techniques require a learning curve to gain skills for completing the procedures quickly and safely.[74,75] Centers that emphasize close supervision of trainees note no differences in complication rates by seniority of operator.[76] Because PDT is the primary technique used in most ICUs, it is the percutaneous technique discussed in the remainder of this chapter.

Contraindications to PDT have decreased with increasing experience with the procedure. Conservative relative contraindications have included age younger than 16 years, bleeding diatheses, severely calcified tracheal rings, and anatomic abnormalities, such as obesity and thyromegaly, that obscure landmarks.[35,77–79] Greater experience with PDT, however, has allowed its application by experienced practitioners in patients with body mass indices equal to or greater than 27 kg/m^2 [80] and equal to or greater than 35 kg/m^2.[81] Preoperative ultrasonography allows selection of patients with anatomic abnormalities of the neck for successful PDT.[82,83] Trauma and burn patients with known or suspected cervical injury, patients 5 to 6 days after anterior spinal fusion, and patients with previous tracheostomies have also undergone successful PDT.[83–89] Studies report successful PDT for patients with thrombocytopenia,[90,91] coagulopathies secondary to liver disease,[92] and systemic heparinization.[91,93] PDT has been performed successfully for patients with acute respiratory failure and dependence on high levels of positive end-expiratory pressure (mean: 16.6 cm H_2O; range: 12 to 20 cm H_2O positive end-expiratory pressure).[94]

Purported advantages of PDT as compared with standard surgical tracheotomy include speed of the procedure (less than 10 minutes), ICU placement without operating room transport, avoidance of general anesthesia, decreased cost, reduced operating room use, and limited personnel requirements that include a single operator, a bronchoscopist, a nurse, and a respiratory therapist.[95,96] Such simplifications decrease costs,[97] avoid complications from intrahospital transport, and eliminate dependency on the operating room schedule, thereby decreasing the time from the decision to place a tracheotomy to when it is actually performed.[98] Some centers, however, obviate some of these benefits by performing standard surgical tracheotomy in the ICU.[99–109] Standard surgical tracheotomy in the ICU has similar costs and complication rates comparable to PDT if performed under controlled circumstances with all of the resources that would be available in the operating room.[108,109]

Percutaneous tracheotomy has a potential advantage over standard surgical tracheotomy by dilating rather than incising cervical tissues thereby producing a tracheostoma that fits snugly around the tracheotomy tube.[110] This tight fit has potential for improving anchoring of the tracheotomy tube, decreasing the incidence of inadvertent extubation (1.4% incidence),[43] compressing blood vessels in the stoma tract thus decreasing postoperative bleeding (2% to 4% incidence),[35,43,111] and diminishing the incidence of wound infections observed with conventionally placed surgical stomas.[111] The smaller skin incision also may result in a better cosmetic appearance after extubation.[111,112]

Many observational studies and a smaller number of randomized, controlled trials[73,86,95,96,98,104,111–119] have addressed the potential benefits of PDT by comparing the outcomes of the procedure with those of standard tracheotomy. These trials, however, are relatively small, often employ varying tracheotomy techniques, have considerable spectrum bias, usually exclude patients with relative complications to PDT, and measure heterogeneous outcomes with differing definitions between studies. Five meta-analyses have critically analyzed these studies and come to varying conclusions.[109,120–123] The meta-analysis by Dulguerov et al concluded that PDT had a higher complication rate than standard tracheotomy, but the analysis suffered from methodological flaws (double counting) and included retrospective studies.[109] The three most recent meta-analyses[109,122,123] have the usual limitations from heterogeneity of primary studies, but conclude that PDT and surgical tracheotomy have comparable major complication rates. The analyses differ regarding relative rates of early postoperative complications, but Delaney et al performed a subgroup analysis by type of PDT and found a similar rate of postoperative bleeding for PDT as compared with surgical tracheotomy performed in the operating room.[123] General conclusions from these analyses indicate that the choice of technique should be individualized by an interdisciplinary approach and PDT can be performed more quickly with similar outcomes as compared with surgical tracheotomy performed in the operating room or at the bedside in appropriately selected patients.[109] A shorter time from the decision to perform tracheotomy to its actual completion may result from PDT.[98,111] Prospective comparative data of surgical versus PDT for patients with underlying bleeding diatheses, neck anatomic abnormalities, and other risk factors for complications do not exist.[124] Also, up to 7% of PDT procedures require conversion to surgical tracheotomy because of technical difficulties.[122]

Cricothyroidotomy

Cricothyroidotomy, or more specifically *surgical cricothyroidotomy,* is a surgical technique for placing an airway through the cricothyroid space (see Fig. 40-1). The term has also been applied to percutaneous placement of a cannula by Seldinger technique (*cannula* or *percutaneous* cricothyroidotomy) or a needle (*needle* cricothyroidotomy) through the cricothyroid space to establish an emergency airway. Because of its simplicity and the superficial location of the cricothyroid space, cricothyroidotomy has become the preferred procedure for emergency airway placement for patients who cannot undergo translaryngeal intubation.[125–128] After training on simulators or cadavers, operators can complete surgical or cannula cricothyroidotomy in less than 60 seconds.[129–131] Some centers, however, prefer emergency PDT after failed intubation attempts.[21–27] Up to 62% of patients have vertically oriented arteries and veins overlying the cricothyroid membrane, which can complicate cricothyroidotomy.[132]

Most intensivists do not employ cricothyroidotomy for elective, long-term airway access in critically ill patients because of concern for delayed airway damage, which has been reported to occur more commonly in patients with 6 to 7 days of prior translaryngeal intubation.[133–137] More recent studies propose that cricothyroidotomy has a low complication rate and represents a reasonable option for critically ill patients with challenging neck anatomy.[106,138,139] These studies were retrospective, however, and did not provide systematic patient follow-up to detect long-term airway complications.

Cricothyroidotomy presents potential long-term risks to vocalization after decannulation because the tube inserts through the cricothyroid membrane, which lies within 1 cm of the true vocal cords, and can thereby cause glottic and direct vocal cord scarring and also prevent anterior pivoting of the laryngeal cartilage, which is required to stretch the vocal cords.[140,141] Up to 78% of patients treated with a cricothyroidotomy experience hoarseness.[140–144] No studies, however, have compared the relative risk of voice changes after cricothyroidotomy as compared with tracheotomy,[125] which have been reported to cause vocalization problems in 24% of cardiovascular surgery patients after tracheotomy.[145]

Because of concerns for long-term airway damage, traditional recommendations propose converting emergency cricothyroidotomies to tracheostomies within 72 hours for patients who require continued airway support.[146] Such recommendations, however, have not been studied. Small case series report serious complications in approximately 50% of ventilator-dependent trauma patients undergoing conversion and longer hospitalizations as compared with patients maintained with their initial cricothyroidotomies.[18,147] A meta-analysis of 1134 patients undergoing emergency cricothyroidotomy reports a 2.2% incidence of subglottic stenosis overall and a 1.1% incidence in trauma patients, with only 0.3% of trauma patients requiring reconstructive airway surgery.[125] The study emphasized that the primary studies had considerable deficiencies, no studies support routine conversion, and a need exists for further investigations in light of the potential risks of conversion to tracheotomy.

Although cricothyroidotomy has been recommended for long-term airway support after median sternotomy to avoid mediastinitis, recent reports report an acceptably low risk of mediastinitis when tracheotomy is performed after cardiac surgery.[148–151] The advent of PDT has further decreased concern regarding contamination of fresh sternal incisions,[150–153] although PDT remains an independent predictor of deep sternal infections (odds ratio [OR] 3.22, 95% confidence interval [CI] 1.14 to 9.31, $p < 0.0001$) after cardiac surgery.[154]

Currently, cricothyroidotomy serves as the primary approach for emergency airway support when translaryngeal intubation fails and as a secondary approach for elective long-term airway access in support of mechanical ventilation. When performed electively, most,[134,136,142] but not all,[106,138,147] clinicians reserve cricothyroidotomy for patients intubated less than 7 days. Cricothyroidotomy should also be avoided if possible for patients who depend occupationally on their voice, such as singers or actors,[144] despite absence of comparative outcome data with tracheotomy.[125]

Minitracheotomy

A *minitracheotomy* is a percutaneous technique first described by Matthews et al in 1984 for inserting through the cricothyroid membrane a specialized 4-mm uncuffed tube that accommodates a 10 Fr suction catheter (see Fig. 40-1).[155–157] Performed at the patient's bedside, minitracheotomy provides direct access to the airway for suctioning tracheal secretions without interfering with the patient's cough or speech. The catheter can be capped when not in use for airway suctioning. Because of the tube's small caliber and uncuffed design, a minitracheotomy does not provide airway access for mechanical ventilation, although it has been used during elective otolaryngologic procedures,[158] in patients undergoing jet ventilation,[159] for patients with sternal dehiscence,[160] and for the management of sleep apnea.[161]

The procedure may provide benefit for patients with adequate spontaneous respirations who appear at risk for secretion-related deterioration of lung function.[157,162–168] Patients at high risk for pulmonary complications after thoracic or upper abdominal surgery may benefit from the prophylactic placement of a minitracheotomy at the end of the operative procedure.[162] It has also been used as a transition from PDT for patients who have weaned from mechanical ventilation but who cannot manage secretions.[169] Little outcome data exist, however, to demonstrate efficacy of minitracheotomy with a recent meta-analysis of primary studies demonstrating no benefit in terms of mortality or ICU length of stay for high-risk patients undergoing thoracotomy and lung resection.[170]

Minitracheotomy is usually well tolerated, although 1% develop life-threatening complications[170] and 6% to 57% develop minor complications, such as temporary discomfort, voice changes, subcutaneous emphysema, bleeding, and dyspnea.[156,170–173] Life-threatening complications include pneumothorax after misplacement into paratracheal tissue, profuse bleeding from anterior jugular veins, and esophageal puncture.[174–177] Long-term studies have not reported subglottic stenosis after minitracheotomy.[2,157,163]

SURGICAL TECHNIQUES FOR TRACHEAL CANNULATION

Open Surgical Tracheotomy

Elective standard tracheotomy is performed in an operating room under general anesthesia or an ICU for patients if adequate lighting, personnel, and equipment can provide the resources available in an operating room. The patient's neck is hyperextended with a rolled towel placed between the shoulder blades to bring the trachea and larynx into a superficial and elevated position. The surgeon identifies anatomic landmarks by palpating the cricoid cartilage, tracheal rings, and thyroid cartilage. Some surgeons perform ultrasound to identify structures.[178]

Unless the patient has a vertical scar from a previous tracheotomy, most surgeons perform a 2- to 3-cm transverse incision 2 cm above the suprasternal notch midway between the sternal notch and thyroid cartilage over the second tracheal ring with subsequent dissection of the subcutaneous tissues and platysma. A vertical incision then separates the sternohyoid and sternothyroid muscles from the midline allowing retraction of the strap muscles to reveal the thyroid isthmus. The thyroid isthmus can be pulled superiorly or inferiorly out of the surgical field, but may need to be divided and oversewn to allow visualization of tracheal rings. Vessels can bleed substantially and require electrocautery or suture ligation. Although the anterior jugular veins lie lateral to the incisional plane, communicating venous branches may need to be divided.

The trachea is elevated and stabilized by placing a cricoid hook under the cricoid cartilage or first tracheal ring or using lateral traction sutures around the third or fourth tracheal rings. A vertical incision between the second and third or third and fourth tracheal rings is made with a scalpel, avoiding electrocautery because of flash fire risks. A tracheal wall flap (Björk flap) attached inferiorly to the anterior tracheal wall can be created or a section of the tracheal wall removed. The translaryngeal endotracheal tube is pulled back under direct vision above the tracheal incision. Some surgeons pass the endotracheal tube further into the airway, positioning the tip by bronchoscopic guidance just above the carina, which allows the endotracheal tube cuff to block incisional blood from entering the lower airway.[179]

After positioning the endotracheal tube, the tracheal incision is gently dilated laterally sufficiently to allow insertion of a tracheotomy tube. The tube size is selected by airway inspection, choosing a tube approximately two-thirds the diameter of the tracheal lumen at the level of the stoma. Some surgeons measure the depth of the stoma track and the angle between the stoma and trachea in all patients to determine a need for a nonstandard tube.[180] Specialized tubes are usually required for patients with obesity, short necks, or other anatomic variations,[78] with special attention directed toward assessing the depth of pretracheal tissue before tube insertion.[181] The nonstandard internal diameters of tracheotomy tubes from different manufacturers should also be recognized.[182] After inflation of the tube cuff and confirmation of adequate ventilation, the endotracheal tube is removed. Some surgeons use bronchoscopy to confirm correct tracheotomy tube positioning and to suction bloody secretions.[183] The tracheal traction sutures are removed because they serve little value in facilitating recannulation of the trachea if inadvertent decannulation later occurs.

Percutaneous Dilational Tracheotomy

The PDT Blue Rhino single-dilator Seldinger technique utilizes a kit that contains a J-wire guide, Teflon catheter with introducer needle, a Teflon introducer dilator, a translucent Teflon guiding catheter, and a single curved dilator.

Some operators first examine the neck after the application of positive end-expiratory pressure with the patient in the horizontal position and the neck slightly extended to detect aberrant jugular veins that traverse the operative field.[169] Others examine the neck by ultrasonography to both detect aberrant vessels and select an insertion site.[178,184] The patient is preoxygenated with 100% O_2 and positioned with the head extended as for a standard surgical tracheotomy.[185] Patients with mild to moderate respiratory acidosis may benefit from increasing the minute ventilation before the procedure.[185] Even with a normal baseline partial pressure of carbon dioxide (P_{CO_2}), 26% of patients experience an increased P_{CO_2} by equal to or greater than 3 to 4 mm Hg during insertion of a bronchoscope, with risks for intracranial hypertension in neurosurgical patients[185] unless minute ventilation is adjusted upward.[186] A 2-cm transverse skin incision is made over the second tracheal interspace. Protrusion of fat into the wound is a reliable measure of adequate depth of the incision.[185] Blunt dissection through the incision identifies the anterior tracheal wall.

A fiber-optic video bronchoscope is inserted through the endotracheal tube to visualize the puncture site and ensure its midline position, orientate the endotracheal tube above the needle insertion site, provide suction for pulmonary toilet, and avoid puncturing the posterior tracheal wall.[111,187,188] After withdrawal of the endotracheal tube above the first tracheal ring and reinflation of the cuff, a syringe with the catheter-introducer needle is advanced between the first and second or second and third tracheal rings. Some operators use the bronchoscope to transilluminate the needle insertion site or depress the insertion site with mosquito forceps under bronchoscopic visualization to ensure precise needle insertion[189] and adequate withdrawal of the endotracheal tube above the needle insertion site.[187,190] After air is aspirated through the needle, the J-wire is passed into the trachea toward the carina and the needle is removed. The wire must remain freely mobile throughout the procedure or perforation of the posterior tracheal wall should be suspected.[185] The curved dilator is passed over the wire until the trachea has been dilated sufficiently to receive the tracheotomy tube, which is loaded onto an introducer and inserted over the guidewire. Dilation of the trachea may be difficult in young patients with healthy tracheal tissue.[191]

Some physicians employ methods other than bronchoscopy to ensure proper placement of the tracheotomy tube. A "modified PDT" employs direct palpation of the trachea without bronchoscopy.[192] This technique, however, produces a larger stoma similar to a standard surgical tracheotomy and obviates the advantages from PDT of a snug stoma.[189] Others use an external laser light source for transillumination to obviate bronchoscopy.[193] Intratracheal placement of the needle and dilator guided by capnographic monitoring of exhaled CO_2 has been reported in a randomized trial of fifty-five patients to have similar outcomes as with bronchoscopy.[194] Insertion of a light wand into the trachea can also guide PDT by transilluminating pretracheal tissue.[195]

Most operators, however, use bronchoscopy to guide PDT because of its multiple advantages.[35,123,196] Bronchoscopy ensures withdrawal of the endotracheal tube above the surgical site,[197] decreases risk of injury to the posterior membranous portion of the trachea,[35,198,199] allows early recognition of tracheal puncture if it occurs,[199] and may lower risk of pneumothorax and pneumomediastinum.[35] Bronchoscopy facilitates translaryngeal reintubation if the endotracheal tube inadvertently moves above the glottis.[185] The endotracheal tube size must be 7.5 mm or greater to accommodate the bronchoscope.[185]

Preoperative assessment with ultrasonography may ensure proper placement of a PDT, avoidance of vascular structures, and detection of a deep lying trachea that would indicate a need for surgical tracheotomy.[200,201] One study in seventy-two patients found that ultrasound imaging altered the originally selected needle insertion site in 24% of patients because overlying vascular structures and/or thyroid tissue.[202] Ultrasonography also may be of value in patients with obesity, short necks, and other anatomical variations.[82] Ultrasonography may be increasingly used as an adjunct to bronchoscopic PDT with the advent of highly portable ultrasonographic equipment.[203]

The airway becomes unstable during PDT when the endotracheal tube cuff is withdrawn into the endolarynx. An additional variation of technique employs removal of the endotracheal tube and insertion of a laryngeal mask airway,[204–207] microlaryngeal tube,[208] or 4-mm pediatric endotracheal tube.[209]

Cricothyroidotomy

The cricothyroid membrane is located by palpation of the prominence of the cricoid cartilage. The membrane is 9 to 10 mm in height and trapezoidal in shape, with a surface area of 3 cm^2. It lies 9 to 10 mm beneath the true vocal cords.[126,210]

To perform a surgical cricothyroidotomy, the patient is positioned as for a standard tracheotomy.[127,128] A horizontal 2-cm skin incision is carried through the subcutaneous tissue to the thyroid cartilage. In the emergency setting, a vertical skin incision avoids severing the anterior jugular veins.[78] The lower border of the cricothyroid membrane is incised transversely, and a tracheal hook is placed under the thyroid cartilage. A Trousseau dilator is inserted through the membrane with gentle vertical dilation to allow passage of a 6- or 7-mm tube. The outside diameter of the tube is limited by the height of the cricothyroid membrane (usually 9 mm).

Percutaneous cricothyroidotomy avoids a surgical incision[211] and represents the preferred route in some algorithms for managing difficult airways.[212] Several prepackaged kits are available (Quicktrach Kit, Teleflex Medical, Research Triangle, NC; Portex Minitrach II Kit, Smiths Medical, Dublin, OH; Melker Kit, Cook Critical Care, Bloomington, IN). The various techniques for percutaneous

cricothyroidotomy, necessary training for competency,[213] application of ultrasound guidance,[203,211] and comparative outcomes[130,211,214–216] are discussed elsewhere.

Minitracheotomy

Minitracheotomy can be performed either by a scalpel or Seldinger technique.[156,164] A scalpel kit has a blade that protrudes 1.4 cm from a plastic guard that limits the depth of penetration through the cricothyroid membrane. After positioning as for standard tracheotomy, the cricothyroid membrane is located and marked by palpating the cricoid cartilage. After tissue infiltration with local anesthetic, the guarded scalpel is inserted through the midline of the cricothyroid membrane into the trachea to produce a 1-cm stab incision. The lubricated curved introducer is passed through the incision. A minitracheotomy cannula is then passed over the introducer, which is then removed from the airway.

The Seldinger technique uses a 16-gauge needle that is passed through the cricothyroid membrane. After confirmation of correct placement by aspiration of tracheal air, the needle is angled caudally and a guidewire inserted. The needle is then removed and a minitracheotomy tube loaded over a vein dilator is passed over the guidewire. Once in place, the minitracheotomy tube should be plugged when not in use for suctioning to prevent the inhalation of dry ambient air.

COMPLICATIONS OF TRACHEOTOMY

Techniques and tube designs are sufficiently advanced to allow the safe application of tracheotomy in most ventilator-dependent patients. Although 9% to 40% of patients will experience some type of complication, most of these are minor and the mortality rate is less than 1% (Table 40-1).[17,217–220] The frequency and seriousness of complications correlate with an institution's and operator's expertise in airway management and the use of strict management protocols.[220,221]

Intraoperative Complications

CARDIORESPIRATORY ARREST

Sudden cardiorespiratory arrest is the most feared complication of tracheotomy, occurring in fewer than 1% of patients. Underlying etiologies include vasovagal reactions, misplacement of the tracheotomy tube, tension pneumothorax, arrhythmias, and pulmonary edema after relief of transient upper airway obstruction.[35,222,223]

HEMORRHAGE

Major hemorrhage occurs rarely as an early complication because it can be avoided by identifying anterior jugular veins, vascular anomalies, and the thyroid isthmus to avoid inadvertent transection. Tracheotomies performed below the fourth tracheal ring risk injury to the innominate artery.

Minor hemorrhage occurs in 1% to 40% of surgical tracheotomies, with bleeding rates depending on operator experience and presence of bleeding diatheses.[99] Recent PDT series report less than 2% to 4% bleeding rates,[42,76] although bleeding is the most common individual complication of the procedure.[35,76]

TABLE 40-1: COMPLICATIONS OF TRACHEOTOMY

Aspiration pneumonia
Cardiopulmonary arrest during the procedure
Herniation and fracture of tracheal rings
Inadvertent decannulation
Mediastinitis
Peristomal cellulitis
Pneumomediastinum and pneumothorax
Poor stoma healing after decannulation with scar, keloid, or tracheocutaneous fistula
Posterior tracheal wall perforation
Stomal erosion or breakdown
Stoma site infection
Stomal hemorrhage
Subglottic stenosis or atresia
Surgical emphysema
Tracheal dilation
Tracheal granulomas with obstruction
Tracheal ring rupture
Tracheal stenosis
Tracheoesophageal fistula
Tracheoinnominate fistula
Tracheomalacia

PNEUMOTHORAX AND PNEUMOMEDIASTINUM

Pneumothorax and/or pneumomediastinum occur in 0% to 4% of patients,[97,99,106,119,224] as a result of dissection of air through the incision into the mediastinum, rupture of a lung bleb if transient airway obstruction occurs, or direct injury to the apical pleura.[225] Massive mediastinal insufflation can result from tube misplacement into paratracheal tissue.[226,227]

RECURRENT LARYNGEAL NERVE INJURY

The recurrent laryngeal nerves lie along the tracheoesophageal recesses. A properly placed midline surgical tracheotomy incision should not injure the nerves in their deep positions, but risk of injury is increased in patients with altered cervical anatomy.

TRACHEOESOPHAGEAL FISTULA

Improper technique can puncture or lacerate the posterior membranous tracheal wall and cause an acute tracheoesophageal fistula. Most contemporary studies report an incidence

rate of 0% to 1% of tracheal perforation during PDT performed with bronchoscopic guidance.[198,217,219,220,228,229]

Early Postoperative Complications

HEMORRHAGE

Wound hemorrhage may first present during the early postoperative period when an injured blood vessel ruptures when the patient coughs or moves. Resolution of intraoperative hypotension or dissipation of tissue epinephrine infiltrated during tracheotomy may also cause bleeding to present after the patient leaves the operating room. Prolonged oozing that persists for longer than 2 to 3 days is usually attributable to coagulopathy.[93] Onset of hemorrhage 48 hours or more after surgery suggests a tracheoinnominate fistula.[230] Immediate airway hemorrhage may be less common with PDT as compared with surgical tracheotomy, with rates less than 2%,[42] although instances of massive, fatal airway hemorrhage with PDT have been reported.[231,232]

SUBCUTANEOUS EMPHYSEMA

Subcutaneous emphysema occurs in less than 10% of patients undergoing surgical tracheotomy.[224,233] Positive pressure escapes from the airway around an inadequately sealed tracheotomy tube cuff and decompresses into cervical tissue planes. Avoiding gauze packing in the tracheotomy wound decreases the risk of subcutaneous emphysema. Use of a fenestrated tube during the first week after tracheotomy promotes subcutaneous emphysema because the fenestrations may shift into the stoma tissue tract.[234] Misplacement of a tube into paratracheal tissue may first present with subcutaneous emphysema.[68] Pneumoperitoneum may also occur after tracheotomy.[235] After correction of the underlying cause, subcutaneous air is usually resorbed spontaneously.

INADVERTENT DECANNULATION

Inadvertent decannulation is a life-threatening complication, particularly during the first 72 hours after tracheotomy. During this period, the stoma tract has not fully developed and parastomal tissue can obscure the tracheal window during recannulation efforts. Blind attempts to replace the tracheotomy tube usually result in misplacement into the pretracheal fascia and external airway compression.

Ventilator-dependent patients who experience early inadvertent decannulation should be reintubated through the translaryngeal route if upper airway obstruction is not a factor. The tracheotomy tube can then be reinserted under more controlled conditions. If emergent recannulation of the stoma tract is necessary because of upper airway obstruction, the patient should be positioned as for surgical tracheotomy with a hyperextended neck. Pulling on tracheal traction sutures may allow visualization of the tracheal window. Initial insertion of a smaller size cannula or placement of a guide catheter, such as an intubation stylet, over which a tracheotomy tube is passed, may assist recannulation.

If the tracheal lumen is not clearly seen, a pediatric laryngoscope may assist exploration of the wound and airway visualization. In thick-necked individuals, initial placement of a cuffless pediatric translaryngeal endotracheal tube followed by recannulation with a larger tracheotomy tube later may be required. A fiber-optic bronchoscope or laryngoscope may serve as a guiding stylet to assist tracheotomy tube reinsertion. Regardless of the approach, recannulation should be attempted only by skilled and adequately prepared operators because of the high risk of misplacement.

The 1% to 7% incidence of early inadvertent decannulation can be decreased by appropriately securing the tracheotomy tube.[99] Tracheotomy tape should wrap closely around the neck, allowing sufficient space for insertion of a single finger. Tape should not be secured over gauze dressings that may later shift. Although avoided by some surgeons, suturing the tracheotomy plate to the skin is an additional preventative approach. Risks of accidental decannulation are especially high in obese patients, who benefit from selection of an appropriately configured tube to fit through the stoma tract.[181]

STOMA WOUND INFECTION

Although rapidly contaminated with nosocomial pathogens,[236] only 11% to 30% of surgical tracheostomies[17,111,237] and 4% to 9% of PDT procedures[111,237] are complicated by wound infections, probably because the stoma is left open to drain secretions. Patients with purulent wound drainage without tissue infection usually respond to local tracheostoma care. Systemic antibiotic therapy is reserved for parastomal cellulitis and signs of deep tissue infection. Necrotizing stomal infections can dissect into cartilaginous tracheal structures, adjacent major blood vessels, and the mediastinum.[238] This complication requires drainage, débridement, and replacement of the tracheotomy tube with a translaryngeal endotracheal tube.[239]

PNEUMONIA

All ventilator-dependent patients are at risk for ventilator-associated pneumonia (VAP). Tracheotomy has theoretic potential for both increasing the rate of VAP by promoting drainage of colonized stomal pathogens into the lungs and for decreasing VAP rates by allowing removal of the endotracheal tube and promoting normal glottis closure, which may prevent aspiration. However, up to 35% of patients with a tracheotomy experience aspiration,[240–242] which is most often silent.[242] No evidence exists that aspiration occurs more commonly in ventilator-dependent patients after conversion to a tracheotomy.[243]

Although observational studies indicate that VAP occurs more commonly in patients with a tracheotomy as

compared with patients intubated through the translaryngeal route,[244–246] it is difficult to control these studies for duration and severity of respiratory failure.[247] One study examined risk factors for VAP with multivariate analysis and reported tracheotomy as an independent predictor of VAP (adjusted OR = 3.56).[248] Studies also report an increased rate of VAP in patients undergoing tracheotomy while receiving sedation[249] or after placement of an internal jugular central venous catheter.[250] A retrospective case-control study, however, reported tracheotomy as an independent predictor of a lower rate (episodes per 1000 mechanical ventilator days) of VAP.[251] The relationship between tracheotomy and risk for VAP appears to be highly complex, with many interactions with other clinical factors, which prevent strong conclusions regarding whether tracheotomy is associated with a higher or lower incidence of VAP in patients undergoing mechanical ventilation.

TUBE OBSTRUCTION

Partial obstruction of tracheotomy tubes decreases airflow and increases work of breathing for patients receiving partial assist modes of mechanical ventilation (intermittent mechanical ventilation or pressure support). Obstruction usually results from inspissated secretions or clotted blood, but may occur with incorrect selection of cannula size that places the tip of the tracheotomy tube against the tracheal wall or carina. Tracheotomy tubes with a removable inner cannula decrease the incidence of obstruction by secretions.[252] Tubes with adjustable flanges can be malpositioned in the airway resulting in obstruction of the lumen.[222] Obstruction can also occur when the tip of the tube causes injury to the tracheal wall with invagination of edematous or granulation tissue into the tube lumen[188,253] or when patient repositioning abuts the tube against the tracheal wall.[254]

Late Complications

Up to 65% of patients undergoing tracheotomy in the ICU experience some type of late complication, which may correlate with the duration of preexisting translaryngeal inubation.[255] The seriousness of these complications requires physicians to monitor patients for complications before and after decannulation.

POOR AIRWAY ALIGNMENT

The short length and standardized design of tracheotomy tubes combined with anatomical variation of patients' airways promote malpositioning of the tube tip within the tracheal lumen. Malpositioning increases airflow resistance and ventilatory workload contributing to failure of weaning from mechanical ventilation. One study of mechanically ventilated patients with a tracheotomy at an acute care weaning center reported that 10% of patients had more than 50% occlusion of tube lumens by tracheal tissue, which was associated with prolonged weaning.[256] Replacing a tracheotomy tube with one of different design can improve alignment within the trachea.

TRACHEAL AND LARYNGOTRACHEAL STENOSIS

Tracheal stenosis occurs at the level of the cuff, tracheostoma site, or tip of the tube. Low pressure–high volume cuffs lower, but do not eliminate, risk of tracheal stenosis at the cuff site.[257,258] Inappropriate cuff overinflation or use of too small of a tracheotomy tube that requires cuff overinflation to maintain an airway seal can convert a low-pressure to a high-pressure cuff system. High intracuff pressures transmit to the tracheal mucosa as high cuff tensions that generate pressure necrosis. Resultant mucosal ulcerations become confluent and expose cartilaginous rings that become infected, which leads to weakening of the anterior and lateral tracheal walls.[255] Necrosis generates fibrous scars and transmural airway narrowing. Nontransmural tracheal stenosis can also develop when cartilaginous structures remain undamaged but granulation tissue and proliferative scars in a weblike pattern narrow the airway. The greatest area of scar formation is usually within 3.5 cm of the stoma and ranges from 0.5 to 4 cm in length.

Tracheal stenosis can occur at the distal tip of the tracheotomy tube if a malpositioned tube abuts tracheal mucosa. A tracheotomy tube design should be selected that ensures collinearity with the tracheal lumen, and traction on the tube or ventilator hoses should be avoided.

The stoma has become the most common site for tracheal stenosis after surgical tracheotomy and PDT.[114,122,219,258–262] The airway is narrowed in an anterolateral dimension with relative preservation of the posterior wall. Contributing factors include an overly large tracheal incision and excessive movement of the tube against the tracheal stoma. Fracture of cartilaginous rings during PDT also leads to tracheal stenosis. Patient-related risk factors include female gender, obesity, diabetes mellitus, hypertension, cardiovascular disease, and current smoking.[258]

Tracheotomy can also cause laryngotracheal stenosis above the stoma site.[259,263] One observational study reported a higher incidence of suprastomal stenosis with PDT (24% of patients with more than 50% of lumen) as compared with surgical tracheotomy (7% of patients).[264] A study in cadavers demonstrated the potential of PDT to damage the cricoid cartilage and structures above the stoma site, which may promote subglottic stenosis.[265] A meta-analysis that compared complications from PDT and surgical tracheotomy, however, found no differences in risk of subglottic stenosis.[122]

Clinical manifestations of tracheal stenosis may develop while the tracheotomy tube is in place, but more commonly occur 2 to 6 weeks after decannulation. Delayed onset as late as 4 months after extubation may also occur. Patients with compromised pulmonary function or neuromuscular disease may not manifest symptoms of tracheal stenosis until an episode of bronchitis with increased airway secretions occurs.

The symptoms and signs of tracheal stenosis may be obscured by the patient's underlying disease, but typically include difficulty clearing secretions, dyspnea unresponsive to bronchodilators, exertion-related dyspnea, cough, monophasic wheezing, stridor, and pneumonia. Patients with normal underlying lung function may be relatively asymptomatic until the tracheal lumen is decreased by more than 50%. Clinically important tracheal stenosis occurs in 1% to 11% of patients after 1 year of follow-up.[59,114,219] Because of the nonspecific nature of the clinical manifestations of tracheal stenosis, patients with deteriorating respiratory function and a history of previous intubation should undergo evaluation.

The diagnostic evaluation relies on imaging and endoscopic studies to detect airway narrowing, which may be fixed or dynamic.[266] Chest radiographs and standard chest computed tomography (CT) scans have limited sensitivity, but three-dimensional spiral CT reconstruction imaging provides a valuable adjunct.[267,268] Pulmonary function tests are insensitive (require 80% narrowing) and nonspecific indicators of upper airway obstruction and provide limited diagnostic utility.[269] Direct bronchoscopic visualization remains the gold standard. Most patients with airway stenosis are candidates for corrective interventions either by tracheal resection and reconstruction, neodymium:yttrium-aluminum-garnet (Nd:YAG) laser therapy, mechanical or balloon dilation, or placement of a stent.[270,270–273]

FIGURE 40-3 Flexible tracheotomy tubes with adjustable flanges allow customization of a tube for fitting patients with difficult anatomy or a special need to place the cuff over a specific segment of the airway. (Courtesy TRACOE Medical, Frankfurt, Germany.)

TRACHEOMALACIA

Extensive destruction and necrosis of tracheal cartilages by the tracheotomy tube and ensuing infection of deep tracheal tissue causes tracheomalacia. This complication promotes expiratory tracheal collapse, which can present before or after decannulation. This complication should be suspected in patients who require overdistension of the tracheotomy cuff to maintain an adequate seal.[274] Patients may require a longer tracheotomy tube, bronchoscopic stenting, surgical resection, or tracheoplasty.[183,273]

TRACHEOESOPHAGEAL FISTULA

A tracheoesophageal fistula occurs in less than 1% of patients and results from pressure necrosis of the tracheal and esophageal mucosa caused by the tube cuff.[43,275–277] Risk factors include high cuff pressures, high ventilator-induced airway pressures, excessive tube movement, prolonged intubation, presence of a nasogastric tube, and diabetes mellitus.[276,278] During the course of intubation or after extubation, patients demonstrate increased cough and/or tracheal secretions. Symptoms may only occur after eating solids or swallowing fluids. Patients undergoing mechanical ventilation may experience gastric distension or frequent belching, and chest radiographs may show an air-filled esophagus or gastric distension. Recurrent aspiration may manifest as pneumonia.

A high index of suspicion for tracheoesophageal fistula is required for critically ill patients who have compatible symptoms that may mimic other swallowing or pulmonary problems. The diagnosis is made by tracheoscopy and esophagoscopy, which determine the location and extent of the fistula. Positioning the cuff of an adjustable tracheotomy tube distal to the fistula (Fig. 40-3) and placement of a gastric tube limit airway soiling by aspirated gastric contents. A jejunostomy tube provides nutritional support. Because spontaneous closure rarely occurs, surgical correction is required, which must be delayed until after weaning from mechanical ventilation to avoid anastomotic dehiscence. Primary closure can correct small tracheal fistulae, but most patients require tracheal resection and reconstruction.[276,279] Tracheoesophageal fistulae are universally fatal if left uncorrected.

TRACHEOARTERIAL FISTULA

A tracheoarterial fistula is a major, potentially life-threatening complication of tracheotomy that occurs in less than 1% of patients.[280–283] The innominate artery is most commonly involved because it is nine to twelve tracheal rings below the cricoid cartilage within reach of the tip, and sometimes the cuff, of the tracheotomy tube. In some patients, the innominate artery can traverse the midline just below the tracheotomy stoma where the "elbow" of the tube just above the cuff can induce pressure necrosis.[284] Arterial erosions, however, may also involve the common carotid artery, inferior thyroid artery, the thyroid ima artery, the innominate vein, and the aortic arch.[285] Improper traction on the tracheotomy tube by ventilator tubing, placement of the tracheal window below the fourth tracheal ring, misalignment of the tube with the

tip against the tracheal mucosa, high cuff pressures, prolonged intubation, excessive patient movement or posturing, sepsis, malnutrition, and corticosteroid therapy increase the risks for this complication.[286–289]

Massive airway hemorrhage and asphyxia are the feared complications of tracheoarterial fistula. Hemorrhage can occur as early as several days or as late as 7 months after tracheotomy with the peak incidence between the first and third weeks.[280,283,286,290,291] Up to 50% of patients who experience an episode of airway hemorrhage later than 72 hours after a tracheotomy have an underlying tracheoarterial fistula.[286] Pulsations of the tracheotomy tube and "spotty" herald hemorrhages may portend massive hemorrhage. Any airway bleeding 72 hours after tracheotomy warrants consideration of fiberoptic endoscopy in an operating room environment in case airway manipulation precipitates massive hemorrhage.[230,280] Three-dimensional CT scanning may establish the diagnosis for stable patients.[292] Patients who present with massive hemoptysis should be managed with overinflation of the tracheotomy tube cuff or insertion of a translaryngeal tube with positioning of the cuff over the fistula in an effort to tamponade bleeding. A finger inserted into the stoma tract may allow compression of the innominate artery anteriorly against the sternum (Fig. 40-4).[286,287]

A tracheoarterial fistula represents a surgical emergency and patients require a median sternotomy with ligation and resection of the artery because tissue infection obviates vascular repair.[280,283,285,293] Interruption of the innominate artery is usually tolerated without neurologic sequelae.[280,285,293]

TRACHEOCUTANEOUS FISTULA AND STOMAL SCARS

Epithelialization of the stoma tract may prevent the stoma from closing spontaneously after decannulation. The parastomal platysma or a sternohyoid muscle flap can then be pulled over a surgical stoma repair followed by skin closure.[294–296] Some patients develop excessive scarring at a closed stoma site, which can be managed through reconstructive surgery that fills lost deep tissue bulk, corrects any tracheal skin tugging, and produces a tension-free closure that falls more naturally into the neck folds.[297]

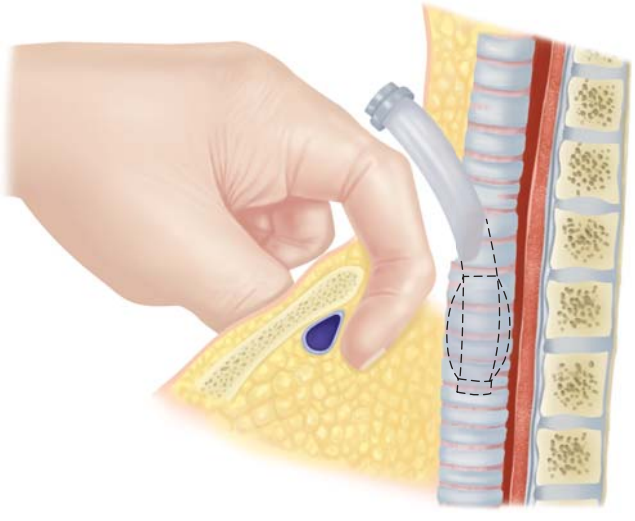

FIGURE 40-4 Hand position for finger tamponade of the innominate artery in a patient with a bleeding tracheoinnominate fistula.

TRACHEAL RING FRACTURE AND HERNIATION

A PDT risks fracture and herniation of tracheal rings because the technique dilates rather than incises intercartilaginous tissue and produces an anteroposterior vector of force at the tracheal insertion site.[298–303] Damaged rings can protrude into the airway causing tracheal narrowing[304] or promote tracheomalacia if extensive loss of cartilaginous support occurs.[305] The frequency of clinically important complications after tracheal ring fractures is unknown. One study followed sixteen patients with tracheal ring fractures and found no instances of tracheal stenosis.[306]

TIMING OF TRACHEOTOMY DURING MECHANICAL VENTILATION

Although translaryngeal endotracheal tubes are relatively well tolerated, patients who require prolonged ventilation eventually benefit from tracheotomy (Table 40-2).[307,308] Selecting patients for tracheotomy and identifying the ideal time for the procedure, however, remain clinical challenges with physicians demonstrating considerable practice variation.[41,309–311] Clinical trials that randomize patients to "early" versus "late" tracheotomy to inform timing decisions face major difficulties.[312] Investigators must be able to identify accurately soon after intubation those patients who will most likely require prolonged ventilation so as to avoid performing unnecessary tracheotomies.[313] Unfortunately, experts doubt their own abilities to predict prolonged intubation during the first days of ventilation.[314] Recent trials report that a large proportion of enrolled patients randomized to control, nontracheotomy groups based on their high risk

TABLE 40-2: ADVANTAGES OF TRACHEOTOMY AS COMPARED WITH PROLONGED TRANSLARYNGEAL INTUBATION

Decreased airway resistance for promoting weaning from mechanical ventilation
Earlier transfer of ventilator-dependent patients from the ICU
Enhanced oral nutrition and oral hygiene
Enhanced phonation and communication
Improved airway suctioning
Increased comfort with opportunities to decrease sedation
Increased patient mobility
Less direct endolaryngeal injury
More secure airway and decreased risk of inadvertent decannulation

of needing prolonged ventilation actually undergo early extubation.[315,316] Collected study data should ideally include comprehensive short-term (e.g., pneumonia, incisional bleeding, duration of mechanical ventilation, patient comfort) and long-term (e.g., tracheal stenosis, speech problems, dysphagia) outcomes, which often have nonstandardized definitions, imprecise or costly approaches to detection, and dependency on case mix.

Additional study design challenges include (a) physician reluctance to allocate patients to the early tracheotomy group when assigned by randomization, (b) difficulties with blinding providers to group allocation, (c) standardizing patient care with protocols for other critical care interventions and approaches to weaning and extubation, and (d) standardizing the tracheotomy technique (i.e., PDT versus surgical tracheotomy). Consequently, most existing prospective trials have limitations because of small and heterogeneous study populations, variations in defining "early" versus "late" tracheotomy, and various methodological flaws that complicate meta-analyses.

These limitations indicate that timing tracheotomy for critically ill patients remains a complex decision that requires individualization of care. No data exist to establish a standard time when tracheotomy must be performed to avoid airway injury related to continued translaryngeal intubation. Moreover, the risks of performing tracheotomy are acceptably low so that it can be safely applied when patients appear likely to benefit from the procedure. Recommendations to "calendar watch" and avoid tracheotomy if at all possible for at least 14 to 21 days because of its attendant risks have become obsolete. Patients should be selected for tracheotomy by considering the unique circumstances of the patient at hand and the likelihood based on existing studies that the benefits of tracheotomy outweigh its inherent risks as compared with the competing risks of prolonging translaryngeal intubation (Table 40-3). Patient and family values and preferences should also influence the decision.

In considering potential benefits, a tracheotomy provides opportunities to improve a patient's comfort and sense of well-being.[316–318] For patients receiving intravenous sedation, some,[319,320] but not all,[316,321] studies indicate that drug requirements to maintain comfort are decreased after tracheotomy. By freeing the oropharynx, tracheotomy promotes oral hygiene and nutrition and facilitates articulated speech,[322–325] allows early mobilization,[312,326] and permits transfer from the ICU to more comfortable and family-centered settings for patients who remain ventilator dependent.[327] More effective oral care and decreased sedative requirements may decrease risks of ventilator-associated pneumonia.[328,329] The largest available randomized trial that assessed impact of tracheotomy timing on pneumonia risk, however, reported no differences between patients undergoing early versus late tracheotomy.[315]

The shorter length and rigid structure of tracheotomy tubes have been stated to decrease airway resistance and promote weaning from mechanical ventilation.[330,331] The resistance to airflow of translaryngeal endotracheal tubes in situ increases beyond in vitro predictions because thermolabile tubes assume angulated configurations and become inspissated with secretions, both of which promote turbulent airflow.[332,333] Studies conflict, however, about whether or not the lower measured resistance of tracheotomy, as compared with endotracheal tubes, produces meaningful benefits. Lin et al noted no clinically important differences in pulmonary mechanics before and after tracheotomy.[334] Three studies, however, noted small decreases in work of breathing after tracheotomy that became more significant with increasing respiratory rates, in addition to decreases in airway resistance, pressure–time product, and auto–positive end-expiratory pressure.[335–337] No changes in tidal volume, respiratory rate, or dead space ventilation were observed.[335–338]

Tracheotomy provides an opportunity to further decrease work of breathing by removing the inner cannula during spontaneous breathing weaning trials.[339] Enhanced ability to suction through a tracheotomy may promote removal of airway secretions, which increase airway resistance of endotracheal tubes; decreased secretions may promote weaning from mechanical ventilation for patients with borderline ventilatory reserve.[336,340]

Most prospective randomized trials report that early tracheotomy within 7 days of intubation decreases duration of mechanical ventilation.[4,315,320,327,341–344] Prospective studies of early tracheotomy also decreases ICU stay, possibly by promoting weaning and allowing transfer of ventilated patients with a stable airway to the wards.[4,315,320,327,344] Some retrospective[10,345,346] and prospective[347] cohort studies indicate that earlier tracheotomy decreases total hospital stay. Other

TABLE 40-3: COMPLICATIONS AND DISADVANTAGES OF PROLONGED TRANSLARYNGEAL INTUBATION

Airway perforation
Aspiration pneumonia
Cricoid cartilage abscess
Damage to intrinsic laryngeal muscles
Dislocation or subluxation of the arytenoid
Granulation tissue forming interarytenoid adhesion
Healed fibrous glottic nodules
Inadvertent extubation

Nasal septal fractures with nasotracheal intubation
Nosocomial sinusitis
Otitis media
Oversedation
Patient discomfort
Posterior glottic stenosis
Subglottic stenosis
Tracheal stenosis
Ulcerative lesions of the nares and pharynx
Vocal cord fixation from fibrosis of the cricoarytenoid joint
Vocal cord laceration
Vocal cord paralysis
Subglottic web formation

retrospective studies note no differences in hospital length of stay.[348,349] Of note, however, the largest prospective randomized trial to date of early tracheotomy did not find any effect on duration of hospital stay even though time in the ICU was decreased.[315] This study, however, excluded patients with chronic obstructive pulmonary disease and pneumonia. If future randomized studies demonstrate tracheotomy does not decrease hospital stay, any decreases in duration of ICU stay would be expected to result in only small total decreases in total costs of hospitalization.[350]

One randomized trial of early PDT reported decreased hospital mortality for patients in medical ICUs who received early (32% mortality, 2 days before tracheotomy) versus late (62% mortality, more than 14 days before tracheotomy) PDT.[320] The study, however, limited enrollment to patients with an Acute Physiology and Chronic Health Evaluation score of greater than 25, which limits its generalizability to patients with lower mortality risks.[351] Other prospective trials[4,315,316,327,341,343,344] and a retrospective review of a large dataset[352] demonstrate no mortality benefit. Most retrospective and prospective studies of trauma and burn patients report no benefit on mortality between early and late tracheotomy.[236,341,343,344,346,348,349,353–357] Guidelines exist, however, that recommend early tracheotomy for trauma patients estimated to require ventilation for more than 7 days.[358]

Inadvertent extubation occurs in 8.5% to 21% of ventilator-dependent patients[317,359–361] and exposes patients to risks of adverse cardiopulmonary events that include nosocomial pneumonia.[360,362–364] Tracheotomy decreases the risk of self-extubation.[319,320,360,365]

Tracheotomy allows removal of a translaryngeal endotracheal tube and interrupts ongoing injury by the endotracheal tube to intralaryngeal structures. Risks of prolonged translaryngeal intubation include oropharyngeal injury, pressure necrosis of the larynx resulting in subglottic stenosis, and nosocomial sinusitis.[366–368] The decision to perform tracheotomy would be simplified if evidence existed that the risk of laryngotracheal injury correlated with duration of endotracheal intubation. Aggregate data indicate that some degree of clinically important laryngeal injury occurs in 10% to 19% of patients managed with prolonged translaryngeal intubation.[369] It is not clear, however, that laryngeal injury can be predicted by the duration of endotracheal intubation or the detection of acute airway lesions in intubated patients.[370–373] No support exists, therefore, that "calendar watching" with the performance of tracheotomy after a specific duration of translaryngeal intubation prevents long-term airway injury.

In contrast to calendar watching, many clinicians endorse "the anticipatory approach" to timing tracheotomy that tailors the decision to perform a tracheotomy to an individual patient's unique needs.[308,369,374,375] With this approach, the decision to perform of tracheotomy centers less on "when" tracheotomy should be performed and more on "for whom." Patients with respiratory failure first receive necessary critical care to allow stabilization. Patients who appear likely to achieve extubation within the first several days of ventilation are not considered for tracheotomy. If patients remain ventilator dependent for several days and appear likely to require ventilation for 7 or more days, a tracheotomy can be considered. The actual decision to perform the procedure, however, depends on multiple patient-dependent factors that determine whether the patient will likely experience the benefits associated with tracheotomy and on patient and family values. The decision can usually be made for most patients within the first week of intubation.[376]

The anticipatory approach requires daily reassessments of patients to estimate the likelihood that weaning and extubation remains unlikely because the accurate prediction of prolonged ventilation with various scoring systems remains elusive.[6,315,377–390] A standardized protocol to assess patients for tracheotomy may result in more appropriate application of the procedure and less practice variation.[391]

SPECIAL PATIENT CARE CONSIDERATIONS

After tracheotomy, ventilator-dependent patients benefit from a well-organized treatment plan and an interdisciplinary team experienced in tracheotomy management. Skills in evaluating patients for oral communication and nutrition, avoiding airway-related complications, initiating an airway weaning protocol, and recognizing complications after decannulation improve patient outcome.[392] These skills are especially important as pressures increase for earlier transfer of patients with tracheotomy tube to wards or intermediate care units.

Management of Tube Cuff Pressure

Tube cuff pressures should be maintained between 18 mm Hg (approximately 24 cm H_2O) to 25 mm Hg (approximately 34 cm H_2O). Cuff pressures greater than 25 mm Hg can tamponade mucosal capillaries and cause mucosal ischemia, leading to tracheal stenosis.[393] Intracuff pressures below 18 mm Hg may promote microaspiration and nosocomial pneumonia.[394–396] Various techniques exist to estimate cuff pressure, such as finger palpation of the external inflation bulb, minimal occlusive volume, and subjective assessment of tension required on a syringe to inflate the cuff. None, however, reliably substitutes for direct cuff pressure measurements with a pressure gauge.[397–401] In the absence of routine cuff pressure monitoring, up to 45% of critically ill patients have excessively high endotracheal tube cuff pressures.[402] Unfortunately, use of manometry to monitor cuff pressure does not ensure the avoidance of excessively high inflation pressures because of measurement practice variation.[403,404] Chest radiographs can detect overdistension of the tracheal lumen by a hyperinflated cuff and provide an additional safeguard against overinflation.[405] Tube cuffs from different manufacturers may seal airways at different pressures.[406]

Several factors contribute to elevated cuff pressure. High peak airway pressures externally compress the cuff surface raising intracuff pressure and tracheal wall tension.[407] Patients undergoing general anesthesia experience a rapid increase in cuff pressure as anesthetic gases infuse into the air-filled cuff.[408] An inappropriately small tracheotomy tube can also cause increased tracheal wall tension with resultant delayed airway stenosis by necessitating cuff overinflation to maintain an airway seal.[409] Elevated cuff pressures may signify the presence of tracheal dilation (e.g., tracheomalacia), which requires cuff overdistension to produce a seal.[274] Transport to high altitude can also increase cuff pressure.[410]

Standards of respiratory care call for recording cuff pressures measured by a calibrated device and recording pressures once a shift or whenever the tube is changed or other events occur that may alter cuff pressure.[411] Cuff pressure should be monitored with the use of a syringe, stopcock, and manometer that allow simultaneous communication between all three compartments while pressure is being adjusted and measured.[411] Use of the minimal leak technique or palpation of the pilot balloon is not recommended.[409,411]

Swallowing

Normal swallowing is a complex physiologic event comprised of simultaneous and sequential contractions of muscles of the oral–facial region, pharynx, larynx, and esophagus. To initiate swallowing, upward and backward motion of the tongue moves a food bolus to the posterior oral cavity or oropharynx,[412–414] where stimulation of neuroreceptors triggers pharyngeal swallowing and halts respiration, typically in the expiratory phase.[415–418] The pharyngeal swallow comprises five overlapping events that protect the airway and clear the pharynx of ingested material. These events are (a) elevation and retraction of the soft palate, (b) elevation and anterior displacement of the hyoid bone and larynx, (c) laryngeal closure, (d) pharyngeal contraction, and (e) opening of the pharyngoesophageal region.[412,419–424]

Contraction of the pharyngeal constrictors occurs coincident with forceful retraction of the tongue, which propels the bolus posteriorly to assist pharyngeal clearance.[424] Contractions of the thyrohyoid and submental extrinsic tongue muscle group elevate and move forward the hyoid bone and larynx as a functional unit. This hyolaryngeal complex movement closes the larynx to prevent aspiration and pulls the cricoid cartilage anteriorly and away from the posterior pharyngeal wall, thereby opening the pharyngoesophageal segment region to permit entry of the bolus into the cervical esophagus.[420–426] The pharyngoesophageal segment becomes compliant by synchronized relaxation of the cricopharyngeal muscle. The larynx then descends toward its resting position and respiration resumes characterized by a small expiratory airflow.[415–417] Once in the cervical esophagus, the bolus is propelled by primary and secondary esophageal peristaltic muscle contractions.[427,428] These contractions continue until the bolus progresses into the stomach through the passively relaxed lower esophageal sphincter.

A tracheotomy tube and/or inflated cuff may interfere with the mechanics of swallowing (Fig. 40-5). A tube can anchor the hyolaryngeal complex and prevent its normal excursion during swallowing causing incomplete airway closure and penetration of liquid and food into the laryngeal vestibule with aspiration below the vocal folds.[429,430] Prevention of the normal upward and forward mobility of the hyolaryngeal complex impedes anterior displacement of the cricoid cartilage leading to incomplete opening of the cervical esophagus and retained pharyngeal contents, which may be aspirated into the open airway after completion of the swallow. An inflated tube cuff may disturb esophageal motility and slow esophageal clearance causing retrograde flow of ingested material into the pharynx with aspiration. Coexisting gastroesophageal reflux disease with esophageal refluxate increases the risk for aspiration.[431] Preexisting translaryngeal intubation presents an additional risk factor for aspiration even in patients who do not progress to tracheotomy with more than 50% of patients experiencing dysphagia after prolonged translaryngeal intubation.[432]

Tracheostomized patients at risk for aspiration should undergo a systematic assessment to determine the nature of any swallowing disorder to prevent aspiration and facilitate weaning to decannulation. Coordination of services between speech therapists and critical care providers provides resources for assessing aspiration risk, monitoring the extent of aspiration, and managing risk to prevent complications during tracheotomy use, weaning, and postdecannulation (Table 40-4).[433–436]

Nutrition

Feeding patients with a tracheotomy through a nasoenteric tube increases the risk of aspiration and pneumonia. Up to 69% of patients with a tracheotomy aspirate at least once every 48 hours regardless of mental status.[395,437]

Although a tracheotomy offers opportunities to resume an oral diet, patients recovering from critical illness with a tracheotomy in place commonly have severe swallowing dysfunction,[242,438,439] either from underlying disease or effects of the tube itself.[440,441] Before resuming oral feeding, patients should undergo evaluation by an interdisciplinary team that includes a speech-language pathologist trained in swallowing assessment.[433,441,442]

Communication: Voice, Speech, and Language

A tracheotomy disrupts normal speech production. For patients previously intubated with an endotracheal tube, however, a tracheotomy may improve patient well-being by increasing options for communication.[375,433,443–448] Personal isolation and an inability to communicate during mechanical

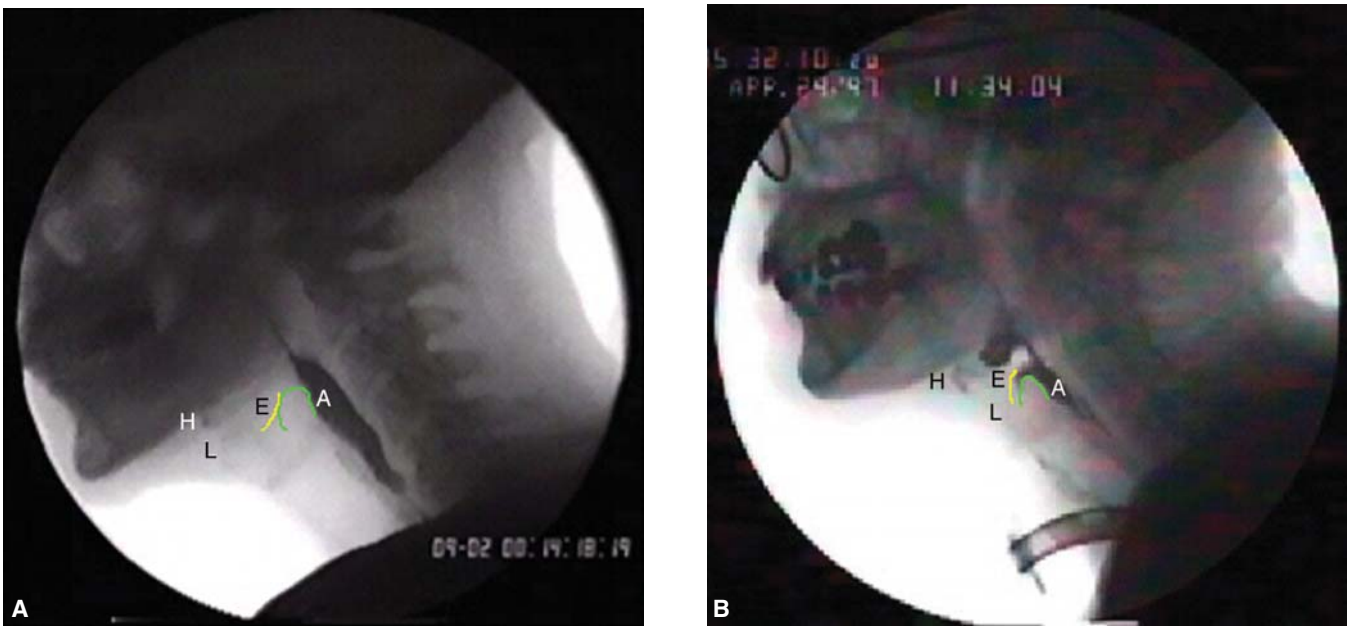

FIGURE 40-5 **A.** Superior and anterior displacement of the hyoid (*H*) and larynx (*L*) results in approximation of the arytenoid cartilages (*A*) and epiglottic petiole (*E*), and release of the posterior cricoid area from the posterior pharyngeal wall. **B.** The hyoid (*H*) and larynx (*L*) are anchored by the inflated tracheotomy tube cuff leading to incomplete approximation of the arytenoid cartilages (*E*) to the epiglottic petiole (*E*) with resultant penetration, aspiration, and incomplete opening of the cervical esophagus.

ventilation are leading factors in increasing anxiety in patients, families, and health care providers.[324,325,444,448–451]

Several techniques for promoting verbal communication can be tailored to the individual patient's ability to participate in speech therapy. Patients may also graduate through increasingly more complex techniques as medical conditions allow. Table 40-5 outlines the clinical features and applications of these techniques.

TABLE 40-4: CLINICAL WARNING SIGNS SUGGESTIVE OF SWALLOWING IMPAIRMENT AND ASPIRATION

- Adventitious lung sounds
- Articulatory imprecision
- Breathy vocal quality
- Decreased frequency of swallow
- Decreased laryngeal sensation
- Decreased orofacial sensation
- Delayed cough

Patients undergoing positive-pressure ventilation with moderate to low minute ventilation requirements may be able to whisper during brief periods of partial cuff deflation. Patients mechanically ventilated because of neuromuscular disease can be managed by a cuffless or fenestrated tracheotomy tube during positive pressure ventilation and retain the ability to speak.[452–454] A portion of the ventilator-delivered tidal volume enters the lower trachea and flows around the tracheotomy tube toward the upper airway during inspiration allowing the patient to talk.

The above approach limits speech to inspiration and a short portion of expiration. Speech throughout the respiratory cycle can be promoted by partial cuff deflation as described above, prolongation of the ventilator's inspiratory phase, and application of low levels of positive end-expiratory pressure.[443,455,456] The resultant continuous air leak around the cuff allows more spontaneous speech.[457] Pressure-support ventilation in the presence of a leak around a tracheotomy tube causes an increase in inspiratory time and volume,[458–460] both of which may theoretically assist speech production.

Specialized tracheotomy tubes, termed *pneumatic speaking tubes* or *talking tubes,* promote speech by supplying pressurized gas mixtures to the trachea above the tube cuff.[461–464] The gas escapes through the glottis allowing whispered or vocalized speech. A pressurized gas source is connected to

TABLE 40-5: METHODS OF COMMUNICATION FOR INTUBATED PATIENTS

Communication Option	Advantages	Disadvantages	Considerations	Select Patient Use
Lip reading, mouthing	• Follows a natural communication style • Closely resembles normal speech movement • Limited training required • Makes use of oral motor functions • Allows for natural production of facial expression • Communication letter board assists communication	• Decreased understanding of mouthed messages • May result in patient frustration • Unnatural for patient to decrease rate and length of message • Very limited for orally intubated patients	• Patient should be alert • Requires intact motor functioning • Works best for nasally intubated patients • Requires proper tube taping technique in orally intubated patients for maximal oral movement • Patient at times requires encouragement to mouth words • Patients often require cueing to decrease rate and length of messages	• Can be used with a variety of nonparalyzed patients • Can be used with patients who are unable to use other alternatives for communication
Gestural language (yes–no [Y–N] responses, facial expressions, hand gestures)	• Y–N responses result in effective and rapid communication of basic needs • Appropriate facial expressions can greatly enhance communication and emotion • Message intent is usually understood	• Limited interpretation • Difficulty expressing complex or lengthy messages • Requires coordination and dexterity	• Establish Y–N response mode and communicate to staff and family (strive for natural Y–N responses with head nods) • Patients may require encouragement to use consistently	• Especially helpful for patients with oral intubation and/or oral motor dysfunction
Written communication	• Can be used for effective expression of basic needs and wants	• Timely method of communication • Requires significant patient endurance and alertness • Limited expression of complex ideas and emotion • Often difficult to read patient writings • May require staff assistance • Requires interpretation (language, writing style, etc.) by receiver	• Requires: motor coordination, strength of upper extremity, use of arm free from medical restraints, adequate visual acuity and perception, and supplies at bedside • May require prepositioning for writing comfort and visibility • Use a felt-tip marker or other antigravity dark marking device • Provide a clipboard for firm writing surface • Provide glasses before writing attempts	• Can be used as an alternative to other communication options

Communication boards (picture, alphabet, and word boards)	• Effective communication of basic needs	• Timely communication process • Communication limited to items on board • High degree of frustration with alphabet use • Requires coordination for pointing response • Requires intact visual acuity/ perception • Potential source of contamination when board used from room to room • Requires immediate accessibility, patient training, and staff patience	• Provide glasses to prescription lens wearers • Board should be kept at bedside • Position board and size of characters to meet patient's needs	• Can be used with a variety of nonparalyzed patients • Can be used with patients who are unable to use other alternatives for communication
Augmentative communication devices ("parrot," "voice-aided," "text-to-speech" computer software and tablet apps, direct selection, and scanning devices)	• Effective communication of *basic* needs but newer software (i.e., tablet apps) capable of sophisticated touch screen text-to-speech • Provides a programmed speaking voice when text selected or typed • Communication programs can be highly individualized to the patient • Easy access to provide complete phrases • Provides a means for more sophisticated, complex communication • Requires minimal energy once patient is familiar with device • Timely communication process	• Must be programmed or existing software modified to meet patient needs • Communications limited to items on the board or touchscreen unless patient can type • May be frustrating because of limited options or difficulty with typing or use of touchscreen • Requires operator training • Requires concentration for selection of appropriate phrases • Requires coordination for pointing response • Potential source of contamination if device is used from room to room • Requires visual acuity • Requires maintenance (software update, battery charging, electrical safety, repairs) • May be costly to the patient (equipment, support of speech therapy)	• Patient and family need to be included in programming and selection of communication choices • Provide glasses to prescription lens wearers • Device should be kept at the bedside	• Can be used with a variety of nonparalyzed patients • Can be used with patients who are unable to use other alternatives for communication

(*continued*)

TABLE 40-5: METHODS OF COMMUNICATION FOR INTUBATED PATIENTS (*CONTINUED*)

Communication Option	Advantages	Disadvantages	Considerations	Select Patient Use
Electrolarynx with or without oral adapter and intraoral electronic larynx (multiple brands)	• Provides a voice without using vocal cords • Provides auditory component to speech productions for better understanding • Allows verbal communication of basic needs and emotions • Makes use of oral motor functioning • Useful when tracheotomy cuff cannot be deflated for other speaking techniques	• Poor mechanical quality of voice (monotonal) • Requires assistance from staff, significant patient and staff training, dexterity and hand coordination, and intact oral and motor functioning • Patient must be alert and cooperative • Patient must have energy reserve to use effectively • Oral adapter may be uncomfortable and awkward	• Dentures should be in place • Mouth and lips should be moist • Demonstrated technique to patient and family and allow for return demonstration • Allow time for experimentation for this and other options (including oral adapter)	• To be used with tracheotomy patients (free use of mouth for motion)
Deflated/cuff leak methods (cuff leak on ventilator, T-piece)	• Allows use of own voice through vocal cords' natural communication styles • Results in efficient communication • Requires minimal staff assistance if patient can tolerate deflation • No cost requirements	• May be limited to use for short periods depending on tolerance level of patient • Requires staff assistance to deflate and monitor cuff • Methods contraindicated for acute or medically unstable patients • Requires intact oral motor functioning and respiratory reserve • Requires staff training (to monitor cuff pressures and exhaled volumes)	• Patients must be alert • Patients with copious secretions should be suctioned before deflation • Procedure must be fully explained to the patient • Ventilator-dependent patients require cueing for proper voice initiation • T-piece users must have T-piece occluded for voice to be audible • Ventilator adjustments often needed	• For use with ventilator patients who are stable with cuff leak/deflation and who have complex communication needs • Excellent for chronic/long-term ventilator and tracheotomy patients (especially nonventilator-dependent patients) • Nasotracheal or T-piece patients (stable respiratory status)
Tracheotomy phonation valves (Olympic, Passy-Muir, Boston Medical)	• Allows for phonation and production of patient's own voice • Natural communication method • Some can be used on ventilated patients	• May be limited to use for short periods • Requires staff assistance to plug in most patients • Requires intact oral and motor functioning • Patients without respiratory reserve may not tolerate • Works poorly on patients with stiff lungs or with copious secretions	• Provide support and encouragement during initial valve applications • Close observation is required • Valve is routinely removed when not in use in acute setting	• For use in long-term and chronic tracheotomy patients • Some may be used for ventilated patients

a cannula that travels through the wall of the tracheotomy tube and exits at its greater curvature. A gas flow rate of 1.5 to 10 L/min successfully produces intelligible speech in 75% of properly selected patients.[465] Prognostic indicators for successful use of pneumatic speaking tubes include adequate mental status, availability of a well-trained speech-language pathologist for training and positive reinforcement, absence of laryngeal pathology such as vocal fold paralysis, patient motivation, and encouragement from the critical care staff and patient's family.[466]

Pneumatic speaking tubes may fail because the pressurized gas may flow retrograde through the tracheostoma around the tube. Because this retrograde flow can cause subcutaneous emphysema in patients with recent tracheotomies, pneumatic tubes are contraindicated during the first 5 to 7 days after surgery. Pneumatic tubes may also fail because secretions or granulation tissue above the cuff may occlude the exit port for gas flow.[467]

Other complications of pneumatic speaking tubes include desiccation and inflammation of laryngeal mucosal structures caused by the drying effect of the gas flow. Warming and humidification of the gas source along with intermittent use of the technique can prevent the onset of laryngitis. An air mixture rather than pure oxygen should be used to avoid further airway injury from hyperoxia.[468]

An "electrolarynx" is a valuable device for promoting speech that has a high rate of success in critically ill patients with a tracheotomy.[469,470] These devices consist of a vibrator unit with an attached handheld battery pack that generates a vibratory tone with variable loudness and pitch. Held firmly against the patient's neck midway between the mandibular angle and the notch of the thyroid cartilage or attached with an intraoral stem that applies intraoral vibrations when inserted through the mouth, the electrolarynx substitutes for the vocal cords as an amplifier for speech. More than 90% of mentally alert patients with a tracheotomy can learn to use an electrolarynx successfully.[469] Critical care team members may require frequent in-servicing on correct application of the device because of the loss of enthusiasm that develops when patients do not quickly learn the technique.

Patients being weaned from mechanical ventilation who have achieved periods of spontaneous ventilation can speak with the assistance of a fenestrated tracheotomy tube.[457] Fenestrated tubes with an inner cannula can provide airway access for mechanical ventilation and a system for speech when the inner cannula is removed. Occlusion of the tracheotomy tube with a gloved finger or plug can divert airflow through the upper airway allowing whispered or vocalized speech. Deflation of the tube cuff can further improve expiratory airflow through the larynx.

A fenestrated tracheotomy tube can also be combined with a one-way "phonation valve" (e.g., Passy-Muir valve, Passy and Passy, Irvine, CA) that allows inspiratory airflow through the tube but closes during expiration diverting airflow through the larynx (Fig. 40-6).[471] Phonation valves can be applied to the tracheotomy tube of spontaneously breathing patients and patients undergoing positive pressure ventilation. In the latter setting, it is essential that the patient is being ventilated with the tracheotomy cuff deflated and no upper airway obstruction exists. Commercially available one-way valves vary in their airflow resistive properties[464,472] and effectiveness for promoting understandable speech.[473]

FIGURE 40-6 Passy-Muir one-way valves that allow articulated speech through the native airway for spontaneously breathing patients with a tracheotomy or patients undergoing mechanical ventilation through a tracheotomy tube. (Courtesy Passy-Muir Tracheotomy Valves, Passy-Muir Inc., Irvine, CA).

Weaning from Tracheotomy and Decannulation

Patients recovering from prolonged respiratory failure may either tolerate rapid decannulation or require stepwise tracheotomy weaning. The presence of underlying cardiorespiratory or neuromuscular disease increases the likelihood that a period of weaning will be required.

Evaluation for decannulation begins with an interdisciplinary evaluation after the patient demonstrates success with spontaneous breathing for 48 hours.[474] Persistent difficulties with spontaneous ventilation through the tracheotomy tube may occur if the tube is malpositioned in the airway causing partial obstruction[256] or has a narrow internal diameter. Unfortunately, guidelines do not exist to inform clinical practices and extensive practice variation occurs between centers in evaluating patients for decannulation.[475] Moreover, standardized decannulation protocols akin to protocols for weaning patients from mechanical ventilation have not been adequately studied to determine their effectiveness.[14,391,476,477] Extensive practice variation occurs, therefore, with weaning patients from tracheotomy.[478]

Essential criteria for considering patients for decannulation include level of consciousness, cough effectiveness, volume of airway secretions, oxygenation, effectiveness of swallowing, and ability to breathe spontaneously with the tracheotomy tube capped.[479] The ability to manage secretions is assessed by deflating the tube cuff and observing the patient for clinical signs of aspiration or retained secretions.[480] Capping the tracheotomy tube and observing the patient during spontaneous respiration for 30 minutes allows evaluation for the presence of upper airway obstruction.[481,482] Increased inspiratory effort, stridor, or dyspnea provide evidence that the patient might benefit from

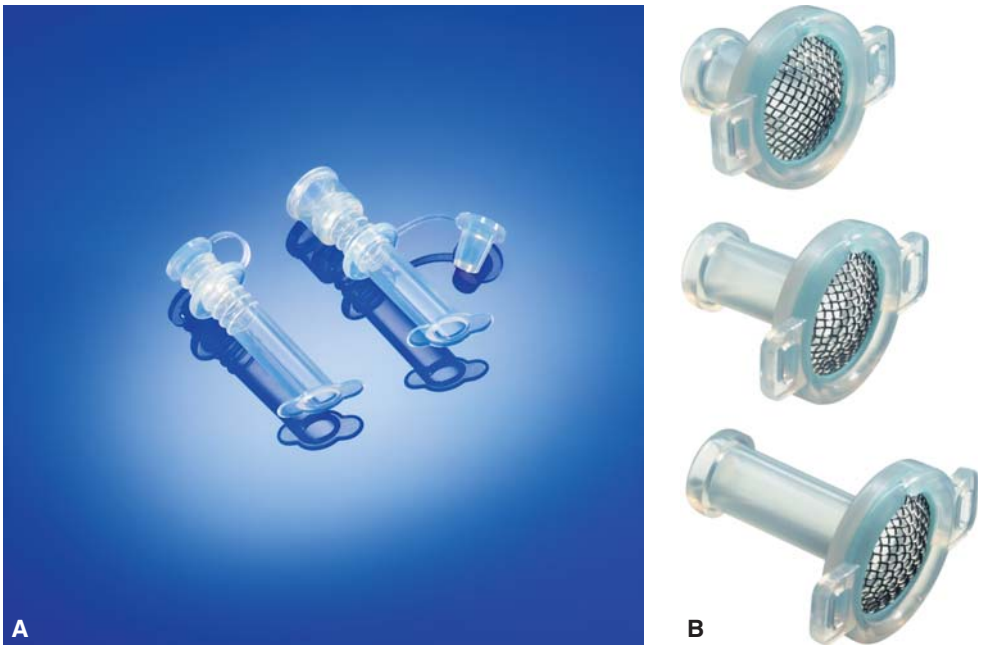

FIGURE 40-7 A stoma stent can maintain patency of the stoma after tracheotomy tube decannulation for patients who require ongoing airway access for suctioning or replacement of a tracheotomy tube if failure of decannulation occurs. Some stents are more adaptable for either long-term use (**A**, Montgomery Long-Term Cannula, courtesy Boston Medical Products, Westborough, MA) or shorter-term use (**B**, TRACOE Stoma Button, courtesy TRACOE Medical, Frankfurt, Germany), but each has allied attachments to promote articulated speech or provide oxygenation with humidification.

downsizing the tracheotomy tube[477] or tracheoscopy to evaluate for vocal cord or subglottic abnormalities.[482] Some centers routinely examine the airway by fiber-optic endoscopy before decannulation.[483] Difficulty with spontaneous breathing while the tracheotomy is capped in the absence of airway abnormalities may indicate ventilator muscle weakness and potential benefits from weaning toward cannulation with a capped tracheotomy tube supplemented by noninvasive face-mask ventilation.[484]

Patients with moderate airway secretions and severely compromised lung function may not tolerate spontaneous breathing with partial obstruction of their airway with a tracheotomy tube. Such patients may benefit from a tracheotomy plug, also termed *stoma stent* or *stoma maintenance device,* which frees the airway but allows airway suctioning and maintenance of the stoma track for reinsertion of a tracheotomy tube if needed (Fig. 40-7).[411]

After prolonged ventilation, the failure rate of decannulation ranges from 5% to 20%.[485] Up to 40% of patients may require translaryngeal intubation with readmission to the ICU.[485] Most patients fail within the first 4 to 24 hours with retained secretions representing the major factor.[485]

PATIENT PROGNOSIS AND QUALITY IMPROVEMENT

Patients who require tracheotomy for respiratory failure have a worse prognosis as compared with other ventilator-dependent critically ill patients and experience substantial health care costs.[486] They represent the most resource-consuming diagnostic categories for many acute care hospitals.[487,488] Their hospital mortality rate ranges from 49% to 78% if they undergo tracheotomy in the ICU.[6,489–491] Among those who survive hospitalization, 24%, 30%, and 42% are no longer alive at 100 days, 6 months, and 2 years after discharge, respectively,[489] and the presence of a tracheotomy is an independent predictor of long-term functional debility[492] and mortality.[493] If decannulation occurs before hospital discharge, 92% of patients are alive 1 year later,[489,494–496] but lack of decannulation before transfer from the ICU to a ward has an independent association with hospital mortality[497,498] with highest mortality among patients with obesity or neurologic injuries. Among mixed medical and surgical patients who survive acute hospitalization after tracheotomy, 57% are successfully weaned and 30% decannulated before hospital discharge.[489] At 1 year, 9% of patients who require prolonged mechanical ventilation have no functional dependency, 26% are alive with moderate dependency, and 65% are either alive with complete functional dependency or dead.[486] Older patients with more comorbid conditions are more likely to require discharge to post–acute care facilities.[486] Incremental costs per quality-adjusted life-year exceed $100,000 in older age groups.[499]

Unfortunately, clinical outcomes are significantly worse than projected by patients' surrogates and physicians at the time they make the decision to proceed with tracheotomy.[500] Efforts to develop predictive models to estimate long-term outcomes for critically ill patients being considered for tracheotomy have had variable results.[388,498,501]

Unfortunately, specialist clinicians in the ICU demonstrate practice variation for tracheotomy care that often does not conform to best clinical practices[310,502] and delays decannulation.[503] Combined with increasing trends for earlier transfer of patients from the ICU to hospital wards and post–acute care hospitals, an increasing number of patients with a tracheotomy are managed outside of the ICU by providers with limited knowledge and skills in airway care.[14,504,505] Some centers have approached this challenge to quality care by developing interdisciplinary teams that provide tracheotomy care both in the ICU and after transfer to a non-ICU setting.[15,392,474,506–508] Studies are limited regarding the impact of tracheotomy teams on patient outcomes, but a recent meta-analysis reported that all existing studies found that tracheotomy teams decreased time to decannulation, length of stay, and adverse events.[509]

COMPLICATIONS ASSOCIATED WITH MECHANICAL VENTILATION

Karin A. Provost
Ali A. El-Solh

Critically ill patients are at risk of succumbing to their primary disease or the undesired sequelae associated with their therapy. Although frequently lifesaving, the use of positive airway pressure therapy has numerous undesired physiologic and clinical complications. These complications have their origins in the endotracheal or tracheostomy tube, the positive-pressure ventilation (PPV), or from therapies delivered during the care of mechanical ventilation. Other complications may result from coexisting illness or comorbid conditions. Although not commonly recognized as important effects of PPV or positive end-expiratory pressure (PEEP), alterations in organ functions ought to be recognized and addressed accordingly to reduce morbidity and mortality.

GASTROINTESTINAL TRACT COMPLICATIONS

The interaction between PPV and the gastrointestinal tract in critical setting is a complex one. Gastrointestinal changes are reported frequently in critically ill patients receiving PPV. The true incidence of gastrointestinal complications is not known, but it is reported to be up to 100% for those receiving PPV for more than 3 days. Splanchnic hypoperfusion seems to play a pivotal role in the pathogenesis of these complications, including mucosal damage, motility disorders, and mesenteric ischemia (Fig. 41-1).[1] Unlike many other vascular beds, the splanchnic exhibits limited autoregulation when faced with reduction in mean arterial pressure.[2] Without altering total blood flow to the organs of the digestive tract, sympathetic stimulation redistributes blood flow to the muscularis of the wall by decreasing mucosal perfusion.[3] This poses severe ischemic changes to the mucosal layer because the mucosa is metabolically more active than the muscle layer and is more vulnerable to the destructive effects of a compromised blood supply.

Mechanical ventilation influences the gastrointestinal function by impacting systemic hemodynamics via high PEEP or potentially injurious ventilator strategies such as a high tidal volume (V_T). The effect of PEEP on splanchnic

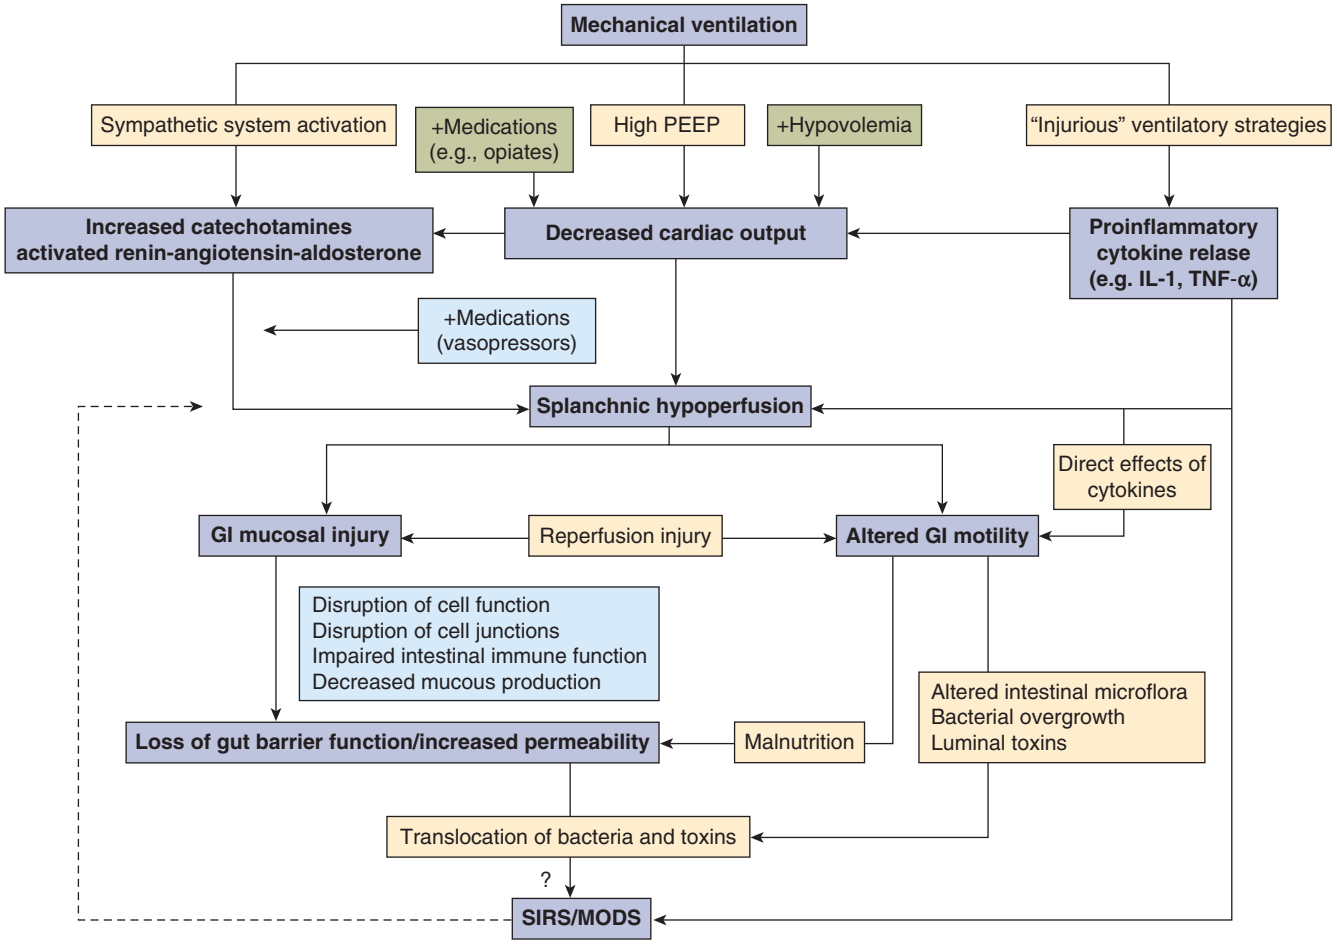

FIGURE 41-1 Suggested mechanisms for the development of gastrointestinal (GI) complications during mechanical ventilation. *IL,* interleukin; *MODS*, multiple-organ dysfunction syndrome; *PEEP*, positive end-expiratory pressure; *SIRS*, systemic inflammatory response syndrome; *TNF*, tumor necrosis factor. (Used, with permission, from Mutlu.[1])

blood flow has been shown in animal models to be dose-dependent.[4] PEEP decreases venous return and reduces preload, which in turn reduces cardiac output and results in splanchnic hypoperfusion.[5] The reduction of splanchnic blood flow is limited at PEEP levels below 10 cm H_2O but it is more pronounced at PEEP levels of 15 to 20 cm H_2O.[6] In rats, the addition of 10 cm H_2O of PEEP resulted in reduction of cardiac output and mesenteric blood flow by 31% and 75%, respectively.[7] PEEP also promotes plasma-renin-angiotensin-aldosterone activity, as well as catecholamine release, which limits splanchnic hypoperfusion.[4,7] Interestingly, high PEEP levels interfere with mesenteric leukocyte–endothelial interaction. In rats with healthy lungs, 10 mbar of PEEP was associated with an increase in the number of rolling, adherent, and migrated leukocytes when compared with anesthesia alone or with mechanical ventilation with 0 or 5 mbar PEEP.[8]

Alternatively, mechanical ventilation with high V_T can modify the inflammatory responses irrespective of the underlying lung injury. Experimental data suggest that mechanical ventilation with high V_T and zero end-expiratory pressure induces not only cytokine release (tumor necrosis factor [TNF]-α and interleukin [IL]-8) but also translocation of cytokines from the lungs to the systemic circulation and vice versa.[9,10] These cytokines lead to a number of clinical sequelae in the gastrointestinal tract including splanchnic hypoperfusion and intestinal smooth muscle impairment.[11,12]

Indirectly, medications administered to patients on mechanical ventilation can have deleterious effects on gastrointestinal function. Opiates and sedatives, such as benzodiazepines, can decrease gut motility and impair venous return.[13] Other agents, like vasopressors or inotropes,[14,15] may alter hemodynamic parameters that, in turn, reduce mesenteric blood flow and put a critically ill patient at risk of developing stress-related mucosal disease.[4]

Stress-Related Mucosal Disease

EPIDEMIOLOGY

Stress-related mucosal disease is the most common cause of gastrointestinal bleeding in patients receiving mechanical ventilation. An estimated 74% to 100% of critically ill

patients have endoscopically detectable lesions in the gastric mucosa within hours after admission.[16,17] These lesions are most frequently reported in the acid-producing areas of the stomach in contrast to peptic ulcers, which are more common in the antrum and the duodenal bulbs. Overt stress-related gastrointestinal bleeding occurs in up to 5% of critically ill patients.[18] Other studies have demonstrated an even lower incidence of clinically significant bleeding, ranging from 0.17% to 1.5%.[19] The risk increases with increasing number of days of mechanical ventilation and length of intensive care unit (ICU) stay.[20] Other contributing factors include major surgery, head trauma, severe burns, sepsis, glucocorticoids, and renal and hepatic disease on admission.[20] Unsurprisingly, clinically significant gastrointestinal bleeding has been linked to prolonged ICU length of stay by as much as 11 days and to a markedly increased mortality, although the primary cause of mortality is attributable to the primary disease process rather than gastrointestinal hemorrhage.[20]

PATHOPHYSIOLOGY

The pathophysiology of stress-related mucosal disease underlines a complex interaction of opposing vectors (Fig. 41-2).[21] Under normal physiologic conditions, the integrity of the mucosa depends on a delicate balance between injurious factors (gastric acid, enzyme secretion) and protective mechanisms (mucous production, prostaglandins).[22] Gastric acid is considered essential for stress ulceration but it is not the sole factor in the pathogenesis of mucosal disease. In the setting of decreased splanchnic blood flow, oxygen radicals are released, prostaglandins synthesis is reduced, and nitric oxide production is exaggerated. These changes perpetuate the release of inflammatory cytokines and triggers cell death.[23] As a result, increased back diffusion of hydrogen ions and pepsin occurs without the mitigating effect of bicarbonate-rich mucous layer and the protective effect of prostaglandins. Collectively, the imbalance between the noxious gastric acid and the impaired reparative mechanisms

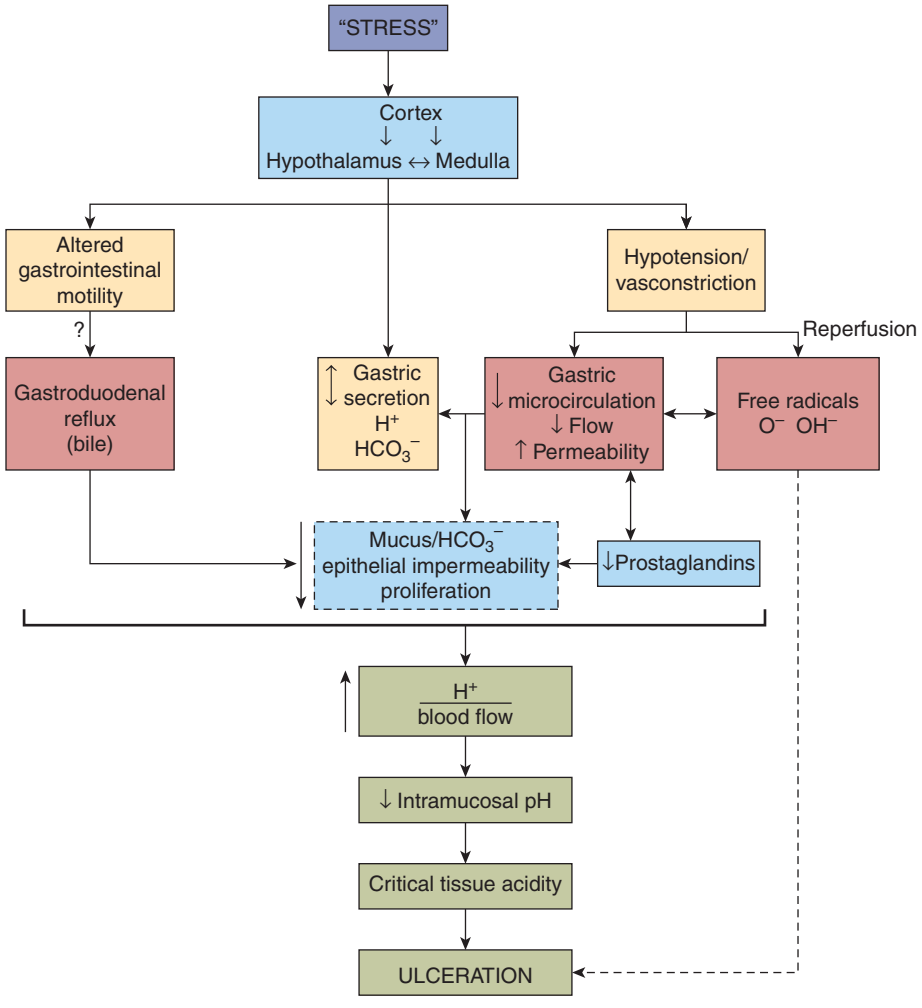

FIGURE 41-2 Proposed mechanisms for the development of stress ulceration during mechanical ventilation. (Used, with permission, from Bresalier.[21])

predisposes patients on mechanical ventilation to stress-related mucosal injury.

THERAPEUTIC INTERVENTIONS

The mainstay of the clinical management of stress-related mucosal bleeding in patients who are mechanically ventilated is prevention. Several classes of antistress agents have been introduced since antacids were first evaluated in 1976.[24] Antacids directly neutralize luminal gastric acid, bind pepsin and bile acids,[25] and may stimulate prostaglandin release from the mucosa.[26] The efficacy of antacids in preventing clinically significant stress-related bleeding has been demonstrated in randomized controlled trials.[27] The frequent dosing interval needed to achieve and maintain a pH greater than 4, however, is one of the disadvantages of this therapy. In addition to impairing the absorption of other medications, aluminum-containing antacids may be associated with hypophosphatemia and toxic aluminum levels in renal-failure patients, while magnesium-containing antacids may be associated with diarrhea and hypermagnesemia. Sucralfate is another agent that shields the gastric mucosa by forming a protective barrier from the acid in the gastric lumen, stimulating mucous and bicarbonate secretion, and enhancing prostaglandin release.[28] A meta-analysis of the efficacy of sucralfate compared with that of histamine-2-receptor antagonists and antacids for the prophylaxis of stress ulcers indicated that sucralfate was at least as effective as the other agents.[29] Sucralfate is generally well tolerated but may cause constipation, and aluminium toxicity may occur in patients with renal failure. Misoprostol, a synthetic prostaglandin E_1 analog with gastric cytoprotective and antisecretory properties, has also demonstrated effectiveness in preventing gastric injury and complications induced by nonsteroidal antiinflammatory drugs.[30] Its use is limited, however, by the high rate of diarrhea and the need for multiple daily doses.

The introduction of histamine-2-receptor antagonists and proton pump inhibitors eclipsed the use of antacids, and medications in these classes are currently the standard therapy for stress-related mucosal disease. Although continuous infusions may be more effective in suppressing gastric acid,[31] no studies have demonstrated improved safety, more effective prophylaxis, or a lower rebleeding rate with either method. A major concern of using histamine antagonists is the development of tolerance, which occurs within 42 hours after intravenous administration by both bolus and continuous infusion.[32] Histamine antagonists are also associated with adverse chronotropic and inotropic effects and, experimentally, may induce a dose-dependent coronary vasoconstriction.[25] The clinical significance of these effects is unclear.

Proton pump inhibitors irreversibly bind the hydrogen-potassium-adenosine triphosphatase, the enzyme responsible for secreting acid into the gastric lumen. Unlike histamine antagonists, proton pump inhibitors do not seem to develop tolerance with sustained therapy. Although both histamine antagonists and proton pump inhibitors can elevate intragastric pH to more than 4, proton pump inhibitors are more likely to maintain a pH above 6.[18] Yet in a meta-analysis of randomized, controlled trials that directly compared proton pump inhibitors with histamine antagonists in prevention of stress-related upper gastrointestinal bleeding in ICU patients, both agents were equally efficacious in preventing stress-related bleeding.[33]

The safety consideration of acid-suppressive therapies has been a concern after several studies suggested that acid-suppressive agents may increase the risk of pneumonia.[34,35] Numerous small studies[36,37] have examined this issue in ICU patients, but multicenter randomized studies did not demonstrate any significant difference in pneumonia rates between sucralfate and histamine antagonists[38] or between proton pump inhibitors and histamine antagonists.[33] Other potential adverse effects for acid-suppressing agents include higher rates of *Clostridium difficile*-associated diarrhea[39] and enteric infections.[40] None of these associations, however, have been confirmed in randomized trials.

Because acid injury may potentiate mucosal ischemic changes, enteral nutrition could potentially decrease stress ulceration by raising intragastric pH. Several studies in mechanically ventilated patients[41] and in burn patients[42] have associated enteral feeding with a lower incidence of stress-related bleeding. Other studies in critically ill patients, however, have demonstrated that enteral feeding does not have a significant effect on increasing gastric pH and therefore may be ineffective in affording gastroprotection.[43,44] Definite recommendations regarding the role of enteral nutrition for stress-ulcer prophylaxis are not possible at the present because of lack of prospective, randomized trials.

Motility Disturbances

Several studies indicate that abnormal gastrointestinal motility is common in mechanically ventilated patients.[45,46] The prevalence of abnormalities in gastric emptying is estimated to be as high as 50%.[15] Using manometric evaluation, it was demonstrated that the contractile activity of the stomach is severely depressed in patients receiving PPV—but persistent, albeit reduced, in the duodenum.[47] These abnormalities are thought to result from the dysfunction of the interstitial cells of Cajal that act as the controller of gastrointestinal motor activity.[48] Several factors are implicated in the pathophysiology of altered gut motility, including preexisting diseases, release of endotoxin[49] and corticotropin-releasing factor[50] during severe stress, and drugs routinely used in the management of patients on mechanical ventilation (e.g., sedatives and opioid analgesics, catecholamine vasopressors, anticholinergics, and α_2-adrenergic receptor agonists). Hyperglycemia has been considered as a risk factor to impair pyloric and antral contractions in healthy volunteers.[51] A relationship, however, between hyperglycemia and delayed gastric emptying remains unclear.

Current recommendations for the treatment of impaired gastrointestinal motility focus on optimizing fluid intake, correcting electrolyte disturbances, and minimizing the use

of drugs that slow gut motility. Prokinetic agents are not routinely recommended though a recent survey revealed standard prokinetic use in 39% of critically ill patients.[52] A combination therapy of erythromycin and metoclopramide provides the most effective regimen in improving the delivery of nasogastric nutrition.[53] Owing to a rapid tachyphylaxis following erythromycin or metoclopramide administration, however, therapeutic use should be limited to 3 days. Newer therapeutic approaches, such as μ-opioid receptor antagonists and cholecystokinin-1 receptor antagonists, hold promise in alleviating motility disorders but have not been studied so far in critical illness.

If treatment of gastric stasis fails or is contraindicated, the stomach can be bypassed with an intestinal feeding tube. Early enteral feeding can be more successful if feeds are delivered directly to the small intestine. Postpyloric tubes have been shown to be equally effective as prokinetic treatment in patients who failed nasogastric feeding,[54] but there is currently no evidence to support routine use of these tubes in critically ill patients.

Acalculous Cholecystitis

Acalculous cholecystitis is a serious and potentially life-threatening illness in critically ill ventilated patients if unrecognized. The condition accounts for 5% to 10% of all cases of acute cholecystitis.[55,56] The etiology of the disease remains unknown, although PPV for more than 72 hours is considered a risk factor.[55] Other predisposing conditions include shock, dehydration, multiple transfusions, total parenteral nutrition, and drugs (opiates, sedatives, ceftriaxone) (Table 41-1).[57,58] Clinical assessment may not be reliable, particularly in intubated and sedated patients. Ultrasonography remains the diagnostic test of choice, although computed tomography has the advantage of being more sensitive in diagnosing acalculous cholecystitis.[59,60] Evidence of gallbladder wall thickness greater than or equal to 4 mm, pericholecystic fluid or subserosal edema without ascites, intramural gas, or a sloughed mucosal membrane are considered diagnostic criteria for acute acalculous cholecystitis. Hepatobiliary scintigraphy is compromised by frequent false positives and is more helpful in excluding rather than confirming the diagnosis.[59] The mainstay of therapy for acalculous cholecystitis has been cholecystectomy, but for the critically ill patients percutaneous cholecystostomy is considered an alternative to open procedures.[61]

TABLE 41-1: PREDISPOSING FACTORS FOR ACALCULOUS CHOLECYSTITIS IN CRITICALLY ILL PATIENTS

Decreased motility
- Surgery
- Burns
- Mechanical ventilation
- Narcotic analgesics

Decreased cystic artery blood flow
- Arteriosclerosis
- Diabetes
- Shock
- Cardiac failure

Infection
- Salmonella
- Cholera
- Campylobacter
- HIV

Obstruction of cystic duct
- Lymphadenopathy
- Metastatic malignancy

HEPATIC COMPLICATIONS

The normal adult liver has a dual blood flow and oxygen supply. Approximately two-thirds of hepatic blood flow and one-half of the oxygen supply is derived from the portal vein while the rest is provided by the hepatic artery. Institution of PPV has significant implications on hepatic perfusion. The reduction in cardiac output observed during PPV causes a proportional drop in global hepatic blood flow.[62,63] In addition, the descent of the diaphragm during PPV results in a direct compression of the liver parenchyma and a dramatic rise in intraabdominal pressure. The combination of these two forces leads to an increase in hepatic vascular resistance, which, in turn, impedes portal venous flow. Maintenance of spontaneous breathing during airway pressure release ventilation results in higher hepatic venous oxygen saturation and better hepatic lactate elimination as compared with full ventilator support at equal airway pressure limits.[64]

The addition of PEEP further complicates the picture. In clinical studies of patients with acute lung injury secondary to septic shock, an increase in PEEP to 15 cm H_2O resulted in decrease hepatic vein oxygen saturation compared to 10 cm H_2O.[65] Similarly, PEEP levels of 15 cm H_2O but not 10 cm H_2O was associated with a decrease in hepatic glucose production. After liver transplantation, patients are especially vulnerable to change in blood flow because of vascular anastomoses and liver function recovery after cold ischemia. Despite an increase in central venous and pulmonary capillary occluding pressure following 10 mbar of PEEP, there was fortunately no deterioration in Doppler flow velocities of portal and hepatic veins.[66]

Permissive hypercapnia has been observed to increase hepatic and splanchnic blood flow in a biphasic manner. Blood flow is initially reduced because of sympathetic stimulation and is then increased secondary to the direct vasodilator effect of CO_2.[67] The heterogeneity, however, observed in the individual changes of splanchnic perfusion secondary to decreased V_T supports the concept that the direct local vasodilation of an elevated tissue partial pressure of carbon dioxide (P_{CO_2}) is opposed by the increased release of catecholamines in the systemic circulation, with an end result of no significant change.[68]

PNEUMOPERITONEUM

An association between PPV and pneumoperitoneum has long been described.[69,70] The mechanism involves airflow dissection through overdistended alveoli into the pulmonic perivascular sheaths.[71] The pocket of air dissects to the mediastinum and migrates through the foramina of Morgagni and Bochdalek to cause free air in the peritoneal space.[72,73] Risk factors include high airway pressures, large V_T, noncompliant lungs, and preexisting pulmonary disease, including obstructive airway disease and acute respiratory distress syndrome. The diagnosis may be easily mistaken for a perforated viscus. In the absence of leukocytosis, abdominal pain, and peritoneal signs, perforation can be excluded by radiographic imaging with water-soluble contrast material administered via oral, rectal, or enterostomy tube.[74,75] Other approaches to define the etiology of pneumoperitoneum include aspiration and analysis of the partial pressure of oxygen (P_{O_2}) of the intraperitoneal free gas.[76,77] Spontaneous resolution usually occurs within a few days.[62,78] On rare occasions, "tension pneumoperitoneum" has been described, in which surgical decompression is necessary, even in the absence of peritoneal signs, to relieve vascular collapse.[79]

CARDIOVASCULAR COMPLICATIONS

Cardiovascular complications are associated with critical illness and mechanical ventilation, but are rarely a direct complication. The most common complications include arrhythmias, myocardial ischemia, usually a type II or demand non–ST-segment elevation myocardial infarction, although primary acute coronary syndrome (ST-segment elevation myocardial infarction) may also occur, as most patients have antecedent risk factors for coronary artery disease.

Arrhythmias

Most arrhythmias in medical ICU patients are tachyarrhythmia (90%), which are divided almost equally between supraventricular (atrial fibrillation 30%) and ventricular foci (monomorphic V_T 49%).[80] In surgical ICU patients, 61% of tachyarrhythmias were atrial fibrillation.[81] Although arrhythmias may occur as a result of underlying structural heart disease, physiologic alterations associated with the presenting illness and intrathoracic changes associated with PPV may also contribute. Ventilated patients often experience significant hypoxemia and hypercapnia, acidemia or alkalemia, hypokalemia, hypomagnesemia, and hypocalcemia that can all precipitate arrhythmias. Arrhythmias can also be precipitated by many drugs: vasopressors, inotropes, and inhaled β-agonists being the most common offenders. Clinicians must weigh the risk-to-benefit ratio of the drug relative to the degree of arrhythmia: specifically, is the arrhythmia more likely to have been triggered by the bronchospasm, hypoxemia or hypercapnia, or a β-agonist? Impaired electrical conduction of the normal cardiac impulse has obvious systemic effects, leading to decreased cardiac output and compounding the preexisting respiratory compromise. Identification and management of the inciting cause of the arrhythmia is important, as is appropriate management, as directed by advanced cardiac life support guidelines of the American Heart Association.[82]

Myocardial Ischemia

Myocardial ischemia in ventilated patients can be primary acute coronary syndrome (plaque rupture) or demand-related ischemia (non–ST-segment elevation myocardial infarction) in patients requiring mechanical ventilation for noncardiac indications. In patients presenting with acute coronary syndrome, the need for mechanical ventilation has been associated with increased mortality rates (as high as 50%).[83] Myocardial ischemia can occur at any time during the period of mechanical ventilation, and the increased systemic and myocardial oxygen demand during the time of weaning trials may precipitate acute ischemia.[84–88] Diagnosis is complicated by the lack of classical symptoms of chest pain and the low sensitivity of continuous electrocardiogram (ECG) monitoring.[89] The diagnosis should be considered in patients failing weaning trials. Diagnostic criteria should include clinical, ECG, and cardiac biomarkers, recognizing the limitations associated with biomarker use in the ICU (troponin elevation in clinical presentations of right-heart strain and elevated pulmonary vascular resistance, false elevations in renal failure). Treatment is based on advanced cardiac life support guidelines,[90] including interventional procedures.

RENAL COMPLICATIONS

The first report to show the impact of PPV on renal function was published in 1947.[91] Since then, several studies have documented an association between mechanical ventilation and development of renal failure in the ICU setting.[92–94] PPV increases the odds of developing renal failure threefold when PEEP is below 6 cm H_2O and more than 17-fold when PEEP is above 6 cm H_2O, despite volume replacement, maintenance of normal filling pressures, and adequate oxygen delivery.[92] Various mechanisms have been proposed to explain the alterations in renal function in patients receiving PPV, although three mechanisms are judged dominant: hemodynamic, neurohormonal, and biotrauma (Fig. 41-3).

The systemic hemodynamic effects of PPV originate in a complex interaction between intrathoracic pressure, intravascular volume, and cardiac output. The increase in intrathoracic pressure has been shown to correlate with a decrease in renal plasma flow, glomerular filtration rate, and urine output.[95,96] The reported effects, however, of PPV on glomerular filtration rate and renal blood flow are variable and may

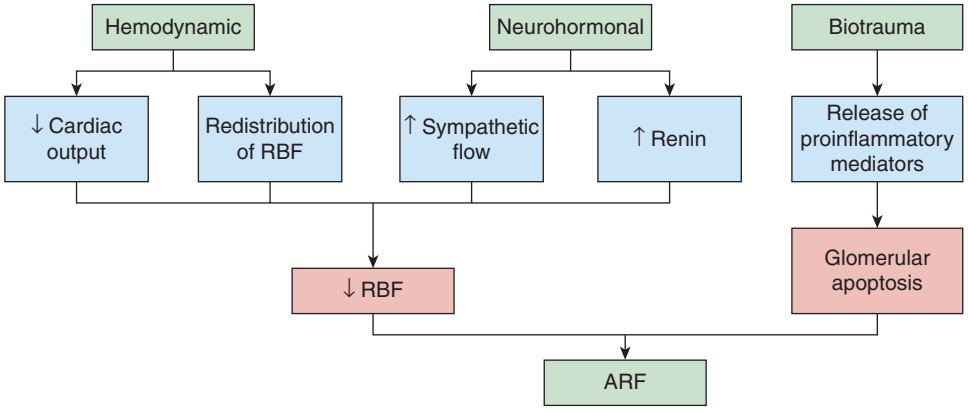

FIGURE 41-3 Mechanisms of acute renal failure during mechanical ventilation. *ARF*, acute renal failure; *RBF*, renal blood flow.

reflect differences in hydration status, underlying pulmonary and cardiac dysfunction, and use of vasoactive agents.[97] It has been suggested that redistribution of intrarenal blood flow from the cortical to juxtamedullary nephrons may play an important role in causing reduction of renal function during PEEP.[98] This may lead to decreased urinary output and creatinine clearance suggesting that small decreases in renal blood flow can seriously affect renal function.

PPV induces several neurohormonal changes in the sympathetic outflow, the renin–angiotensin axis, nonosmotic vasopressin release, and the atrial natriuretic peptide production. Thus far, no definite correlation between antidiuretic hormone levels[99,100] or atrial natriuretic factor,[101,102] and renal function during PPV has been confirmed. PPV, however, increases plasma renin levels by twofold,[96,102] driven by an increase in sympathetic tone. Consequently, renal blood flow and glomerular filtration are reduced, causing[103,104] a drop in distal tubule delivery of sodium. This, in turn, leads to further activation of the renin–angiotensin–aldosterone axis and increased sodium avidity. Clinically, these changes are manifested by a decrease in urine output as a result of decreased osmolar excretion. There are no definitive therapeutic trials for the treatment of PPV-induced renal hypoperfusion. Several small trials have shown that fluid administration and the use of vasoactive drugs (dopamine at 5 μg/kg/min or fenoldopam) may improve renal function,[101,105] but results are not conclusive. It is unlikely that approaches focused solely on the hemodynamic and neurohormonal mechanisms of PPV-induced renal dysfunction will be clinically effective in preventing or treating this multifactorial problem.

In addition to altering renal blood flow, PPV can impact renal function through the release of proinflammatory cytokines. These include IL-8, IL-6, and TNF-α, which promote glomerular and tubulointerstitial sequestration of neutrophils, upregulation of leukocyte adhesion molecules, and a decrease in filtration fraction associated with alterations in vascular tone.[106–111] Moreover, injurious ventilation strategies, such as high V_T and low PEEP, induces glomerular cell apoptosis via a soluble FasL-mediated pathway.[107] Regardless of the proposed mechanism, it is clear that derangements in the innate immune/inflammatory response, oxidative stress and cellular necrosis/apoptosis are important components of this organ cross talk in response to injury.

Several authors have described the effects of other ventilation techniques on renal function. Comparison of controlled mechanical ventilation plus PEEP with low-frequency ventilation and extracorporeal carbon dioxide removal resulted in an immediate increase in urinary flow, osmolar clearance, and creatinine clearance.[112] Spontaneous breathing during airway pressure release ventilation provides improved systemic blood flow and regional perfusion to the kidneys.[113] The effect of permissive hypercapnia on renal function is also well documented: Partial pressure of arterial carbon dioxide (Pa_{CO_2}) levels correlate inversely with renal blood flow.[114] Hypercapnia causes renal vasoconstriction directly[115] and stimulates noradrenaline release through activation of the sympathetic nervous system.[116] Indirectly, hypercapnia induces systemic vasodilation, which results in a drop of the systemic vascular resistance and subsequent activation of the renin–angiotensin–aldosterone system.[117] As a result, renal blood flow becomes compromised and worsen glomerular filtration rate. These hypocapnic changes occur independently of partial pressure of arterial oxygen (Pa_{O_2}),[118] suggesting that Pa_{CO_2} plays a pivotal role in determining the vascular response to changes in blood-gas pressures.

INFECTIOUS COMPLICATIONS

Most clinical investigations indicate that 25% to 50% of ICU patients experience one or more nosocomial infection.[119–121] Fever is the usual trigger for a set of diagnostic and therapeutic interventions. Although the source of fever is not always identified, ventilator-associated infection, sinusitis, catheter-related bacteremias, nosocomial diarrhea, and wound infections account for most infections.[122] Two of these complications (i.e., ventilator-associated pneumonia and sinusitis) are discussed in Chapters 46 and 47.

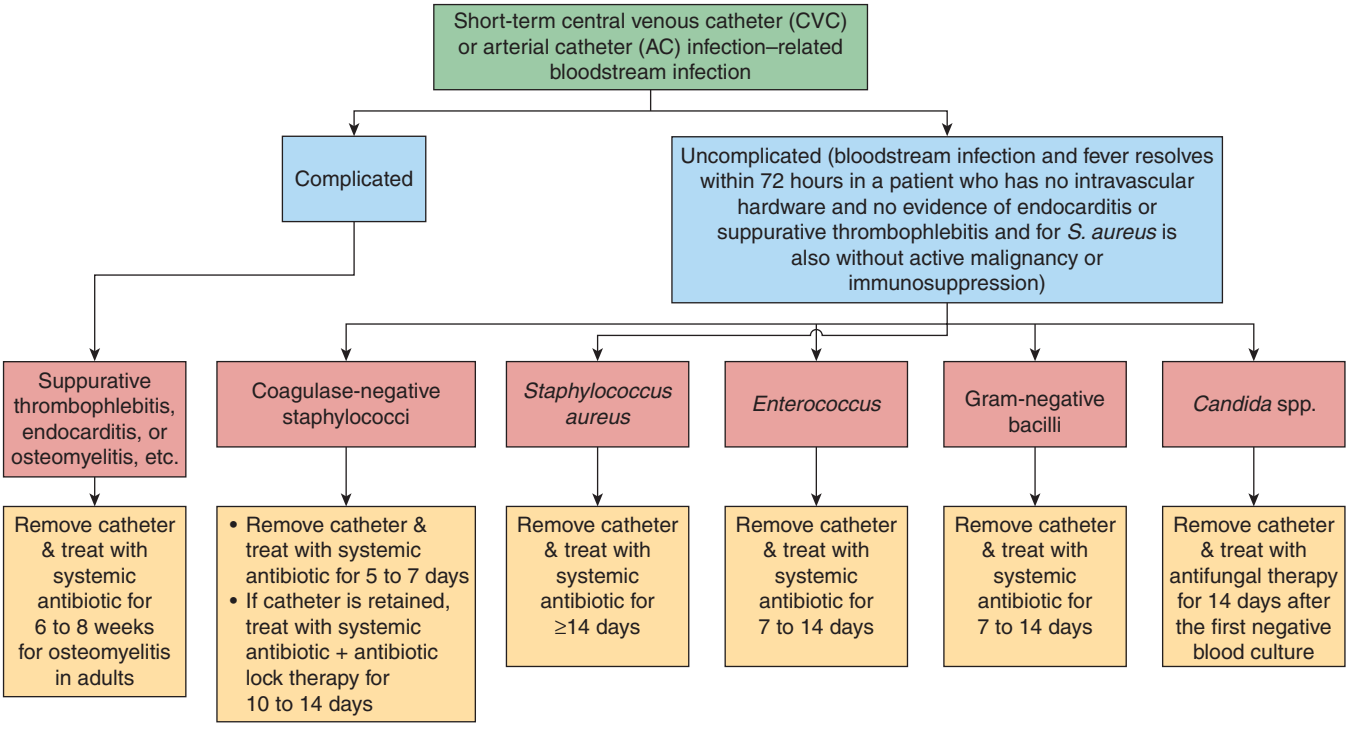

FIGURE 41-4 Approach to the management of patients with central venous catheter-related or arterial catheter-related bloodstream infection. (Reprinted with permission from Mermel LA, Allon M, Bouza E, et al. Clinical practice guidelines for the diagnosis and management of intravascular catheter-related infection: 2009 Update by the Infectious Diseases Society of America. *Clin Infect Dis.* 2009;49:1–45 with permission of Oxford University Press.)

Infection of central venous catheters is a particular problem with a mortality of 10% to 35%.[123] The absolute number of catheter-related infections is rising annually because of increasing use, although incidence per catheter days has actually decreased.[124] The catheter insertion site itself provides the most direct route of entry for the pathogen and this is the most common cause of infection.[123] These infections are caused mainly by gram-positive bacteria, in particular *Staphylococcus aureus* and coagulase-negative staphylococci such as *Staphylococcus epidermidis.*[125] Infections, however, can be caused by a wide range of microorganisms including *Enterococci, Candida* spp., *Acinetobacter* spp., *Pseudomonas* spp., and *Klebsiella* spp.[126] Catheter management depends on the likely specific pathogens and the individual colonization profile of the patient (Fig. 41-4).[126]

Infectious causes of nosocomial diarrhea include *Pseudomonas aeruginosa, Escherichia coli,* and cryptosporidium, although *C. difficile* accounts for the majority of hospital-acquired diarrhea or colitis.[127] Prior antibiotics, advanced age, gastric acid suppression, and gastrointestinal surgery or manipulation are major risk factors for symptomatic infection. At least 20% of adults ventilated for more than 1 week are colonized with *C. difficile* and up to 4% develop infection.[128] A hypervirulent strain, the North American pulse-field gel electrophoresis type 1 (NAP1) strain, has been implicated as a cause of *C. difficile* infection of increasing severity.[129,130] A deletion in the toxin regulatory gene, *tcdC,* is thought to allow this strain to overproduce toxin A and toxin B by as much as 15- to 20-fold.[129] Outbreaks caused by this strain are strongly associated with use of fluoroquinolones, although other antibiotics are also implicated.[131] For *C. difficile* infection of every severity, cessation of the inciting antibiotic is the first step in management whenever possible. Metronidazole and vancomycin are the antibiotics most commonly used to treat *C. difficile* in patients with symptomatic infection. A novel macrocycle antibiotic, OPT-80, is currently in phase 3 trials. OPT-80 is minimally absorbed from the gastrointestinal tract and well tolerated in most subjects.[132] Although highly effective against *C. difficile,* OPT-80 leaves the majority of the gram-negative anaerobic flora of the gastrointestinal tract intact. Another commonly employed strategy is the administration of probiotics. In several randomized controlled trials,[133–135] however, the combination of *Saccharomyces* or *Lactobacillus* probiotics with conventional antibiotic therapy has failed to show significant benefit.

HEMATOLOGIC COMPLICATIONS

Anemia

Ninety-five percent of ventilated patients develop anemia after the third ICU day.[136] A significant part is attributed to frequent and excessive blood draws. ICU patients are phlebotomized 3.4 times a day (mean volume of 41.5 mL of blood) as compared to 1.1 times a day for patients on a general ward.[137] Occult gastrointestinal bleeding represents

another source of blood loss. The condition is aggravated by coagulation disorders that include platelet dysfunction, thrombocytopenia, loss of coagulation factors, and endothelium-related coagulation disorders.[138] Several investigations in the last decade, however, suggest that anemia in ICU patients bears many similarities to that associated with chronic disease. More than 90% of ICU patients have low serum iron, total iron-binding capacity, and iron-to-total-iron-binding-capacity ratio, but have a normal or, more usually an elevated, serum ferritin level.[139,140] At a time when the iron studies are abnormal, serum erythropoietin levels are only mildly elevated with little evidence of reticulocyte response to endogenous erythropoietin.[139] Various proinflammatory cytokines are implicated in this blunted response. Inhibition of renal erythropoietin-gene expression in rat kidneys has been demonstrated for IL-1 and TNF-α.[141] In some cases, a shorter erythrocyte life span may aggravate the anemia. There are strong indications that the mononuclear phagocytic system plays a key role, with enhanced iron entrapment and a temporary inhibition of iron release,[142] while the bone marrow is still capable of incorporating iron and of reacting to exogenous erythropoietin.

Critically ill patients respond to treatment with recombinant human erythropoietin and parenteral iron with increased erythropoiesis.[143] Despite early promising results,[144,145] two large placebo-controlled trials investigating the exogenous erythropoietin in critically ill patients failed to show improved 28-day mortality, shorter duration of mechanical ventilation, decreased ICU length of stay, or reduction in red-cell transfusions.[143,146] There was, however, an increased propensity for thrombotic vascular events in the erythropoietin arm.[146]

Thrombocytopenia

The incidence of thrombocytopenia in ICU patients varies from 23% to 41%, depending on the definition of thrombocytopenia and the ICU type.[147–149] Thrombocytopenia is often multifactorial (Table 41-2) and a marker of disease severity.[150] Nearly all studies have found an inverse correlation between platelet count and prolonged ICU stay or hospital mortality.[151–153] The magnitude of the drop in platelet count correlates more closely with adverse outcomes than the nadir in absolute count. The platelet count pattern over time provides important clues as to the cause of the thrombocytopenia. A gradual decrease in platelet counts over several days suggests worsening of the underlying disease and is often associated with multiorgan failure, whereas a new, rapid decrease in platelet count that begins after the fourth day is typical for immune-mediated causes. A classic example is heparin-induced thrombocytopenia, which is frequently considered as a cause of thrombocytopenia in ICU patients, although its incidence is only 0.3% to 0.5%.[154,155] It occurs in two forms. With the more common, type I, form, which occurs in 10% to 20% of patients receiving unfractionated heparin, nonimmune mechanisms produce a drop in platelet counts 1 to 4 days after the onset of therapy. The type I form is not associated with hemorrhagic or thrombotic sequelae, and management involves observation; platelet counts normalize in most patients despite heparin continuation.[156] With the type II form, in contrast, 30% to 80% of patients experience thrombotic sequelae. Venous thromboses outnumber arterial thromboses by 4:1, and life-threatening pulmonary embolism occurs in 25% of patients who have thrombosis.[156] The type II form occurs in 1% to 3% of patients who receive unfractionated heparin, and is induced by antibodies of the immunoglobulin G class against platelet factor 4-heparin complexes.[156] Heparin-induced thrombocytopenia is suspected when a platelet count falls by more than 50% after 4 days of treatment, and can present with new thrombosis, typically occurring 5 to 14 days after the start of prophylactic or therapeutic doses of heparin. To prevent new thrombosis, nonheparin anticoagulant therapy is required. Four drugs are approved for this purpose: (a) two direct thrombin inhibitors, lepirudin and argatroban; (b) a heparinoid, danaparoid; and (c) an antifactor Xa inhibitor, fondaparinux.

TABLE 41-2: ETIOLOGY OF THROMBOCYTOPENIA IN MECHANICALLY VENTILATED PATIENTS

Hemodilution	• Large volume of fluid infusion Excessive transfusion of packed red cells or plasma exchange
Increased platelet consumption	• Sepsis • Thrombotic thrombocytopenic purpura • Disseminated intravascular coagulopathy • Hyperfibrinolysis (metastatic prostate/ovarian cancer) • Intravascular devices
Decreased platelet production	• Myelodysplasia or leukemia • Drug-induced bone marrow depression • Radiation
Increased platelet destruction	• Autoimmune thrombocytopenia • Drug-induced thrombocytopenia • Posttransfusion purpura
Sequestration	• Hypersplenism • Hypothermia

NEUROMUSCULAR COMPLICATIONS

Critical illness polyneuropathy is an acute axonal sensory motor polyneuropathy, mainly affecting the lower limb nerves of critically ill patients including those receiving mechanical ventilation. Critical illness polyneuropathy is often associated with critical illness myopathy and differentiating between these entities may be difficult. For both, the clinical presentation is one of limb weakness or flaccidity, and respiratory muscle weakness or persistent respiratory failure, manifesting as unexplained difficulty in ventilator weaning. Most patients have an antecedent diagnosis of sepsis or septic shock, and the diagnosis should be considered in all patients with difficult weaning. Occurrence varies from

58% of patients with prolonged ICU stay,[157,158] to 70% to 80% of patients with sepsis, septic shock, or multisystem organ failure,[158–162] to 100% of patients with sepsis and coma.[158,163]

Etiology

The cause is believed to be microvascular damage, depletion of bioenergetic neuron reserves, altered sodium channel inactivation, and altered glycemic control, mediated by inflammatory cytokines,[158,162,164–170] and an association with use of glucocorticoids.[171] Although previous data ascribed increased risks with the use of depolarizing neuromuscular blockade and aminoglycoside administration, more recent data suggests that their association may be related to underlying severity of illness.[171–173] A multivariate analysis has identified four independent risk factors: female gender (odds ratio [OR] 4.66), number of days with dysfunction in equal to or greater than two organs (OR 1.28), duration of mechanical ventilation (OR 1.10), and corticosteroid administration (OR 14.9).[171]

Diagnosis

Electrophysiology is required to make the definitive diagnosis in distinguishing between polyneuropathy, myopathy, and neuromuscular blockade, as clinical neurologic examination is insensitive. These studies, however, can be difficult to obtain. Evaluation usually includes needle electromyography in upper and lower limbs. Phrenic nerve conduction studies and needle electromyography of the respiratory muscles may suggest critical illness polyneuropathy as a cause of difficult weaning. The classic electromyography pattern in critical illness polyneuropathy is one of primary axonal degeneration, and manifests as a reduction in the amplitude of the compound action potentials and sensor nerve action potentials. A decrease in the amplitude and prolonged duration of compound action potentials, which suggests an associated myopathy, may be one of the first signs of a developing polyneuropathy.[174,175] Additional features include inexcitability of the muscle on direct stimulation and abnormal spontaneous electromyographic activity. The decline in sensory nerve conduction may present after the above findings. Electrophysiologic studies may help to differentiate between generalized neuromuscular disorders associated with critical illness (Table 41-3); however, these studies require fully cooperative patients. Those afflicted do not necessarily have a fatal outcome as had previously been ascribed[163,176] to comatose patients with acute paralysis, because many patients make a full or near-full recovery.[158,162]

Prognosis

Patients with severe respiratory and limb weakness with electromyelogram evidence of predominant muscle involvement, minimal elevations of creatine phosphokinase and normal muscle biopsy may make a rapid recovery, whereas patients with significant enzyme elevation and evidence of muscle necrosis may have lasting deficit.[175]

NUTRITIONAL SUPPORT

Appropriate nutritional support in ventilated patients has emerged as an important variable in outcomes of ICU patients. The metabolic response to stress and injury is characterized by increased release of cytokines (IL-1, TNF-α, IL-6) with increased production of counterregulatory hormones (catecholamines, cortisol, glucagon, and growth hormones). Counterregulatory hormones induce catabolism and oppose the anabolic effects of insulin. The resultant effects are hypermetabolism and hypercatabolism with a loss of body energy stores through proteolysis, lipolysis, and glycogenolysis.[177–179]

Adverse Effects of Malnutrition

The adverse effects of malnutrition on ventilated patients include altered ventilatory drive; reduction in the ventilatory response to hypoxia; decreased mass; force contractility and endurance of the diaphragm; decreased respiratory muscle strength; hypercapnia; reduced synthesis of alveolar surfactant; and altered humoral and cellular immunity.[180] Despite the general consensus that nutritional support is important, and guidelines advocating provision of enteral nutrition within 24 to 48 hours of ICU admission,[181–184] observational studies reveal that up to 40% of critically ill patients receive no nutritional support during their ICU stay and 60% of patients in the ICU for at least 3 days remain without nutritional support for 48 hours or longer.[183,185–187] A recent meta-analysis of enteral nutrition in critically ill patients[186] demonstrated a reduction in mortality and pneumonia attributable to the inception of standard enteral nutrition within 24 hours of injury (trauma, burn) or ICU admission. Although five of the six trials were nonmedical critically ill patients,[188–192] the one medical trial focused on ventilated patients.[193] Earlier trials have demonstrated that failure to deliver adequate nutritional support or delaying nutritional support leads to cumulative energy deficit, which correlates with longer ICU stay, increased duration of mechanical ventilation, and more infectious complications.[194,195]

Recognition of the effects of undernutrition has led to the recent development of screening guidelines, as well as disease-specific nutritional guidelines.[196] Nutritional support studies have been challenged by major methodological problems in terms of defining the populations studied, standardization of severity of illness scoring, metabolic derangements, variability in enteral nutritional formulations, and outcome measures. The European Society for Clinical Nutrition and Metabolism generated the *ESPEN Guidelines on Enteral Nutrition* in 2006,[181,197–202] and the *ESPEN Guidelines on Parenteral Nutrition* in 2009;[184,203–206] the American Society

TABLE 41-3: GENERALIZED NEUROMUSCULAR CONDITIONS ENCOUNTERED IN MECHANICALLY VENTILATED PATIENTS

Condition	Clinical Findings	Electrophysiologic Findings	Creatine Phosphokinase	Muscle Biopsy	Prognosis
Polyneuropathy					
Critical illness polyneuropathy	Flaccid limbs, respiratory weakness	Axonal degeneration of motor and sensory fibers	Nearly normal	Denervation atrophy	variable
Neuromuscular Transmission Defect					
Transient neuromuscular blockade	Flaccid limbs, respiratory weakness	Abnormal repetitive nerve stimulation studies	Normal	Normal	good
Critical Illness Myopathy					
Thick filament myosin loss	Flaccid limbs, respiratory weakness	Abnormal spontaneous activity	Mildly elevated	Loss of thick (myosin) filaments	good
Rhabdomyolysis	Flaccid limbs	Nearly normal	Markedly elevated	Marked necrosis	good
Necrotizing myopathy of intensive care	Flaccid weakness, myoglobinuria	Severe myopathy	Markedly elevated (myoglobinuria)	Marked necrosis	poor
Disuse (cachectic) myopathy	Muscle wasting	Normal	Normal	Normal or type II fiber atrophy	good
Combined polyneuropathy and myopathy	Flaccid limbs, respiratory weakness	Indicate combined polyneuropathy and myopathy	Variable	Denervation atrophy and myopathy	variable

TABLE 41-4: GUIDELINES FOR ENTERAL NUTRITION IN CRITICALLY ILL PATIENTS

Population	Enteral Nutrition Summary Recommendations
Critically Ill (Nonsurgical)	1. All patients not expected to be on oral diet within 3 days should receive enteral nutrition (EN) 2. EN should be started within 24 hours of admission to ICU 3. 20 to 25 kcal/kg body weight (BW)/day replacement during the acute phase of illness 4. 25 to 30 kcal/kg BW/day replacement during anabolic recovery phase 5. No significant data to support immune-modulating EN formulas or supplements with the exception of: * Acute respiratory distress syndrome (ARDS)—consider EN enriched with omega-3 fatty acids 6. No significant difference in efficacy of jejunal as compared to gastric feeding 7. Parenteral nutrition should be avoided in patients who can tolerate EN and achieve target intake
Gastroenterology	
Liver Disease Alcoholic Steatohepatitis (excludes NASH)	1. Whole protein formulations are generally recommended. Oral nutritional supplements (ONS) are recommended to supplement oral intake 2. Tube feeding (TF) are recommended if oral intake remains inadequate (even if esophageal varices are present) 3. Use branched-chain amino acid EN formulations in patients in whom hepatic encephalopathy begins during EN 4. Consider the use of concentrated high-energy EN formulations in patients with ascites to avoid positive fluid balance 5. Percutaneous endoscopic gastrotomy (PEG) placement is associated with higher complication rates because of ascites and varices 6. There is no increased risk of bleeding with fine bore nasogastric tubes 7. Recommended energy intake: 35 to 40 kcal/kg BW/day 8. Recommended protein intake: 1.2 to 1.5 g/kg BW/day
Cirrhosis	All of the above and: 1. The use of branched-chain amino acid supplements may improve clinical outcome in advanced cirrhosis
Fulminant Liver Failure	1. Patients should receive enteral nutrition via nasoduodenal tube, with lose observation for hypoglycemia 2. No recommendations for specific EN formulations (absence of data) 3. Calorie recommendations as per critical illness (absence of data) 4. Glucose, lactate, triglyceride, and ammonia levels should be monitored as used as surrogate markers of substrate utilization
Renal Failure	
Acute renal failure	1. Standard critical care EN formulations are adequate, but patients should be assessed individually 2. If there are significant electrolyte abnormalities, EN formulations for chronic renal failure may be advantageous 3. Nonprotein nutritional requirements: 20 to 30 kcal/kg BW/day as carbohydrate 3 to 5 g/kg BW/day, fat 0.8 to 1.2 g/kg BW/day 4. Protein requirements differ depending on clinical status: a. conservative therapy 0.6 to 0.8 g/kg BW/day b. extracorporeal therapy 1.0 to 1.5 g/kg BW/day c. continuous renal replacement therapy (CCRT), hypercatabolism: up to maximum of 1.7 g/kg BW/day 5. Parenteral micronutrient supplementation in prolonged CRRT can be considered, with vitamin C 30 to 100 mg/day, folate, magnesium, calcium, selenium, and thiamine

for Parenteral and Enteral Nutrition generated the *ASPEN Clinical Guidelines* in 2009.[207] The guidelines are similar in their recommendations (Table 41-4), with some notable differences. The ASPEN guidelines advocate withholding enteral nutrition in patients with hemodynamic compromise or high-dose catecholamine requirements. This data is derived from mixed human and animal models and although splanchnic perfusion is increased with enteral nutrition,[208–216] multiple animal studies suggest differential splanchnic vasoconstriction with vasopressor agents (vasopressin > dopamine > phenylephrine). Of note, norepinephrine, the leading vasopressor for septic shock, and dobutamine are both associated with improved gut mucosal pH or perfusion.[217–219] Consequently, the decision to initiate enteral feedings in cases of hypotension is left to clinical judgment to weigh the risks of bowel ischemia against the benefits of enteral nutrition.

Complications of Nutritional Support

Complications of enteral nutrition in ventilated patients include improper tube placement, aspiration (more related to supine positioning because gastric residual volumes have not consistently correlated with aspiration risks[220,221]), vomiting, diarrhea, abdominal distension, and constipation. Most of these problems can be avoided or managed by altering the enteral formulation and with the use of promotility and stool-bulking agents.[53,222–231] The presence of gastric residual volumes of 250 to 500 mL in two consecutive measurements

over 8 hours should prompt the use of a prokinetic agent; if gastric residual volume consistently exceeds 500 mL, interruption of enteral nutrition should be stopped and jejunal feedings considered.[232]

Parenteral Nutrition

Parenteral nutrition should be reserved for patients unable to tolerate or attain their targeted energy requirements within 2 days of enteral feeding, and patients not expected to be on normal nutrition within 3 days.[184] In some meta-analyses,[233,234] parenteral nutrition has been associated with increased rates of infectious complications, which may be associated with the hyperglycemia that is seen more often with parenteral than with enteral nutrition. Parenteral nutrition is administered through a dedicated central venous device, given the osmolarity. Low-osmolarity (<850 mOsm/L) mixtures, designed to cover only a portion of the nutritional needs (usually supplementing enteral nutrition), can be infused through peripheral venous access devices.[184] Lipid emulsion is required as a source of energy as well as essential fatty acids (linoleic [omega-6] and α-linolenic [omega-3] fatty acids). The meta-analysis that suggested an increased complication rate with the use of lipid emulsion was thought to have suboptimal control for total calories and carbohydrates, as per the ESPEN committee on parenteral nutrition, which may have negatively affected outcome. The evidence for a detrimental effect of lipids was not strong.[184] More recent data suggest that delaying the use of lipids does not change complication rates.[235] The choice of long-chain triglycerides from soybean oil or mixtures of long-chain and medium-chain triglycerides from coconut oil is at a practitioner's discretion. Evidence supports tolerance of the mixed emulsions and several small studies have demonstrated clinical advantages (less immunosuppression and fewer infections,[236–238] and lower rates of oxygen consumption in ventilated patients) than with long-chain triglycerides alone, although prospective controlled studies are lacking. Olive oil-based formulations are also available and thought to be safe and well tolerated in other patient populations (burn, home total-parenteral nutrition for intestinal failure), but only one small retrospective observational trial has been done in critically ill patients. There is conflicting data on the addition of eicosapentaenoic acid and docosahexaenoic acid infusions to lipid emulsion, but may decrease length of stay in critically ill patients.

VENOUS THROMBOEMBOLISM

Incidence and Risk Factors

The clinical manifestations of venous thromboembolism (VTE) are protean, ranging from asymptomatic tachycardia and mild dyspnea to hemodynamic collapse. Given this range of presentation, the wide case fatality rate (1% to 60%) is not surprising.[239] Deep venous thrombosis (DVT) is the leading risk factor for the development of VTE, and proximal DVT is found in up to 60% of critically ill patients with venous thrombosis; more proximal thromboses are associated with a 40% to 95% incidence of pulmonary embolism (PE).[240–243] DVT can be clinically silent, and 10% to 100% of ultrasonographically detected thromboses were not detected on clinical examination.[241,244–246] There are differences in incidence of DVT in different ICU settings: medical and surgical ICU patients not receiving thromboprophylaxis have an incidence of approximately 30% within 2 weeks, trauma patients 60%, orthopedic surgery patients 40% to 60%, general neurosurgical patients 20% to 50%, and spinal cord injury patients 50% to 80%.[240,247,248] Risk factors for the development of venous thrombosis include malignancy, duration of mechanical ventilation, immobility (associated with use of sedatives and paralytic agents), severity of illness, emergent surgery, vascular injury from central venous catheterization (femoral), prior VTE, female gender, obesity, cardiac failure, acute myocardial infarction, and inadequate implementation of thromboprophylaxis.[244,249–251]

Diagnosis

PE should be suspected in all ventilated patients with new or unexplained hypoxemia, tachypnea, or sustained hypotension without an obvious alternative diagnosis. It should be considered in the evaluation of unexplained fever and progressive right heart failure.

The diagnostic approach varies with the severity of illness and is tailored to a patient's hemodynamic stability. The ultimate goal is to objectively define the presence or absence of VTE (Fig. 41-5). In ventilated patients who are hemodynamically stable, the diagnostic approach includes pretest probability evaluation and multidetector CT scanning. D-dimer is excluded from this evaluation. Unlike in the evaluation of outpatients, D-dimer is of little value in hospitalized patients, as it lacks specificity in oncology patients, hospitalized patients, pregnant women, the elderly, and in situations where the pretest probability of VTE is high.[252] Most probability scoring systems (Wells Score, Modified Wells Score, Geneva Score, revised Geneva Score, Christopher Study, PERC [Pulmonary Embolism Rule-out Criteria], and PISA-PED [Prospective Investigative Study of Acute Pulmonary Embolism Diagnosis]) are designed for outpatient use or have been evaluated in only small populations of noncritically ill inpatients.[253–257] If the pretest probability of PE is anything but low, a patient should proceed to CT-angiography, which has been well validated with respect to pulmonary angiography[258–260] and has an accepted negative predictive value of 95%. Ventilation–perfusion scanning has limited utility in ventilated patients.

The diagnostic approach for hemodynamically unstable patients is not as clearly defined. The focus here is to rapidly exclude embolism-associated obstructive shock from the differential diagnosis. A recently published algorithm divides the hemodynamically unstable group into critically ill and

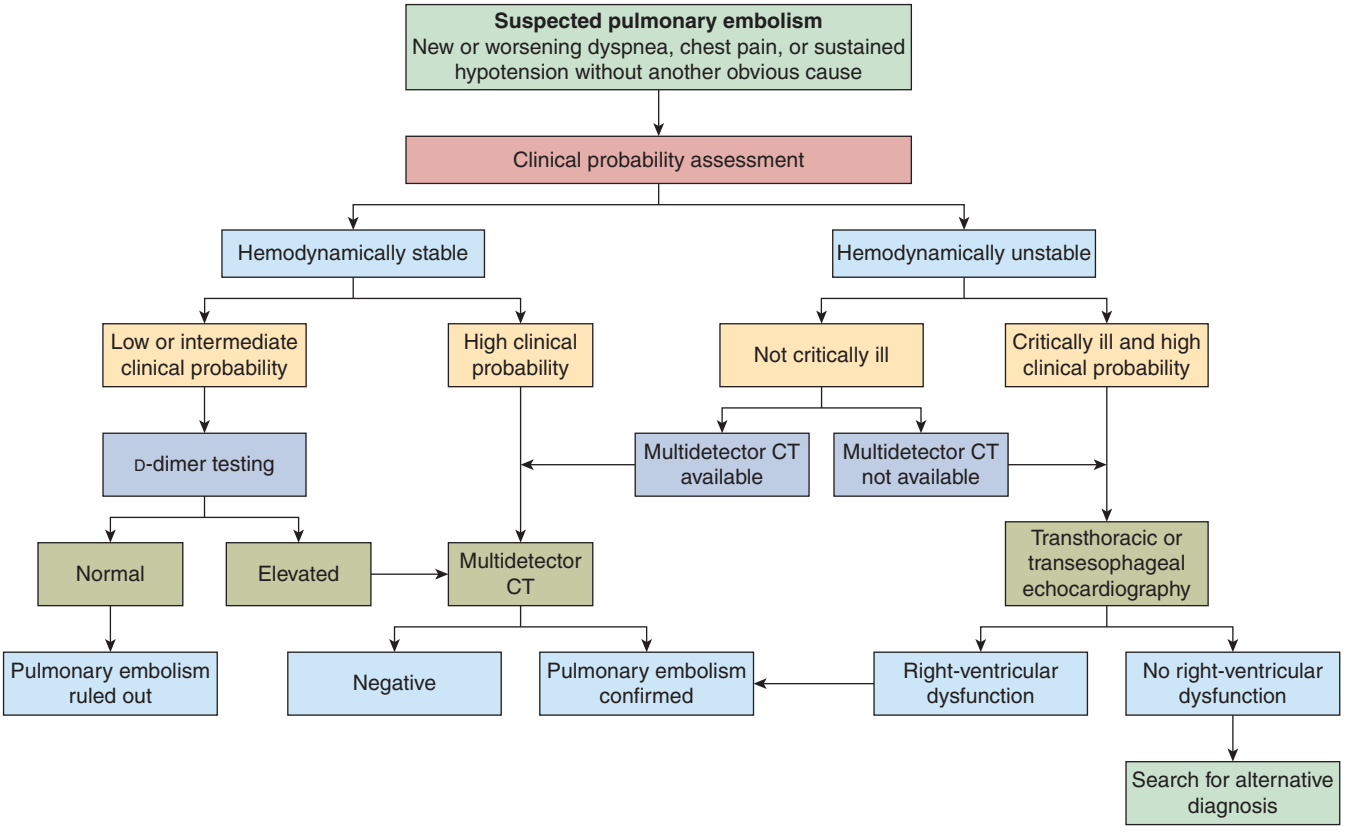

FIGURE 41-5 Diagnostic work-up for suspected pulmonary embolism. (Used, with permission, from Agnelli.[260])

not critically ill, but this can be a difficult distinction.[261] If the patients can be transported for CT-angiography, they should undergo this procedure, which has a 97% sensitivity for detecting emboli in the main pulmonary arteries.[253] If they are too unstable for transport and they have a high pretest probability of PE, they can undergo either transthoracic echocardiography or transesophageal echocardiography, with the goal of detecting right-ventricular dysfunction (defined as a ratio of right-ventricular-to-left-ventricular end-diastolic diameter of greater than 1 in the apical four-chamber view), right-ventricular end-diastolic diameter greater than 30 mm, or paradoxical septal motion. The absence of right-ventricular dysfunction indicates a low likelihood of obstructive shock secondary to PE as the cause of hemodynamic compromise and an alternate source should be identified. The use of the natriuretic peptides and troponin values has a more defined role in the risk stratification and prognostication of patients with an established diagnosis of PE than in initial diagnostic evaluation.

Risk Stratification

Most of the risk stratification tools apply more to the patients on their initial admission and evaluation, and not specifically to ventilated patients who have been in the hospital for some time.

Early mortality rates from PE range from 5% in patients who are hemodynamically stable, to 58% in patients with hemodynamic collapse.[239,262,263] Clinical variables include prognostication scores in the Pulmonary Embolism Severity Index (PESI)[264,265] and Simplified PESI[266] and were designed to identify patients with low risk for death who could be managed safely as outpatients or candidates for early hospital discharge.

More pertinent to ICU population is the use of troponin, natriuretic peptide and right-ventricle-to-left-ventricle (RV/LV) ratio in identifying patients at risk for adverse outcomes. Previous studies have demonstrated increased short-term mortality associated individually with right-ventricular dysfunction in hemodynamically stable PE ("submassive PE") (defined by RV/LV ratio, pooled from CT angiography and echocardiographic studies) elevated brain natriuretic peptide (BNP) or N-terminal pro brain natriuretic peptide and myocardial injury as detected by elevated troponin.[267–273] The PREP study,[263] a prospective cohort study of 570 patients demonstrated combining the individual variables into a prognostic scoring system could further assist in identifying high-risk and low-risk patients. When pooled with the biomarker data, the multivariate model independently associated the highest risk of 30-day adverse events were altered mental status, cardiogenic shock, malignancy, BNP, and RV/LV ratio. The risk factors were used to calculate a prognostic score and based on this score, assigned to three risk classes

(low, intermediate, and high risk). In the group as whole, the risk of adverse of events for Class I (low risk), Class II (intermediate risk), and Class III (high risk) were 2.5%, 11.6%, and 43.2%, respectively. In the hemodynamically stable subgroup, the risks were 1.8%, 11.7% and 22.2%, respectively.

Prevention

Prevention of VTE is important in ventilated patients although the optimal method of thromboprophylaxis is difficult to ascertain. The first difficulty is the lack of studies of routine surveillance screening and the lack of a reference standard for the diagnosis of DVT. Ultrasonography is less sensitive as a screening tool, but venography is not uniformly utilized for many reasons. Studies utilizing ultrasound to determine the incidence of DVT in two treatment arms may underestimate the true incidence. Recognizing the variability in the reported studies, chemoprophylaxis, in general, is uniformly superior to mechanical prophylaxis in all critically ill populations, with the exception of neurosurgical patients (in whom chemoprophylaxis is routinely avoided, despite a lack of sound evidence of increased risk of bleeding).[240,241,247] Recent evidence-based guidelines have been published by the American College of Chest Physicians and by the International Union of Angiology. Despite accumulating evidence of significant reductions in the incidence and mortality of DVT and PE with the use of thromboprophylaxis, and at least three consensus statements guiding appropriate thromboprophylaxis,[248,274,275] three recent reports point out that only 40% to 60% of at-risk medical patients and 53% to 86% of surgical patients received American College of Chest Physicians recommended prophylaxis.[276–278]

Studies demonstrate that appropriate chemoprophylaxis with unfractionated heparin, low-molecular-weight heparin, or direct antithrombin III inhibitors (fondaparinux) can reduce the incidence of VTE by approximately 50%, without a significant increase in bleeding.[240,247,248,274,279–286] The recommendations listed below are from the 2008 *American College of Physicians Clinical Guidelines.* For patients with a moderate risk (medical ICU or postoperative patients), low-molecular-weight heparin or low-dose unfractionated heparin should be used for thromboprophylaxis. For high-risk (trauma or orthopedic surgery) patients, low-molecular-weight heparin should be given. For critical care patients at high risk for bleeding, optimal use of mechanical thromboprophylaxis with graduated compression stockings and/or intermittent pneumatic compression devices should be prescribed at least until the bleeding risk decreases. At that point, pharmacologic thromboprophylaxis should be substituted for or added to the mechanoprophylaxis.

SUMMARY AND CONCLUSIONS

Critically ill patients are at risk of succumbing to their primary disease or the undesired sequelae associated with their therapy. Although frequently lifesaving, the use of positive airway pressure therapy can have deleterious physiologic consequences. Alterations in renal, hepatic, and gastrointestinal functions have been described. Many of these derangements appear to be a direct result of increased intrathoracic pressure, sympathetic stimulation, and neurohormonal changes. Other indirect complications pertain to therapeutic interventions designed to optimize gas exchange and to alleviate the discomfort of mechanical ventilation. Among these complications are neuromuscular dysfunction, malnutrition, and venous thromboembolism. As ventilators become more complex and offer more options, the potential of unintended consequences increase in tandem. While preventing these untoward events may not be always feasible, recognizing their manifestations may be lifesaving.

VENTILATOR-INDUCED LUNG INJURY

Didier Dreyfuss
Nicolas de Prost
Jean-Damien Ricard
Georges Saumon

The deleterious effects of mechanical ventilation on the lungs have long been referred to as *barotrauma*. For many years, clinicians defined barotrauma as the occurrence of air leaks resulting in the accumulation of extraalveolar air responsible for a number of manifestations, of which the most threatening is tension pneumothorax. In addition to these "macroscopic" events whose adverse consequences are usually immediately obvious, mechanical ventilation may produce more subtle physiologic and morphologic alterations, especially when it results in high airway pressures. Our knowledge of such alterations has stemmed mainly from experimental studies and has expanded considerably over recent years. Indeed, alterations in alveolar–capillary barrier integrity and release of both inflammatory and antiinflammatory mediators have been reported in animals ventilated with modalities resulting in high lung stretching. Tissue damage also may occur during mechanical ventilation when distal airways close and open repeatedly because of the movement of foam in the airway lumen or rupture of liquid menisci. The clinical relevance of these experimental findings received resounding confirmation with the results of the ARDS Network study, which showed a 22% reduction in mortality in patients with the acute respiratory distress syndrome through a simple reduction in tidal volume.[1]

The first comprehensive work demonstrating that mechanical ventilation may be unsafe in intact animals was performed by Webb and Tierney.[2] Rats ventilated with a peak inspiratory pressure (PIP) of 30 or 45 cm H_2O displayed pulmonary edema within 20 minutes to 1 hour, depending on the pressure level. Microscopic examination of the lungs disclosed moderate interstitial edema in animals ventilated with the lower peak pressure, contrasting with profuse edema and alveolar flooding in animals ventilated with the highest PIP. Other studies subsequently documented the occurrence of pulmonary edema and lung ultrastructural abnormalities[3,4] after even very short periods of intermittent positive-inspiratory pressure with high PIP. Kolobow et al[5] reported progressive lung injury in sheep ventilated with 50 cm H_2O PIP over 48 hours, manifested as decreased pulmonary compliance and deterioration in blood oxygenation. Some of the animals died before the 48-hour end point. At autopsy, lungs exhibited congestion and severe atelectasis.

The mechanisms underlying this ventilator-induced lung injury (VILI) have been for the most part elucidated. Two main factors explain its development: the magnitude of lung overdistension and its duration. Ventilation with very high peak transalveolar pressure results in acute, rapidly fatal, permeability pulmonary edema, whereas more protracted ventilation involving alveolar distension of lesser magnitude produces a lung injury in which inflammatory phenomena may play a role. This chapter presents the current knowledge on VILI. A Medline research employing "ventilator-induced lung injury" as keywords and limited to English articles yielded approximately 1900 results up to January 2005 (when the chapter in the second edition of this book was written). A Medline search employing the same keywords yielded 3860 results when updated to December 2010, reflecting the huge scientific productivity in this field over the past 6 years. To provide the most recent findings to readers, we have condensed material that was presented in greater detail in the second edition of this book.

MECHANISMS OF VENTILATOR-INDUCED LUNG INJURY

Ventilation modalities with very high distending pressures (typically >30 cm H_2O, depending on the species) result in pulmonary edema. Both increased filtration and alteration in capillary permeability participate in edema formation. The reasons for these abnormalities have been partly elucidated.

Evidence in Support of Increased Filtration

The first hypothesis put forward to account for ventilator-induced edema involved hydrostatic alterations.[2,6] Parker et al[6] calculated that mean lung microvascular pressure increased by 12.5 cm H_2O during ventilation of open-chest dogs at 64 cm H_2O PIP. Increased filtration may result from an increase of pulmonary capillary pressure, a decrease in lung interstitial pressure, or both. Surfactant inactivation and increased lung volume participate in the decrease in lung interstitial pressure.

The increase in alveolar surface tension resulting from surfactant inactivation would be expected to further decrease the negative pressures surrounding alveolar vessels, thereby increasing vascular transmural pressure and enhancing fluid filtration. Faridy et al[7] showed that ventilating excised dog lungs altered pulmonary pressure–volume curves and increased surface tension of lung extracts commensurately with the magnitude of tidal volume and duration of ventilation. Comparable findings were reported in excised rat lungs.[8,9] These anomalies were ascribed to depletion or inactivation of surfactant. Of note, surfactant alterations failed to occur when positive end-expiratory pressure (PEEP) was used.[7,8,10,11]

Pattle[12] and Clements[13] suggested that an increase in alveolar surface tension might increase filtration. Albert et al[14] found that the isogravimetric pressure (the vascular pressure at which net fluid flux from pulmonary vessels is zero) decreased when alveolar surface tension was increased by cooling and ventilating lungs at a low resting volume in open chest dogs. The authors interpreted this fall in isogravimetric pressure as indicative of a fall in perimicrovascular pressure.

Aerosolized ^{99m}Tc-DTPA (technetium-99m diethylenetriamine pentaacetic acid) clearance was found to increase following detergent aerosolization in rabbits[15] and dogs.[16] This finding was ascribed to regional overexpansion secondary to uneven lung inflation during mechanical ventilation of alveoli with altered surface tension rather than to elimination of peculiar barrier properties of surfactant.[16]

Increased filtration during mechanical ventilation probably also occurs at the extraalveolar level. During lung inflation, because of "pulmonary interdependence," the pressure in the perivascular space surrounding extraalveolar vessels decreases, which, in turn, increases transmural pressure. This effect of lung volume on pulmonary vessels is well documented.[17] Inflating the lungs dilates the extraalveolar vessels.[18] During inflation from a low transpulmonary pressure, the increase in vessel diameter is such that an effective outward-acting pressure in excess of pleural pressure (1 to 2 cm H_2O for each centimeter of water increase in transpulmonary pressure) expands the vessels.[19] The potential importance of fluid leakage through extraalveolar vessels has been established in both excised lungs[20] and in situ lungs of open-chest animals.[21] Moreover, inflation of in situ lobes under zone 1 conditions (i.e., where alveolar pressure exceeds pulmonary arterial and venous pressures) was found to precipitate hydrostatic pulmonary edema in dogs.[22] Because there is no flow in capillaries under zone 1 conditions, it is likely that the edema fluid leaked from distended extraalveolar vessels. The rate of edema formation was significantly correlated with the level of alveolar pressure and, therefore, the magnitude of distension (Fig. 42-1).

The effects of decreased perimicrovascular pressure and surfactant alterations probably combine with increased intravascular pressure to augment transmural microvascular pressure during overinflation. Although the magnitude

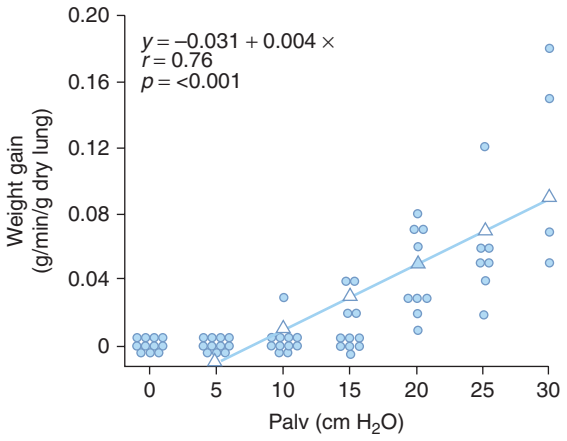

FIGURE 42-1 Relationship between alveolar pressure (Palv) and rate of hydrostatic edema formation in in situ lobes of open-chest dogs. Pulmonary arterial and venous pressures were kept at 1 cm H_2O. When lung volume was low (Palv = 10 cm H_2O), no edema occurred, whereas greater distensions produced a linear increase in lung weight gain, indicating edema formation. (Used, with permission, from Albert et al.[22])

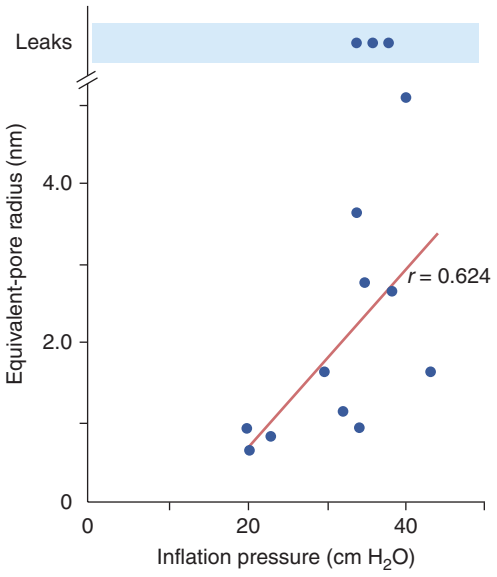

FIGURE 42-2 Effect of inflation pressure on the epithelial permeability of fluid-filled in situ lobes of sheep lung. Permeability is characterized by an equivalent-pore radius. A linear relationship was observed between inflation pressure and pore radius. At the highest levels of inflation, free diffusion of albumin was sometimes observed, indicating the presence of large leaks. (Used, with permission, from Egan et al.[25])

of these changes is difficult to evaluate with precision, the increase in vascular pressure seems relatively modest and is unlikely to explain per se the rapid development of profuse edema (especially in small animals) observed after high PIP ventilation.

Evidence in Support of Permeability Alterations

Many experimental studies in isolated lungs, as well as in open-chest or intact animals, have demonstrated permeability alterations (in response to high airway pressures) in the epithelium and, more unexpectedly, the endothelium.

Epithelial Permeability Changes in Response to High Airway Pressure

The increase in alveolar epithelial permeability to small hydrophilic solutes observed when lung volume increases is a physiologic phenomenon. Elevation of functional residual capacity (FRC), in sheep, obtained by increasing the level of PEEP during mechanical ventilation[23] or spontaneous ventilation,[24] was associated with an increase in aerosolized diethylenetriamine pentaacetic acid (DTPA) clearance. Clearance augmentation was larger than expected from the changes in alveolar exchange surface area.

Effects of overinflation on epithelial permeability were studied extensively by Egan during static inflation of fluid filled in situ lobes.[25,26] The equivalent-pore approach was used to describe the permeability of the epithelium to hydrophilic solutes of various sizes. Equivalent-pore radii increased from about 1 nm at 20 cm H_2O inflating pressure to 5 nm at 40 cm H_2O alveolar pressure. In some instances, free diffusion of albumin across the epithelium was observed, indicating the presence of large leaks (Fig. 42-2). Permeability alterations persisted or even increased after cessation of inflation, suggesting irreversible epithelial injury. High airway pressures applied to in situ lobes, however, resulted in supraphysiologic overinflation because of the compression of adjacent parenchyma. Egan[27] performed experiments under less extreme conditions in rabbits, in which both in situ lobes and entire lungs were distended with 40 cm H_2O airway pressure. Static segmental inflation resulted in a sixfold to 12-fold increase in lung volume from FRC and in an epithelium permeable to solutes such as albumin, cytochrome c, and cyanocobalamin. In contrast, whole-lung inflation resulted in only a threefold to fourfold increase in lung volume and a lesser rate of escape of the smaller solutes from the alveolar spaces. The increase in albumin permeability resulting from whole-lung overinflation was negligible. Hence, only major increases in lung volume produce significant changes in permeability to large molecules.

Although less-well-documented on a quantitative basis, epithelial alveolar permeability alterations are probably present in varying degrees during ventilator-induced pulmonary edema. During positive pressure-ventilation with 41 cm H_2O PIP, increases in alveolar permeability to small (DTPA), but not large (albumin), solutes were observed after 8 hours by Ramanathan et al in lambs.[28] After 2 minutes of high-pressure ventilation, epithelial lining fluid (ELF) volume calculated from bronchoalveolar lavage increased by 180%[4] (Fig. 42-3). ELF protein concentration decreased (Fig. 42-4A) even though protein content increased by 76% (Fig. 42-4B), suggesting that most of the excess fluid

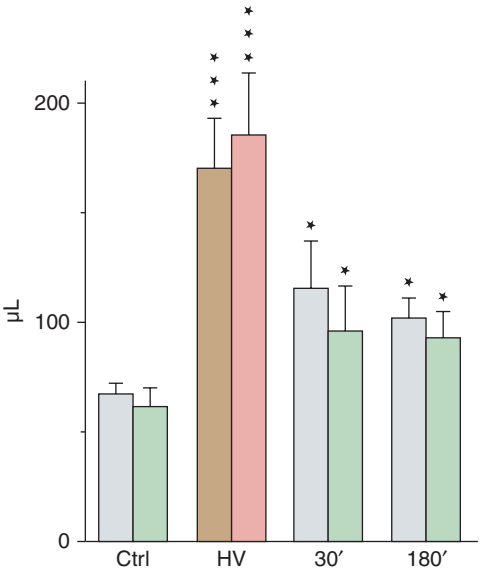

FIGURE 42-3 Estimates of epithelial lining fluid (ELF) volume by bronchoalveolar lavage after ventilation with 45 cm H_2O peak airway pressure for 2 minutes (*HV*) and recovery. Two successive lavages were performed (*grey and brown bars,* first lavage; *green and pink bars,* second lavage). ELF volume increased significantly after HV and then decreased during recovery but remained higher than in control subjects (*Ctrl*). * = $p < 0.05$; *** = $p < 0.001$, as compared to controls. (Used, with permission, from Dreyfuss et al.[4])

entered the alveolar-airway lumen through increased convection. In contrast to the severely altered sieving properties of microvessels after only 2 minutes of overinflation, epithelial permeability appears to be better preserved. This speculation is consistent with the scarcity of epithelial cell alterations on electron microscopic examination, contrasting with the widespread endothelial abnormalities.[4] The presence of blood cells in the alveoli, however, suggested a few large endothelial and epithelial tears. During longer (2 hours) ventilation periods with a lower tidal volume (V_T) (19 mL/kg in rats, resulting in a PIP of 19 cm H_2O), the presence of secretory Clara-cell protein (a protein found in airway lumen) in the vasculature contrasting with a decrease in its concentration in bronchoalveolar lavage fluid further suggests an increase in alveolar barrier permeability.[29] Secretory Clara-cell protein was also found in the plasma of mice ventilated with 35 cm H_2O PIP for 2 hours and even earlier (30 minutes) when PIP was 55 cm H_2O.[30] Resorption of alveolar liquid by distal airway epithelium is decreased during VILI because of depressed sodium transport mechanisms.[31] It can be restored by β-adrenergic stimulation that recruits ion-transporting proteins to the plasma membrane of alveolar epithelial cells or by β_1-sodium-potassium adenosine triphosphatase (ATPase) subunit gene transfer.[32,33]

Microvascular Permeability Alterations during Mechanical Ventilation-Induced Pulmonary Edema

In a study in isolated blood-perfused lobes from dogs, Parker et al[34] demonstrated that ventilation for 20 minutes with graded increases in PIP did not affect microvascular permeability up to 30 cm H_2O. Higher PIP (45 to 65 cm H_2O) was associated with increases in the capillary filtration coefficient (Fig. 42-5) and decreases in isogravimetric capillary pressure, suggesting the existence of an airway pressure threshold. Similarly, the estimated protein reflection coefficient was decreased only at the highest airway pressures. Of note, at an airway pressure above the threshold, the increase in capillary filtration coefficient occurred

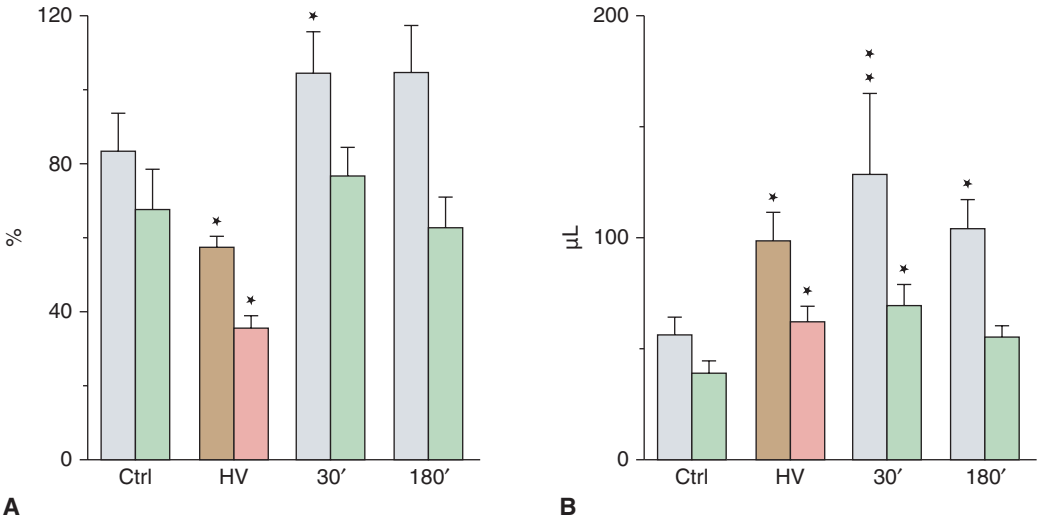

FIGURE 42-4 **A.** Protein concentration and (**B**) protein content in epithelial lining fluid (see Fig. 42-3 for details on the lavages). Protein content (expressed as the equivalent plasma volume) increased after high-pressure ventilation (*HV*) and then remained unchanged during recovery. Protein concentration (as a percentage of plasma protein concentration) decreased after HV and returned to normal during recovery (see text for details). * = $p < 0.05$; ** = $p < 0.01$, as compared to controls. (Used, with permission, from Dreyfuss et al.[4])

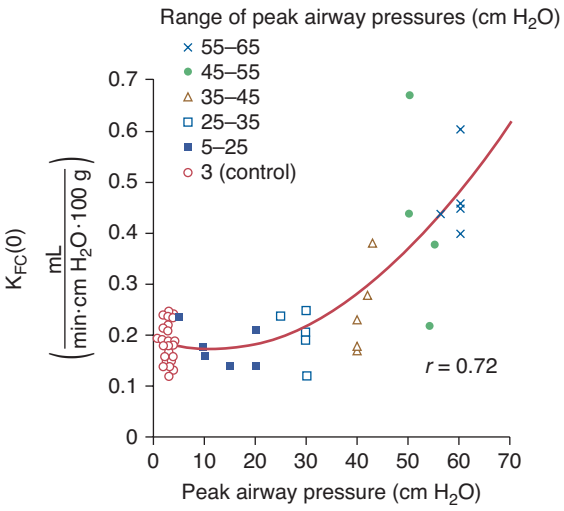

FIGURE 42-5 Effect of peak airway pressure on the capillary filtration coefficient (K_{FC}) of isolated, blood-perfused lobes of dog lungs receiving 20 minutes of intermittent positive-pressure ventilation. Moderate (up to 30 cm H_2O) increases in peak pressure did not affect K_{FC}, whereas higher levels of peak pressure resulted in a very steep increase in K_{FC}. (Used, with permission, from Parker et al.[34])

immediately and continued in some lobes after cessation of distension.

To evaluate permeability alterations in intact animals, extravascular lung water and bloodless dry-lung weight and the distribution space in lungs of ^{125}I-labeled albumin injected in the systemic circulation were measured in intact rats subjected to 45 cm H_2O PIP ventilation.[3] Pulmonary edema developed very rapidly and was easily demonstrable after only 5 to 10 minutes of high-pressure ventilation (Fig. 42-6). Light microscopic examination revealed that, at this stage, edema fluid remained confined to interstitial spaces, where it accumulated in the large peribronchovascular cuffs. No alveolar flooding was apparent. The presence of permeability alterations was indicated by a significant increase in dry-lung weight and of albumin distribution space (Fig. 42-6). After 10 minutes of high PIP ventilation, pulmonary edema was more abundant but still involved only the interstitial spaces. After 20 minutes of ventilation, findings were strikingly different, with tracheal flooding in all animals. Widespread alveolar flooding was obvious upon light microscopic examination. The severity of the permeability alterations was such that the ratio of ^{125}I-albumin activity in tracheal fluid versus plasma was close to unity, indicating the loss of permselectivity of the capillary barrier. The severity of the permeability defect was indicated by the relationship between dry-lung weight and extravascular lung water (Fig. 42-7), which indicated that the concentration of protein in extravasated fluid was high, suggesting the presence of numerous large capillary leaks. Similar findings relating the duration of high-PIP ventilation and alterations in capillary permeability have been made in mice.[30] This increase in endothelium permeability occurs both at the alveolar and extraalveolar level.[35]

The time course of edema development depends on the size of the species: in rats, high PIP ventilation for as little as 2 minutes is sufficient to produce permeability edema,[4] although alterations are minor and result in fairly mild edema. The increase in the ratio of extravascular lung water to blood-free dry-lung weight was increased by only 17%

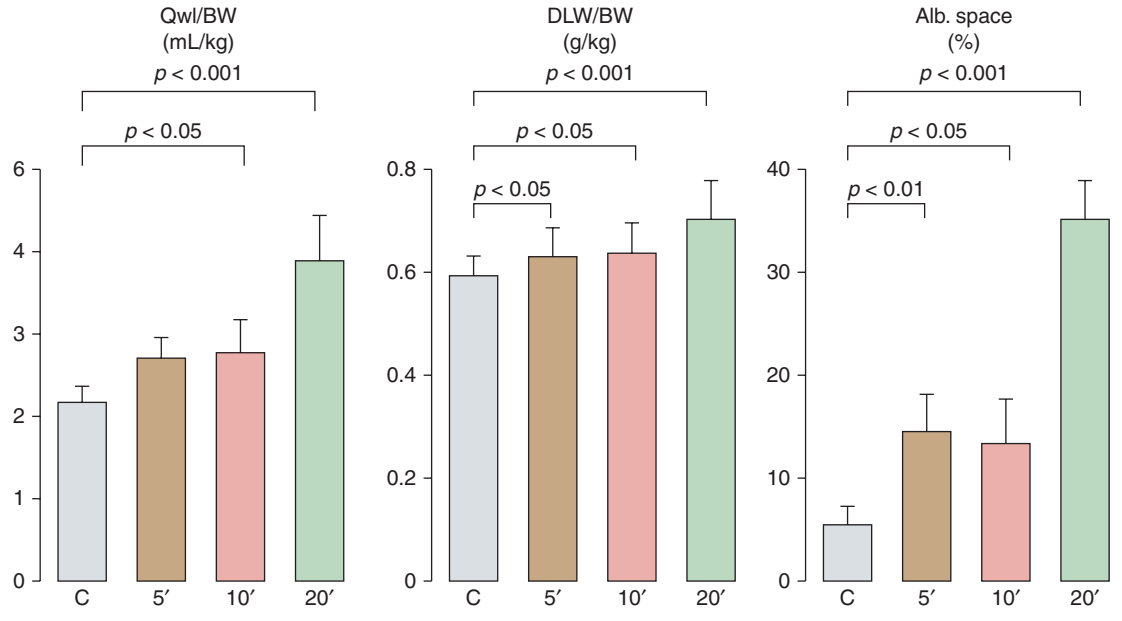

FIGURE 42-6 Effect of 45-cm H_2O peak airway pressure ventilation in intact rats. Pulmonary edema was assessed by the determination of extravascular lung water content (*Qwl/BW*) and permeability alterations by the determination of bloodless dry lung weight (*DLW/BW*) and of the distribution space in the lungs of ^{125}I-labeled albumin (*Alb. Space*). Permeability pulmonary edema developed rapidly (5 minutes). After 20 minutes of mechanical ventilation, there was a dramatic increase in all indexes ($p < 0.01$ versus other groups). (Adapted, with permission, from Dreyfuss et al.[3])

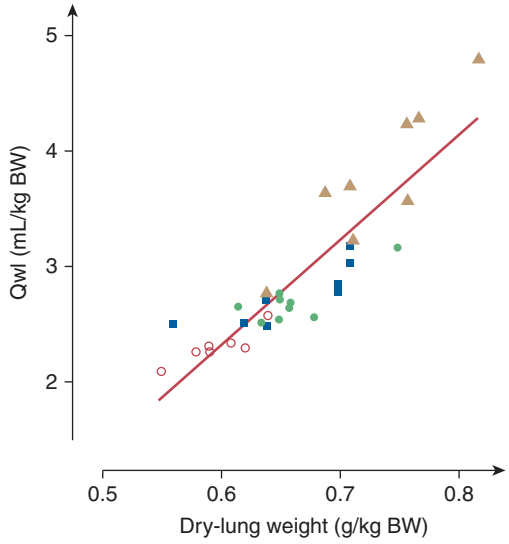

FIGURE 42-7 Relationship between extravascular lung water content (*Qwl/BW*) and dry lung weight during mechanical ventilation with peak airway pressure 45 cm H_2O. The concentration of proteins in the edema fluid estimated from this relationship was consistent with the outpouring of protein-rich edema fluid reflecting severe permeability alterations. *Open circles*, control conditions; *closed circles*, 5 minutes of ventilation; *closed squares*, 10 minutes of ventilation; *closed triangles*, 20 minutes of ventilation. (Used, with permission, from Dreyfuss et al.[3])

after 2 minutes[4] versus 90% when the duration of the challenge was increased up to 20 minutes.[36] In larger animals, considerably longer durations of high PIP ventilation are required to produce significant alterations. For instance, in lambs mechanically ventilated at 58 cm H_2O PIP for 6 hours, Carlton et al[37] found an increase in the ratio of extravascular lung water to dry-lung weight of only 19%. Results of histologic lung studies were either normal or showed only mild perivascular edema with no alveolar edema. In a study by Borelli et al,[38] sheep mechanically ventilated for 18 hours with a PIP of 50 cm H_2O developed both interstitial and alveolar edema.

Wet-lung weight normalized for body weight increased by 89% compared to normal lungs.[39] After 27 hours of ventilation, pathologic abnormalities were much more marked, and lung weight was increased by 136% compared to normal lungs. Clearly, the ventilation time needed to produce severe edema is less than 1 hour in small species but more than 24 hours in large animals. Blood-gas barrier thickness is an important component of capillary resistance to mechanical stretch, and is more important in larger animals.[40] Thus, one reason why permeability alterations were not consistently found is that they may become detectable only after longer ventilation times, in contrast to the immediate occurrence of microvascular pressure anomalies.

In summary, increased microvascular filtration pressure and altered microvascular permeability probably compound their effects to produce high PIP pulmonary edema. Although the hydrostatic component seems to be moderate on a quantitative basis, at least in closed-chest animals, it may nevertheless have a substantial impact. Indeed, in the face of a microvascular barrier with altered sieving properties, any increase in driving pressure will have a dramatic effect on edema formation.[41–43]

Mechanisms of Acute Increase in Alveolo-Capillary Permeability during Lung Overinflation

Interest has increasingly focused on the cellular response to mechanical strain and this subject has been comprehensively reviewed.[44] Tschumperlin and Margulies[45] observed increased cell death when alveolar epithelial cells were submitted in vitro to deformation. Cyclic deformation led to significantly greater cell death than did static deformation. The percentage of dead cells after 1 day ranged from 0.5% to 72% depending on the changes in surface area (up to 50%). In cyclically deformed cells, injury occurred rapidly, with most of cell death occurring during the first 5 minutes of deformation.[46] These authors showed that basement membrane surface area increased approximately 40% when lung volume was varied from FRC to total lung capacity.[47] These increases suggest that epithelial cells undergo significant stretch during large inflations. Vlahakis et al[48,49] labeled membrane lipids to study deformation-induced lipid trafficking and studied in a direct manner (laser confocal microscopy) the response of epithelial cells of the alveolar basement membrane response to forces. A 25% stretch deformation resulted in lipid transport to the plasma membrane that allowed maintenance of its integrity and an increase in epithelial cell surface area. Such lipid trafficking occurred in all cells, whereas plasma breaks were seen in only a small percentage of cells. The authors concluded that deformation-induced lipid trafficking serves, in part, to repair plasma breaks so as to maintain plasma membrane integrity and cell viability, and that this could be viewed as a cytoprotective mechanism against the plasma membrane stress failure seen during VILI.[36,50]

Overinflating the lungs results in the increase in epithelial[25] and endothelial[3,34] permeability, both occurring after inflating the lung above the same end-inspiratory pressure threshold.[51] Using an isolated perfused rat model, Parker et al showed that gadolinium (which blocks stretch-activated nonselective cation channels) annulled the increase in microvascular permeability induced by high PIP.[52] This suggests that entry through stretch-activated channels and an increase in intracellular calcium ion (Ca^{2+}) concentration might initiate the increase in permeability. This increase results in the activation of tyrosine kinases,[53] activation of the Ca^{2+}–calmodulin pathway and phosphorylation of myosin light chain kinase.[54] Taken together, these results suggest that the increase in microvascular permeability below the cell rupture point, which occurs under extreme stretch conditions ("stress failure"[50,55]), is not simply a passive physical phenomenon, but the result of biochemical reactions. In vitro studies show that cell plasticity and deformation-induced

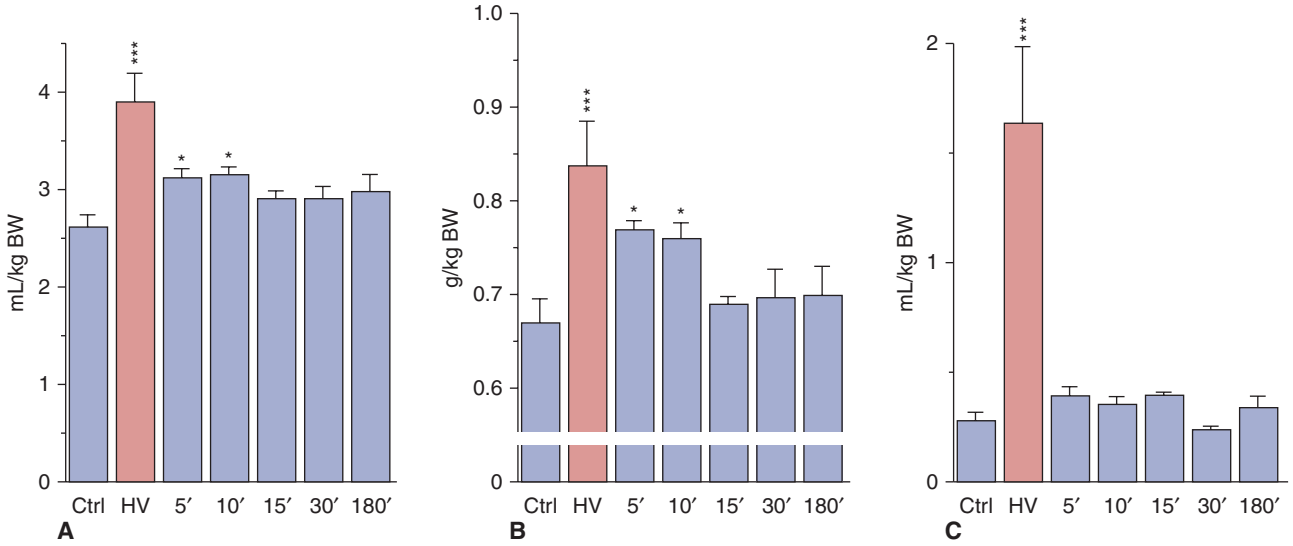

FIGURE 42-8 Effect of 45 cm H_2O peak airway pressure ventilation for 2 minutes (*HV*) and followed by recovery for various lengths of time in intact rats. **A.** Extravascular lung water. **B.** Dry lung weight. **C.** Albumin distribution space. (Used, with permission, from Dreyfuss et al.[4])

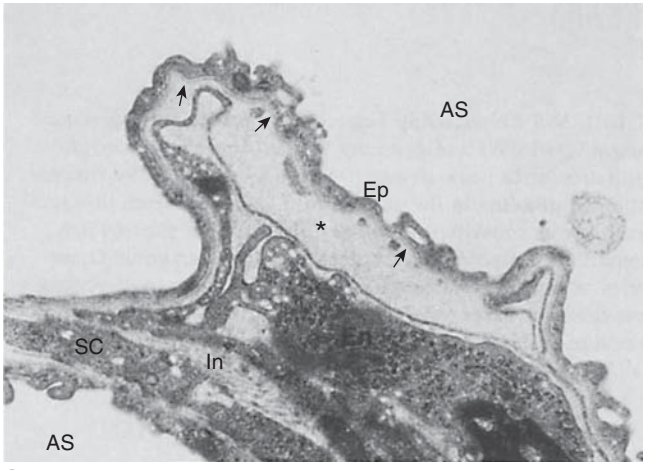
lipid trafficking protect against strain injury. Interventions that impair deformation-induced lipid trafficking reduce the likelihood of plasma membrane resealing[49,56] and increase cell death. It may help explain why the breaks seen across endothelial cells, after short periods of high transmural capillary pressure[57] or overinflation[4] are transient. In this latter study, rats were subjected to mechanical ventilation with 35 mm Hg PIP for only 2 minutes and allowed to recover for graded periods of up to 3 hours. The animals that were killed immediately after the challenge exhibited mild pulmonary edema with severe permeability alterations, as attested by increases in dry-lung weight and albumin space (Fig. 42-8). The very rapid occurrence of microvascular injury was ascertained by the ultrastructural study, which disclosed changes identical with those previously described after longer periods of ventilation.

These data strongly suggest that, at least in small animals, vascular leakage after overinflation is almost immediate and extensive. During recovery, both extravascular lung water and dry lung weight promptly returned to normal (see Fig. 42-8A and B), indicating that resorption of edema can be very rapid. Edema resorption does not necessarily indicate restoration of the alveolo–capillary barrier. The 30-minute distribution space of ^{125}I-albumin in lungs, however, was found to be normal, indicating that no albumin permeability defect was present after the time of tracer injection (see Fig. 42-8C). Because the tracer was injected during the recovery period (i.e., after cessation of overinflation), this finding demonstrated reversal of the alterations in permeability. ELF volume decreased after cessation of overinflation (see Fig. 42-3), reflecting resorption of the excess alveolar fluid concomitantly with the decrease in extravascular lung water. Even after 3 hours of recovery, however, ELF volume remained higher than in control animals. No marked changes in epithelial fluid protein content were observed (see Fig. 42-4B), reflecting the slower-than-water clearance of protein in alveolar edema fluid.[58] The absence of notable protein resorption explains why the protein concentration in ELF increased during recovery (see Fig. 42-4A).

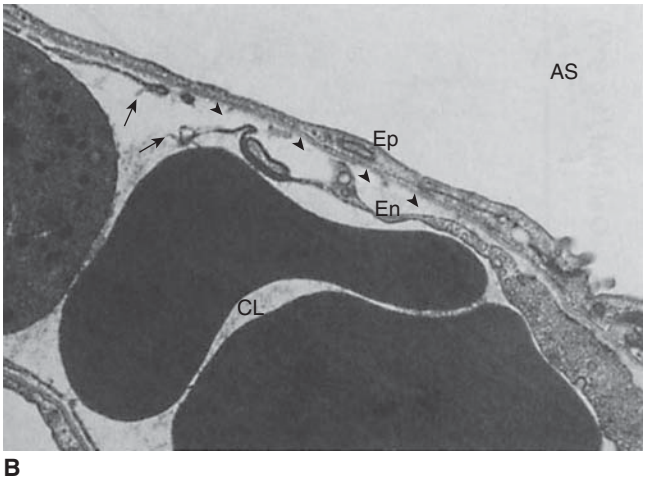
ULTRASTRUCTURAL FINDINGS OF VENTILATOR-INDUCED LUNG INJURY

Electron microscopic studies have confirmed that permeability alterations are prominent in the genesis of ventilator-associated pulmonary edema. Both endothelial and epithelial alterations have been observed.[3,4,30,36]

After short durations (5 to 10 minutes) of 45 cm H_2O PIP mechanical ventilation in rats, striking capillary abnormalities consistent with pulmonary edema of the nonhydrostatic type were observed. Some endothelial cells were detached from their basement membrane, resulting in the formation of intracapillary blebs filled with plasma-like material (Fig. 42-9A). Endothelial cells exhibited focal disruptions (Fig. 42-9B). Bleb formation has been reported in experimental high-permeability edema, regardless of the nature of the causative agent, and in acute respiratory distress syndrome (ARDS),[59–62] but not in experimental hydrostatic pulmonary edema.[59,60,63] Longer durations (20 minutes) of high PIP ventilation in rats resulted in alveolar flooding and obvious permeability alterations. Pathologic studies showed that this severe edema was accompanied with diffuse damage to the alveolar–capillary barrier. In addition to the capillary lesions, ultrastructural studies disclosed profound alterations in the epithelial layer. The severity of alterations varied. In some sites, the epithelial lining appeared intact. In many areas, however, findings included discontinuities (Fig. 42-10A and B) and sometimes



A



B

FIGURE 42-9 Ultrastructural features of the blood–air barrier after 5 minutes of 45 cm H_2O peak airway pressure in a closed chest rat. **A.** The most striking change is the formation of an endothelial bleb secondary to detachment of the thin part of the endothelial cell (*En*) from the basement membrane (*arrows*). This bleb is filled with electron-dense material (*) of the same density as plasma. At this stage, epithelial type I cells (*Ep*) are intact. Note interstitial edema (*In*). *AS*, alveolar space; *SC*, septal cell. (Courtesy Paul Soler, Ph.D.)

almost complete destruction of type I cells, leaving a denuded basement membrane (Fig. 42-10B and C). In contrast, type II cells appeared preserved. Hyaline membranes filled the alveolar spaces in many of the sections examined (Fig. 42-10C). Similar to the endothelial abnormalities, these lesions are not specific and occur in toxic injuries as well as in ARDS.[59–62] In contrast, when pressures remain in the 30- to 40-mm Hg range, hydrostatic edema does not affect epithelial integrity.[59,60,64]

Studies using both transmission and scanning electron microscopy have demonstrated ultrastructural breaks in endothelial and epithelial cells when capillary transmural pressure was raised to 40 mm Hg or more.[55,65,66] These breaks are the morphologic correlates of the increased microvascular permeability reported with very high microvascular pressures[67,68] and described as the stretched-pore phenomenon.[69,70] The similarities between capillary stress failure and VILI are quite remarkable. First, the electron microscopic appearance of endothelial and epithelial cell lesions exhibit similarities (Fig. 42-11).[55,65] Second, both types of damage are partly reversible. Albumin leakage from capillaries during high-volume ventilation ceased almost immediately after discontinuation of ventilation.[4] When capillary pressures were lowered to normal after elevation to a level causing stress failure, the number of endothelial and epithelial breaks fell compared with control experiments in which pressure remained elevated.[57] More importantly, capillary stress failure is influenced by lung inflation: At a capillary transmural pressure of 32.5 cm H_2O, increasing lung volume from a transpulmonary pressure of 5 to 20 cm H_2O resulted in a significant increase in the number of capillary endothelium and alveolar epithelium breaks (Fig. 42-12).[50] Thus, vascular pressures that are too low to affect microvascular permeability when lung volume is normal may produce permeability alterations when combined with a sufficiently marked increase in lung volume.

EFFECTS OF ACTIVATION OF INFLAMMATION BY PROTRACTED HIGH-VOLUME VENTILATION

The endothelial cell disruptions that have been observed during overinflation edema in small animals may allow direct contact between polymorphonuclear cells and basement membrane (see Fig. 42-10B) and promote leukocyte activation. Proinflammatory mediators may also be released by cells undergoing necrosis. Infiltration of inflammatory cells into the interstitial and alveolar spaces is not seen before several hours of injurious ventilation. In mice subjected to high PIP ventilation, leukocyte sequestration in lungs progressively increased with time.[71] Woo and Hedley-White[72] observed that overinflation produced edema in open-chest dogs, and that leukocytes accumulated in the vasculature and macrophages in the alveoli. Further studies confirmed these results[73] and showed that high transpulmonary pressure increased the transit time of leukocytes in the lungs of rabbits.[74] Conversely, high-volume pulmonary edema was less severe in neutrophil-depleted animals. Kawano et al[75] observed that neutrophil-depleted rabbits had preserved gas exchange, little lung albumin leakage, and no hyaline membranes after 4 hours of mechanical ventilation in contrast to nondepleted animals in a saline-lavage model. Whereas it is predictable that healing of wounded tissue would involve inflammation, several authors have suggested that lung tissue stretching might result in lung damage solely through the release of inflammatory mediators and leukocyte recruitment, the so-called biotrauma hypothesis.[76]

The term *biotrauma* encompasses all molecular and cell-mediated mechanisms involved in VILI, such as the production of lung-borne cytokines.[76,77] Although the causative role of those mediators on VILI has been debated,[78] as

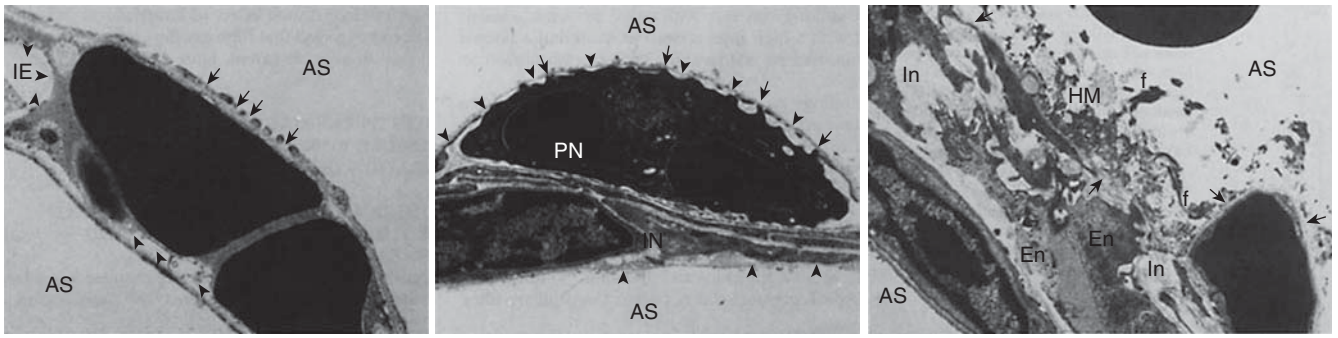


FIGURE 42-10 Ultrastructural features of the blood–air barrier after 20 minutes of 45 cm H_2O peak airway pressure in a closed chest rat. **A.** Type I cells show numerous gaps (*arrows*). *Arrowheads* point at the basement membrane from which the endothelial cell is detached. *AS*, alveolar space; *IE*, interstitial edema. comprehensively discussed in Chapter 42 of the second edition of this book and in "Pharmacologic Interventions" below, several investigators have tested the effect of cytokine modulators on lung dysfunction in experimental models of VILI.

PHYSIOLOGIC DETERMINANTS OF VENTILATOR-INDUCED INJURY

Respective Roles of Increased Airway Pressure and Increased Lung Volume

High inspiratory pressures consistently result in high lung volumes in normal animals. They induce well-documented hemodynamic changes in the systemic circulation,[79] and may potentially affect blood-flow distribution in the lungs because parts of the lungs are placed under zone 1 condition over the ventilatory cycle. Another possibility is that high pressures per se produce regional distortions that may result in specific deleterious effects. Several studies have been conducted to determine the relative roles of intrathoracic pressure increases and lung distension in the genesis of pulmonary edema.

High-volume ventilation with low airway pressure was obtained by ventilating closed-chest rats with intermittent negative perithoracic pressures (using an iron lung). Ventilation with high airway pressures but low tidal volumes was obtained with thoracoabdominal strapping to limit thoracic movements. The effects of high PIP plus high tidal-volume ventilation were compared with those of intermittent negative airway pressure plus high tidal-volume ventilation and intermittently positive high PIP plus low tidal-volume ventilation.[36] Pulmonary edema of the permeability type occurred in both groups of rats that received high tidal-volume ventilation, irrespective of inspiratory pressure (i.e., positive or negative; Fig. 42-13). In both groups, electron microscopic examination disclosed the same abnormalities as described above. In striking contrast with these findings, animals ventilated with a high PIP but a normal tidal volume had no edema (Fig. 42-13) and no ultrastructural changes. These findings have been replicated in rabbits[80] and lambs.[37]

Roles of the Magnitude of Pressure–Volume Changes and of Duration of the Challenge

IS THERE A PRESSURE–VOLUME THRESHOLD FOR THE OCCURRENCE OF EDEMA AND PERMEABILITY ALTERATIONS?

A threshold volume for permeability changes as the lung is overexpanded was suggested by Carlton et al.[37] These authors studied the effects of graded increases in tidal volume on lymph flow and protein concentrations in lambs. Peak inspiratory pressure (and therefore tidal volume) was increased in three successive steps (each lasting 4 hours) from baseline (16 cm H_2O to 61 cm H_2O). During the first two steps (33 and 43 cm H_2O PIP), no changes in lymph flow or protein composition were observed. In contrast, when the highest PIP was reached (corresponding to a tidal volume of 57 mL/kg), lung lymph flow increased fourfold to sixfold compared with baseline. Similarly, the lymph-to-plasma-protein-concentration ratio did not change until the highest PIP was reached, at which time it increased significantly compared with controls. The investigators concluded that microvascular alterations in response to overinflation occurred beyond a pressure threshold rather than gradually as pressure increased. They pointed out, however, that the albumin-to-globulin ratio in lymph versus plasma decreased before maximum PIP was reached, suggesting altered protein sieving and probably abnormal microvascular permeability. Indeed, Tsuno et al[39] demonstrated that ventilation of sheep with a moderately

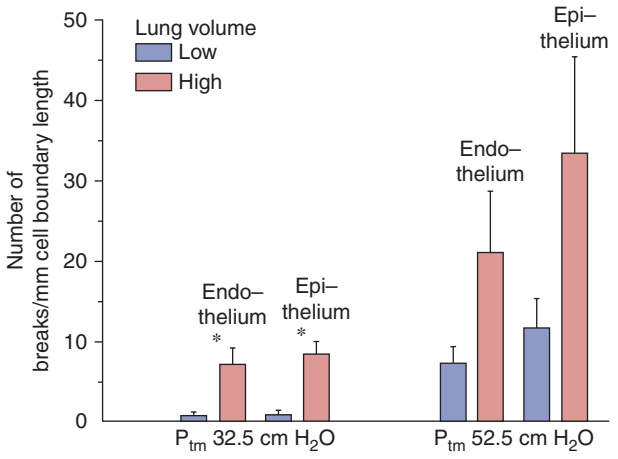

FIGURE 42-12 Effect of lung inflation on capillary stress failure. In situ rabbit lungs subjected to a capillary transmural pressure of 32.5 cm H_2O had more endothelial and epithelial breaks at high lung volume (transpulmonary pressure of 20 cm H_2O) than at low lung volume (transpulmonary pressure of 5 cm H_2O). (Used, with permission, from Fu et al.[50])

elevated PIP of 30 cm H_2O (corresponding to a tidal volume of 30 mL/kg) for more than 40 hours invariably resulted in gross pathologic alterations and an increase in wet-lung weight. Ventilating healthy sheep with tidal volumes ranging from 9 to 51 mL/kg for 54 hours, Protti et al demonstrated that ventilator-induced lung edema developed only when a strain (i.e., the ratio between tidal volume and FRC[81]) greater than 1.5 to 2.0 was applied to the lungs.[82] Interestingly, systemic inflammation and organ dysfunction also developed in pigs ventilated above this strain threshold.[82] In smaller species, such as rats, in which VILI occurs more rapidly, edema was demonstrated with a PIP as low as 30 cm H_2O, provided ventilation was sufficiently prolonged.[2] Recently, scintigraphic methods allowing for real-time imaging of two-way protein fluxes across the alveolo-capillary barrier were used to measure simultaneous changes in alveolar and microvascular permeability during lung inflation in rats.[51] The same end-inspiratory pressure threshold (between 20 and 25 cm H_2O, corresponding to tidal volumes of 13.7 ± 4.69 and 22.2 ± 2.12 mL/kg) was observed for epithelial and endothelial permeability changes (Fig. 42-14). Of note, this threshold corresponds approximately to the pressure at which a decrease is observed in the slope of the respiratory system pressure–volume curve (the so-called upper inflection point) in rats.[83]

These studies emphasize that both the degree and the duration of lung overexpansion are crucial in determining the severity of pulmonary edema. Interestingly, the possibility of a potential pressure–volume threshold for additional lung injury during mechanical ventilation of patients with acute lung injury is also debated. This is discussed in "Clinical Relevance" below.

Respective Contributions of Sustained Inflation (Positive End-Expiratory Pressure) and Large Pressure–Volume Swings

For the same level of overall lung inflation, increasing FRC by PEEP results in less-severe alterations, the reasons for

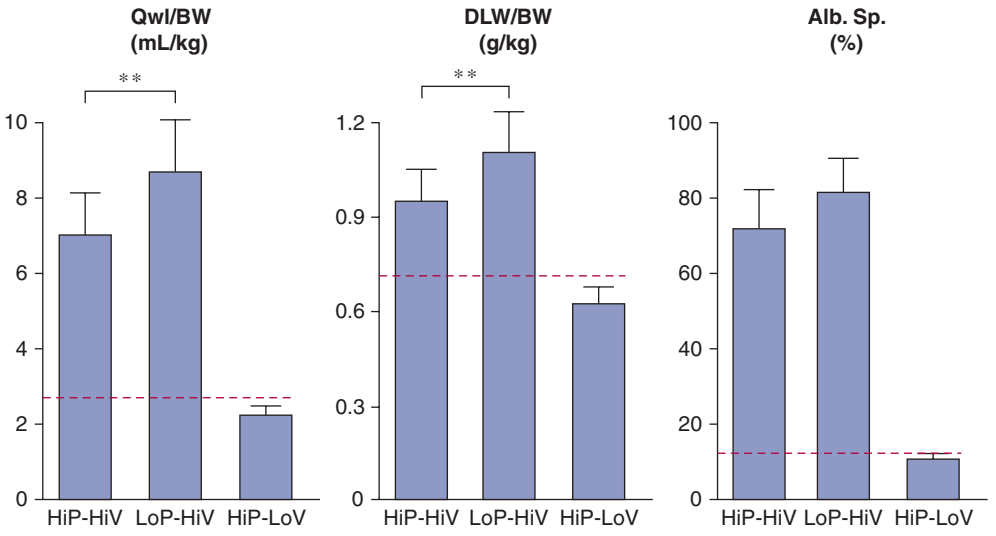

FIGURE 42-13 Comparison of the effects of high peak (45 cm H_2O) positive inspiratory pressure plus high tidal-volume ventilation (*HiP-HiV*) with the effects of negative inspiratory airway pressure plus high tidal-volume ventilation (iron lung ventilation = *LoP-HiV*) and of high peak (45 cm H_2O) positive inspiratory pressure plus low tidal-volume ventilation (thoracoabdominal strapping = *HiP-LoV*). *Dotted lines* represent the upper 95% confidence limit for control values. See Figure 42-6 for details on edema indexes. Permeability edema occurred in both groups receiving high tidal-volume ventilation. Animals ventilated with a high peak pressure and a normal tidal volume had no edema. ** = $p < 0.01$. (Used, with permission, from Dreyfuss et al.[36])

which may be reduction of V_T at the same respiratory rate, and hence of peak inspiratory flow, or stabilization of terminal units.

Several studies assessing the deleterious effects of high gas flow rates on lung function, a minor determinant of VILI, are discussed in detail in Chapter 42 of the second edition of this book. Webb and Tierney showed that, for a given level of teleinspiratory pressure, edema was less severe when a 10-cm H_2O PEEP was applied.[2] It was subsequently shown[36] that, although the amount of edema fluid was smaller with PEEP (Fig. 42-15), permeability alterations were similar to those observed with zero end-expiratory pressure. When rats were ventilated with PEEP, however, less edema occurred and, in particular, no alveolar flooding was observed on light microscopy.[2,36] More strikingly, whereas diffuse alveolar damage was present in the animals ventilated with zero end-expiratory pressure, no epithelial-cell lining alterations were observed on electron microscopic examination of the lungs of animals ventilated with PEEP. The only ultrastructural alterations consisted of endothelial blebbing. It is worth noting that PEEP decreases lung-capillary blood volume,[84] which, in turn, may lessen the capillary permeability alterations caused by high PIP ventilation.[85]

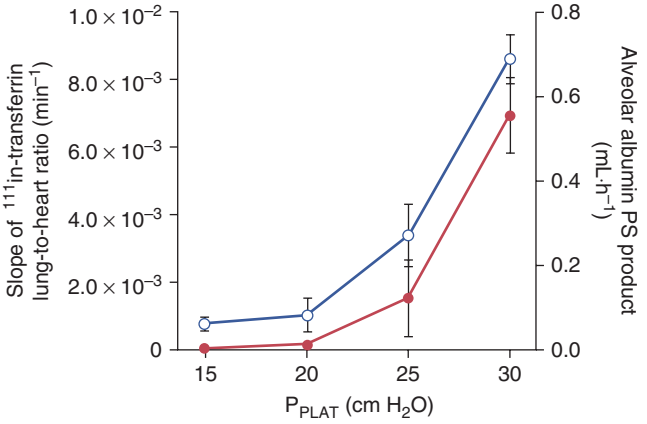

FIGURE 42-14 Relationship between plateau pressure (P_{PLAT}) and ^{111}In-transferrin lung-to-heart ratio slopes (*left axis, open circles*), reflecting lung-endothelial permeability, and alveolar ^{99m}Tc-albumin permeability-surface area product (*right axis, full circles*), reflecting lung-epithelial permeability. There is an increase in the permeability to proteins in both layers of the alveolo-capillary membrane above the same P_{PLAT} threshold, between 20 and 25 cm H_2O. (Used, with permission, from de Prost et al.[51])

This preservation of the alveolar–epithelial layer has received no satisfactory explanation. It may be that PEEP eliminated repetitive opening and closing of terminal airways, thereby decreasing shear stress and the development of surface-tension-induced epithelial cell damage at this level.[86] Alternatively, avoidance of alveolar flooding by PEEP[87,88] may have protected the epithelial lining from injury through the effects of yet unidentified humoral mediators.

One effect of PEEP is to reduce tidal volume for a given end-inspiratory pressure. It is interesting to note that studies using in situ perfused canine lobes[89] found that, for equivalent perfusion-flow rates and microvascular hydrostatic pressures, the rate of hydrostatic edema formation increased with tidal volume. When an identical increase in mean airway pressure was achieved either by applying PEEP or by increasing tidal volume, edema was less marked under the former condition, suggesting that large cyclic changes in lung volume promote the development of edema. This explanation was also put forward by Corbridge et al,[90] who

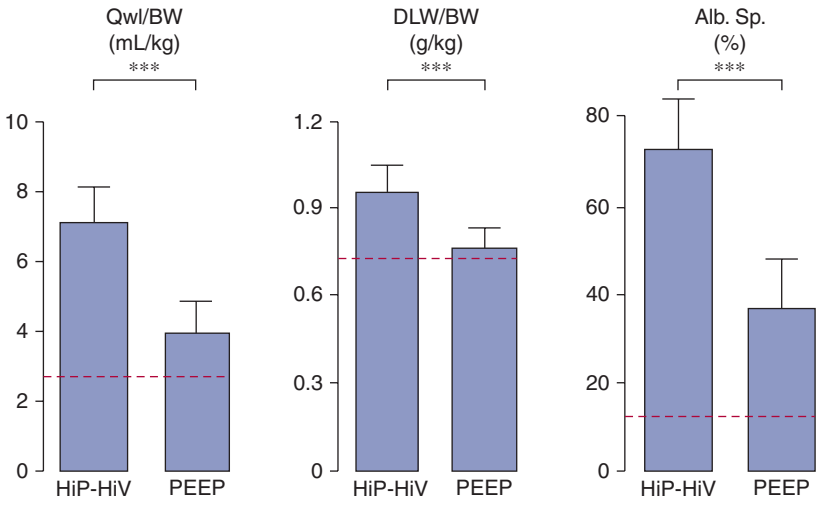

FIGURE 42-15 Effect of 10 cm H_2O PEEP during high peak (45 cm H_2O) positive inspiratory pressure plus high tidal-volume ventilation. *Dotted lines* represent the upper 95% confidence limits for control values. See Figure 42-6 for details on edema indexes. With PEEP, edema was less marked. ** = $p < 0.001$. (Used, with permission, from Dreyfuss et al.[36])

observed in hydrochloric acid-injured dog lungs that ventilation with a large tidal volume and a low PEEP resulted in more severe edema than did ventilation with a small tidal volume and a high PEEP. The effect of the amplitude of tidal volume on alveolar epithelium protein permeability was confirmed in rats using noninvasive scintigraphic techniques.[91] The alveolar albumin permeability-surface area product, measured from the clearance of an intratracheally instilled ^{99m}Tc-labeled albumin solution, dramatically increased, and in a dose-dependent manner, when V_T was increased from 8 to 24 and 29 mL/kg.[91]

Finally, the potential role of hemodynamic alterations during PEEP ventilation should also be considered. For instance, rats ventilated with 45 cm H_2O PIP and 10 cm H_2O PEEP had more edema when PEEP-induced hemodynamic alterations were corrected by dopamine administration (Fig. 42-16).[92] Moreover, arterial blood pressure was found to be significantly correlated with the amount of pulmonary edema under such conditions. The reason why use of PEEP during ventilation with high PIP is associated with reductions in both the amount of edema and the severity of cell damage may be a combination of hemodynamic alterations, shear stress reduction, and surfactant modifications. It should be borne in mind that this beneficial effect of PEEP during overinflation edema contrasts with the usual lack of reduction or even increase in edema reported with PEEP in most forms of experimental pulmonary edema.[93,94]

It would be inappropriate to conclude from the data summarized above that tidal volume, which governs opening and closing of terminal units, is the sole determinant of VILI. On the contrary, the overall degree of lung distension (i.e., teleinspiratory volume) is probably the crucial factor. Hence, rats ventilated with a tidal volume within the physiologic range at two levels of PEEP (10 and 15 cm H_2O) developed pulmonary edema only at the higher level of PEEP (Fig. 42-17).[92] Similarly, doubling tidal volume had no effect in animals ventilated with zero end-expiratory pressure, but resulted in pulmonary edema when 10 cm H_2O PEEP was used (Fig. 42-17).[92] Thus, the safety of small tidal volumes

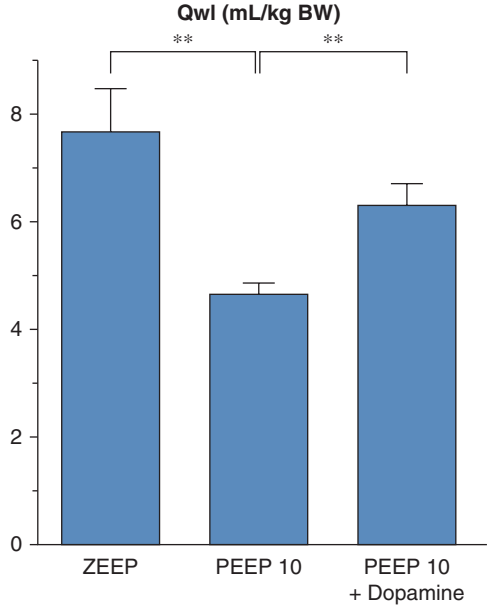

FIGURE 42-16 Effect of hemodynamic support with dopamine during 45 cm H_2O peak pressure ventilation with 10 cm H_2O PEEP on the amount of edema as evaluated by extravascular lung water. Compared with animals ventilated with 45 cm H_2O peak pressure and zero end-expiratory pressure (ZEEP), animals ventilated with 45 cm H_2O peak pressure ventilation with 10 cm H_2O PEEP had less edema. This reduction of edema associated with PEEP was partly abolished when dopamine was administered. ** = $p < .01$. (Adapted, with permission, from Dreyfuss and Saumon.[92])

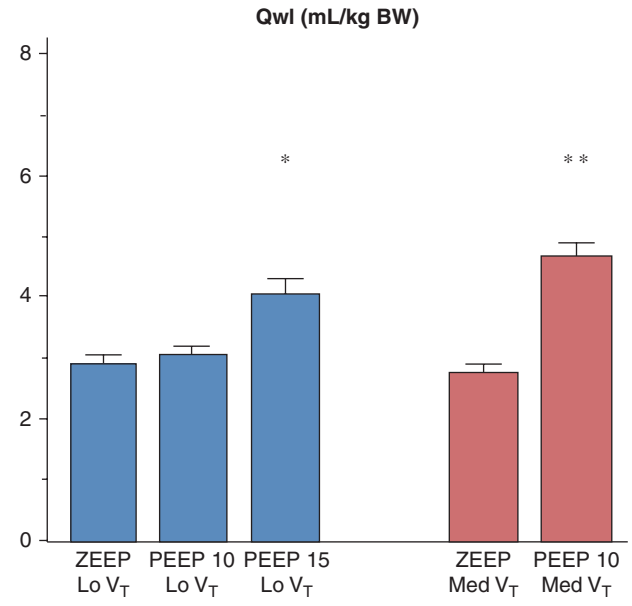

FIGURE 42-17 Effect of increasing PEEP from 0 to 15 cm H_2O during ventilation with two levels of tidal volume (V_T, 7 mL/kg of body weight [BW] = *Lo* V_T; 14 mL/kg BW = *Med* V_T). When PEEP was increased, pulmonary edema (as evaluated by extravascular lung water increases) occurred. The level of PEEP required to produce edema varied with tidal volume: 15 cm H_2O PEEP during ventilation with a low tidal volume versus 10 cm H_2O PEEP during ventilation with a moderately increased V_T. * = $p < .05$; ** = $p < .01$ versus zero end-expiratory pressure (*ZEEP*) and the same V_T. (Used, with permission, from Dreyfuss and Saumon.[92])

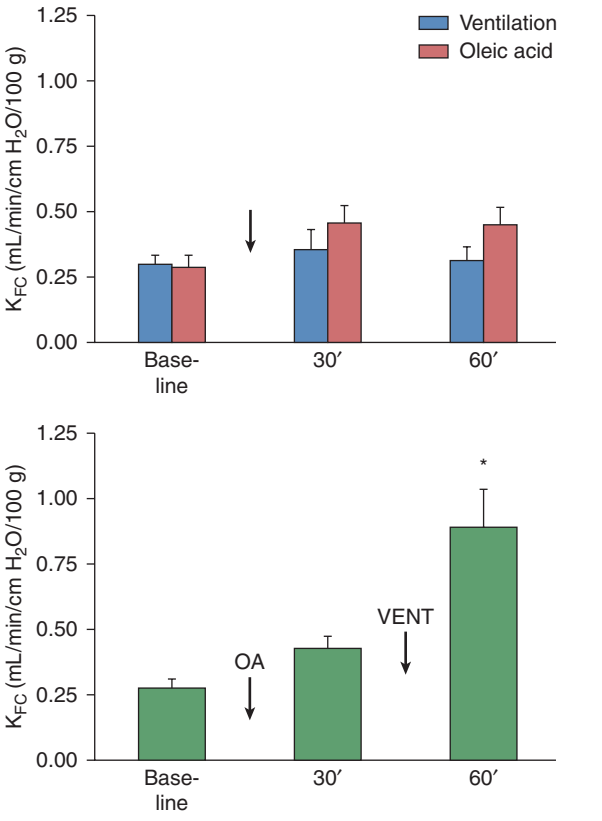

FIGURE 42-18 Effect of single and combined insults on the filtration coefficient of isolated rabbit lungs. A low dose of oleic acid (*OA*) or a moderately high peak pressure (24 cm H_2O) alone failed to induce K_{FC} (capillary filtration coefficient) changes, whereas the combination of both insults was responsible for a significant increase in K_{FC}. (Used, with permission, from Hernandez et al.[97])

depends on whether or not FRC is increased, and raising end-inspiratory volume by increasing FRC may cause lung injury independently of tidal volume.[92]

It is now clear that VILI occurs whenever a certain degree of lung overinflation is reached, by whatever means. For a given level of teleinspiratory pressure (and volume), adjunction of PEEP seems to slow the development or diminish the severity of alterations[95] but does not prevent the occurrence of permeability pulmonary edema.[36,92]

EFFECTS OF VENTILATION ON PREVIOUSLY INJURED LUNGS

This chapter does not consider the problems associated with lung prematurity, which is discussed in Chapter 23.

Combination of High-Volume–High-Pressure Ventilation and Previous Injury

ROLE OF LUNG MECHANICAL PROPERTIES ON SUSCEPTIBILITY TO VILI

The aforementioned studies were conducted on animals with healthy lungs. It is conceivable, however, that diseased lungs may be more susceptible than healthy lungs to the deleterious effects of mechanical ventilation. Diseased lungs with a patchy distribution of lesions may be subjected to considerably greater regional stress than homogeneously inflated lungs. As stressed by Mead et al, the pressure tending to expand an atelectatic region surrounded by a fully expanded lung is approximately 140 cm H_2O at a transpulmonary pressure of 30 cm H_2O.[96]

Hernandez et al[97] showed that whereas low doses of oleic acid or mechanical ventilation with PIP 25 cm H_2O did not affect filtration coefficient and wet-to-dry ratio, the combination of the two did (Fig. 42-18). The same group also reported that the filtration coefficient increase observed during high PIP (30 to 45 cm H_2O) ventilation of isolated perfused rabbit lungs was more marked following inactivation of surfactant by dioctyl succinate instillation.[98] Moreover, whereas light microscopic examination showed only mild abnormalities (minimal hemorrhage and vascular congestion) in the animals subjected to ventilation only or surfactant inactivation only, the combination of both injuries caused severe damage (extensive hemorrhage, pulmonary edema, and hyaline membranes). Thus, ventilator-induced lung edema seems to develop at lower airway pressures in

lungs with preexisting injury. Lung injury is usually inhomogeneous. The more compliant zones will thus receive the bulk of ventilation, which may favor their overinflation, a localized "baby lung effect." Analysis of the pressure–volume curve may help understand how preexisting lung injury may interact with ventilator-induced injury. Before examining this interaction, it is important to understand how lung mechanical properties are modified by lung injury.

The upper inflection point (UIP) often seen on the inspiratory pressure–volume curve of the respiratory system in patients with ARDS has been interpreted as reflecting the beginning of overinflation,[99,100] or the end of recruitment.[101,102] Whether ventilation, however, that results in pressure and/or volume excursions above the UIP is deleterious is unsettled. Better understanding of the UIP significance is required before it can be used to set tidal volume in patients. An experimental study examined the hypothesis that pulmonary edema development alters the pressure–volume curve of respiratory system mainly because of distal airway obstruction,[83] and this reduction in ventilatable lung volume (the baby lung effect) may not only decrease compliance[103,104] but also affects UIP position. When the distal airways of rats were obstructed by instilling a viscous liquid, the changes in the shape of the pressure–volume curve (gradual decrease in compliance, the volume at which UIP was seen and progressive increase in end-inspiratory pressure) were similar to the changes seen during the development of pulmonary edema. The higher the compliance and volume of the UIP, the lesser was the edema observed after high PIP ventilation (Fig. 42-19). Taken together, these results suggest that the position of the UIP is a marker of the amount of ventilatable lung volume, and it is both influenced by, and predictive of, the development of edema during mechanical ventilation.

The effect of high PIP ventilation on injured lungs in intact animals was investigated by comparing different degrees of lung distension in rats whose lungs had been injured by α-naphthylthiourea (ANTU).[105] ANTU infusion alone caused moderate interstitial pulmonary edema of the permeability type. Mechanical ventilation resulted in a permeability edema, the severity of which depended on the tidal-volume amplitude. It was possible to calculate the extent that mechanical ventilation theoretically injures lungs diseased by ANTU by adding the separate effect of mechanical ventilation alone or ANTU alone on edema severity (Fig. 42-20). The lungs of the animals injured by ANTU ventilated at high PIP (45 mL/kg body weight [BW]) had more severe permeability edema than predicted (Fig. 42-20), indicating synergy between the two insults. Even minor alterations, such as those produced by spontaneous ventilation during prolonged anesthesia (which degrades surfactant activity and promotes focal atelectasis), were sufficient to synergistically increase the harmful effects of high-volume ventilation.[105] The extent to which lung mechanical properties deteriorate before ventilation is a key factor in this synergy. The amount of pulmonary edema produced by high-volume ventilation in animals given ANTU, or that had undergone prolonged

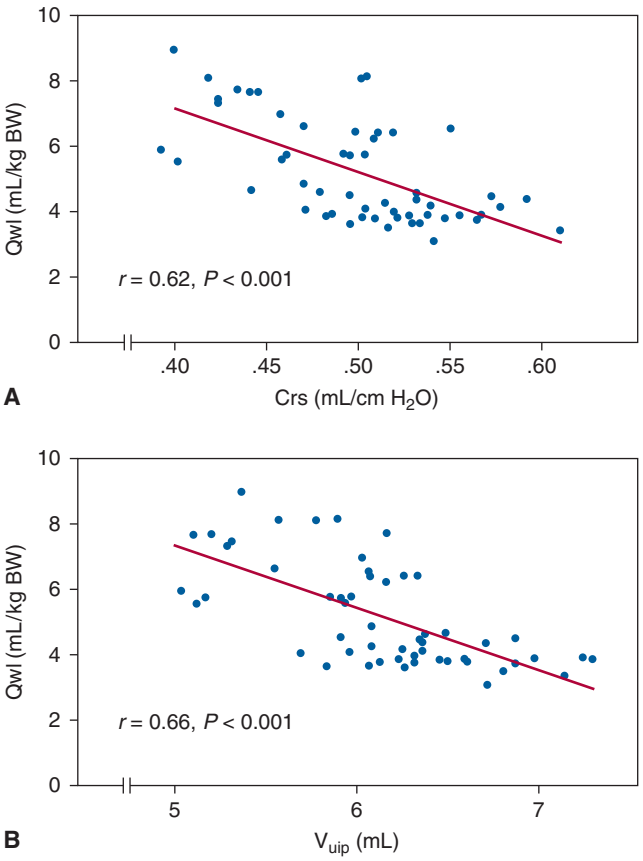

FIGURE 42-19 **A.** Correlation between the amount of edema (extravascular lung water, *Qwl*) produced by high-volume ventilation and the respiratory system compliance (*Crs*) measured before high-volume ventilation. **B.** Correlation between *Qwl* and the volume at the upper inflection point on the pressure–volume curve (V_{uip}) measured before high-volume ventilation. (Used, with permission, from Martin-Lefèvre et al.[83])

anesthesia, was inversely proportional to the respiratory system compliance measured at the very beginning of mechanical ventilation.[83,105] The same conclusions were reached about the volume of UIP.[83]

The reason for this synergy requires clarification. Local alveolar flooding in animals subjected to the most harmful ventilation protocol was the most striking difference from animals ventilated with lower, less harmful, tidal volumes.[105] It is conceivable that edema foam in airways reduced the number of alveoli that received the tidal volume, exposing them to overinflation and rendering them more susceptible to injury, further reducing the aerated lung volume. The result is a positive feedback loop. To explore this possibility, alveolar flooding was produced by instilling saline into the trachea of rats that were immediately ventilated with tidal volumes of up to 33 mL/kg.[106] Flooding with saline did not significantly affect microvascular permeability when tidal volume was low. As tidal volume was increased, capillary permeability alterations were larger in flooded than in intact animals, reflecting further impairment of their endothelial

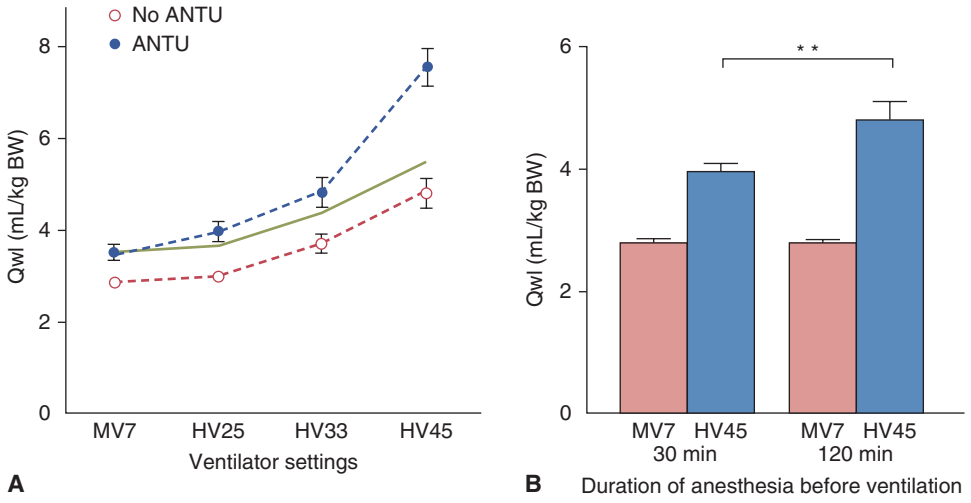

FIGURE 42-20 Interaction between previous lung alterations and mechanical ventilation on pulmonary edema. **A.** Effect of previous toxic lung injury. Extravascular lung water (*Qwl*) after mechanical ventilation in normal rats (*open circles*) and in rats with mild lung injury produced by α-naphthylthiourea (*ANTU*) (*closed circles*). Tidal volume (V_T) varied from 7 to 45 mL/kg BW. The *solid line* represents the Qwl value expected for the aggravating effect of ANTU on edema caused by ventilation, assuming additivity. ANTU did not potentiate the effect of ventilation with V_T up to 33 mL/kg BW. In contrast, V_T 45 mL/kg BW produced an increase in edema that greatly exceeded additivity, indicating synergy between the two insults. **B.** Effect of lung functional alteration by prolonged anesthesia. Intact rats were anesthetized and breathed spontaneously for 30 to 120 minutes before ventilation with V_T 7 mL/kg BW (*pink open bars*) or 45 mL/kg BW (*blue shaded bars*). Qwl of animals ventilated with a high V_T was significantly higher than in animals ventilated with a normal V_T. Qwl was not affected by the duration of anesthesia in animals ventilated with a normal V_T. In contrast, 120 minutes of anesthesia before high V_T ventilation resulted in a larger increase in Qwl than did 30 minutes of anesthesia. ** = $p < 0.01$. (Used, with permission, from Dreyfuss et al.[105])

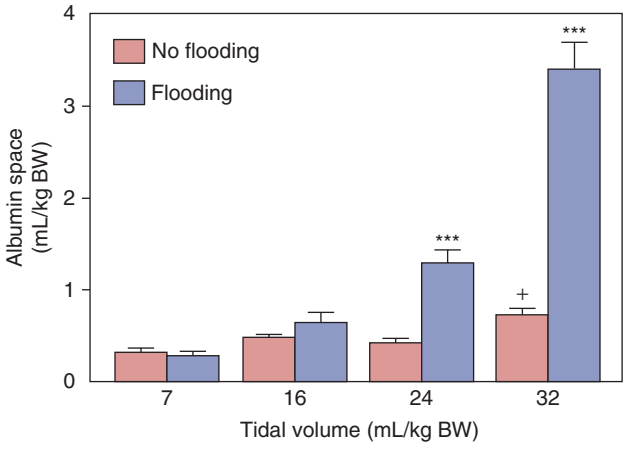

FIGURE 42-21 Effect of increasing tidal volume (V_T) during mechanical ventilation for 10 minutes on lung capillary permeability (i.e., extravascular albumin distribution space in lungs) of rats with intact lungs (*pink open bars*) or with alveolar flooding (*purple closed bars*) produced by saline instillation. There was a moderate increase in albumin space in intact rats at the larger V_T. Lung flooding did not produce significant increases of albumin space when V_T was normal or moderately increased. Albumin space was significantly increased with a V_T of 24 and 32 mL/kg BW. The increase in albumin space greatly exceeded additivity, indicating a positive interaction between the two insults. *** = $p < 0.001$ as compared with intact animals. + = $p < 0.05$, as compared to animals of the "no flooding" group ventilated with V_T 7 mL/kg. (Used, with permission, from Dreyfuss et al.[106])

barrier (Fig. 42-21). There was also a correlation between end-inspiratory airway pressure and capillary permeability alterations in flooded animals ventilated with a high tidal volume. Thus, the less compliant and recruitable the lung was after saline flooding, the more severe were the changes in permeability caused by lung distension.

These studies support the conclusion that the risk of overinflation is more important in diseased than in healthy lungs. Strategies to prevent VILI should oppose the synergy between ventilation and previous lung injury.

Does Ventilation without Overinflation Aggravate Previous Lung Injury?

EFFECT OF POSITIVE END-EXPIRATORY PRESSURE

It has been suggested that mechanical ventilation may worsen lung injury because of increased shear stress in distal airspaces secondary to their repeated closing, either because of obstruction by liquid menisci or collapse and reopening. Coker et al[98] reported that the capillary filtration coefficient of isolated perfused rabbit lungs was not modified by either ventilation at 15 cm H_2O PIP (which results in much larger tidal volumes in isolated lungs than in intact animals) or surfactant inactivation, but doubled the coefficient when the two insults were combined. Several studies have investigated the effects of conventional ventilation on acutely

injured lungs by using sufficiently high PEEP levels to keep the small airways open throughout the entire ventilatory cycle, thereby avoiding repeated closure and reopening.

Sykes et al[107,108] studied the effect of ventilation in rabbits with surfactant-depleted lungs. The animals were ventilated with a PIP ranging from 15 mm Hg at the beginning of the experiment to 25 mm Hg at the end (5 hours later) because of the fall in lung compliance (tidal volume was not stated); PEEP adjusted to position the FRC either above or below the lower inflection point (LIP). Mortality rate was not influenced by PEEP level, although arterial oxygen tension (Pa_{O2}) was better-preserved in the high-PEEP group.[107,108] There was less hyaline membrane formation in animals ventilated with a high PEEP than in those ventilated with low PEEP. This lessening of pathologic alterations was observed even with ventilator settings that achieved identical mean airway pressures in the low and high PEEP groups.[108] Comparable results were reported in isolated, nonperfused, lavaged rabbit lungs ventilated with a low tidal volume and with a PEEP level set either below or above the LIP.[109] The same findings could not be replicated in hydrochloric acid-injured rabbit lungs using similar ventilator settings.[110] Thus, it is conceivable that the protective effect of PEEP, when set above the LIP of the pressure–volume curve, is observed only in the very special setting of surfactant deficiency and not during severe alveolar edema, because lung instability and airspace collapse is observed only during the former.

Using in vivo videomicroscopy, Nieman et al[111–115] directly observed and quantified the dynamic changes in alveolar size throughout the ventilatory cycle during tidal ventilation, in normal lungs and in lungs in which surfactant had been deactivated by generic. Injuries occurred independently of the presence of neutrophils.[111] In normal lungs, alveoli never collapsed. These findings agree with the previous findings of Bachofen and Wilson, who showed that alveoli do not change volume appreciably during ventilation.[116] Collapse and reopening and increase in the alveolar size at end-inspiration were observed in surfactant-deactivated lungs. In a subsequent study, the same authors documented the effect of increasing end-expiratory pressure.[115] The application of PEEP to a surfactant-deactivated lung reversed the observed increase in alveolar size, returning it to control levels.

The reality of the repetitive opening and closure of terminal units and the significance of the LIP on the pressure–volume curve have been challenged by Martynowicz et al,[117] who studied the regional expansion of oleic acid-injured lungs using a parenchymal marker technique. The gravitational distribution of volume at FRC was not affected by oleic acid injury, and the injury was not associated with decreased parenchymal volume of dependent regions. In addition, temporal inhomogeneity of regional tidal expansion did not increase with oleic acid injury. These findings do not support the hypothesis that a superimposed gravitational pressure gradient during VILI produces compression atelectasis of dependent lung, which in turn produces shear injury from cyclic recruitment and collapse.[117] The authors propose that the occurrence of a LIP on the pressure–volume curve represents the transition from the liquid-filled state to the air-filled state, when the lung is initially filled with a liquid with constant surface tension properties.[118] Thus, abrupt expansion of distal lung units is unlikely to occur at the LIP.

The protective effect of PEEP, however, is not restricted to the particular setting of surfactant depletion.[2,3,95] Distal airspace damage during tidal ventilation may occur because of repeated airway opening and closing secondary to the movement of foam with increased surface tension[86] or the rupture of liquid menisci. PEEP may prevent diffuse lung damage during prolonged ventilation by stabilizing these units.[119] The beneficial effect of PEEP, however, is variable in different models of lung injury.[120] The difficulty in proving whether or not PEEP exerts a protective effect on VILI may be explained by taking into account the distinction between atelectatic and fluid-filled distal airways when interpreting LIP. In the case of diffuse filling of distal airways with liquid, VILI may be caused by overdistension of already aerated zones rather than by shear stress secondary to opening of collapsed zones.[121] With this scenario, it would be difficult to expect any reduction of injury by PEEP.

This uncertainty about the actual occurrence of injury at low lung volumes contrasts with the unambiguous demonstration of high-volume (overdistension) injury. This uncertainty has a clinical counterpart that is discussed in "Clinical Relevance" below.

EFFECT ON REMOTE ORGANS AND NORMAL LUNG REGIONS

As further discussed in "Pharmacologic Interventions" below, neutrophilic infiltration and increased levels of proinflammatory cytokines have been found in the lungs of animals that were subjected to long-lasting injurious ventilation.[73,76] These observations led to the hypothesis that mechanical ventilation might promote or aggravate a systemic inflammatory state.[122] In addition to increasing the amount of cytokines in the lung, it has been suspected that overinflation may promote the release of cytokines[123,124] or bacteria[125–127] into the blood, thus suggesting that mechanical ventilation plays a causative role in multiorgan dysfunction.[122,128] Higher levels of proinflammatory cytokines (tumor necrosis factor [TNF]-α, interleukin [IL]-1β and macrophage inflammatory protein [MIP]-2) were found in lung homogenates of rats ventilated for 2 hours with high PIP when they were previously subjected to mesenteric ischemia–reperfusion[129] or hemorrhagic shock and resuscitation[130] (Fig. 42-22). This suggests the validity of the "two-hit" hypothesis, that a preexisting inflammatory state augments cytokine release during VILI.

A few experimental studies have evaluated the consequences of injurious ventilation on peripheral organs. Choi et al[131] found that rats ventilated with high PIP for 2 hours had increased endothelial nitric oxide synthase expression in lung and kidney tissue and increased microvascular permeability in both organs. Nitric oxide was probably involved in these abnormalities, because *N*-nitro-L-arginine

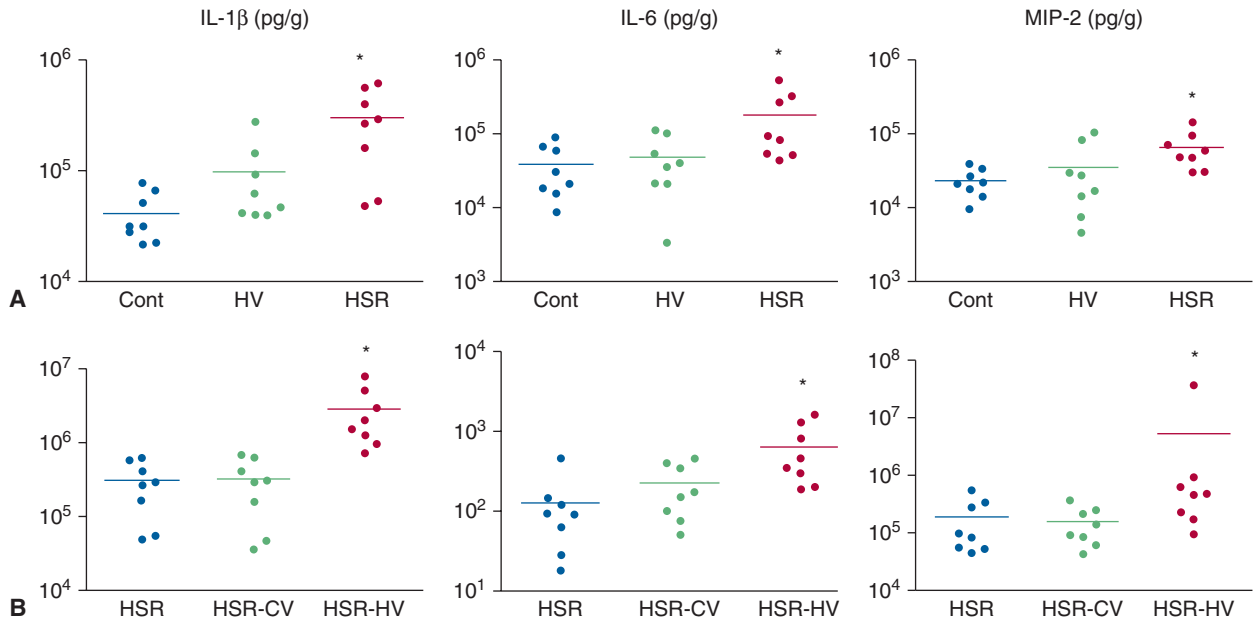

FIGURE 42-22 **A.** Comparison of lung cytokine levels in nonventilated rats (controls [*Cont*]) and in rats subjected to an injurious mechanical ventilation strategy (30 mL/kg tidal volume and zero end-expiratory pressure) alone (*HV*) or to hemorrhagic shock-reperfusion injury alone (*HSR*). Compared with controls, lung cytokine concentrations were higher after HSR but not after HV. **B.** Comparison of lung cytokine levels in rats subjected to HSR alone, HSR combined with conventional ventilation (*HSR-CV*) and HSR followed by HV (*HSR-HV*). Injurious ventilation (HV) after HSR significantly increased mediator release above the levels observed after HSR alone or in combination with conventional ventilation. Results are expressed in pg/g. * = $p < 0.05$ as compared to controls (*A*) or to HSR (*B*). The same observations were made in bronchoalveolar lavage fluid and in plasma. (Adapted, with permission, from Bouadma et al.[130])

methyl ester administration attenuated the microvascular leak of lung and kidney. An increase in gut permeability was also observed during a similarly long-lasting ventilation, albeit with larger tidal volume (30 instead of 20 mL/kg), which was attenuated by anti–TNF-α antibody administration.[132] Injurious ventilation of rabbits with hydrochloric acid-induced lung injury resulted in increased rates of epithelial cell apoptosis in the kidney and small intestine villi.[133]

There is also growing evidence that ventilator settings may localize or disperse proteinaceous lung edema or bacteria. In a model of unilateral *Pseudomonas aeruginosa* pneumonia in rats, Schortgen et al showed that high-volume ventilation with no PEEP promoted contralateral bacterial seeding.[127] Interestingly, ventilation at the same end-inspiratory pressure but with high PEEP, and thus a lower V_T, prevented contralateral lung dissemination. To better understand these observations, the potential effect of adverse ventilator patterns on the dispersal of localized radiolabeled alveolar edema to the opposite lung was studied.[91] A ^{99m}Tc-labeled albumin solution was instilled into the distal airways and it produced a zone of alveolar flooding that remained localized during conventional ventilation. High end-inspiratory pressure ventilation dispersed alveolar liquid in the lungs. This dispersion was prevented by PEEP even when V_T was the same and thus end-inspiratory pressure even higher (Fig. 42-23). Interestingly, contralateral liquid dispersion began almost immediately after high-volume ventilation was started, suggesting that this dispersion might be the consequence of a convective movement induced by the ventilation. High-inspiratory and high-expiratory flows favored fluid transport back and forth toward the alveoli and the airways. In the heterogeneous lung, fluid transfer may be propelled toward regions of normal compliance. PEEP may have prevented dispersion by avoiding lung collapse and stabilizing edema fluid in the distal airways. The clinical relevance of the movement of such noxious biofluids in the airways has been discussed elsewhere.[134]

PROTECTION FROM VENTILATION-INDUCED LUNG INJURY

Strategies That Aim at Improving Lung Mechanics

USE OF PRESSURE–VOLUME CURVES

Taking the presence and value of a LIP on the pressure–volume curve into account when setting the level of PEEP may lessen VILI in some,[107–109] but not all, instances.[110] The concept on lung protection against VILI with the setting of a PEEP above the LIP, however, relies on a putative stabilizing effect of PEEP that would abolish the tendency of distal airways to collapse at end-expiration and reopen during the next inspiration. As discussed above, serious criticisms have been raised against this opening-and-closing theory,[121]

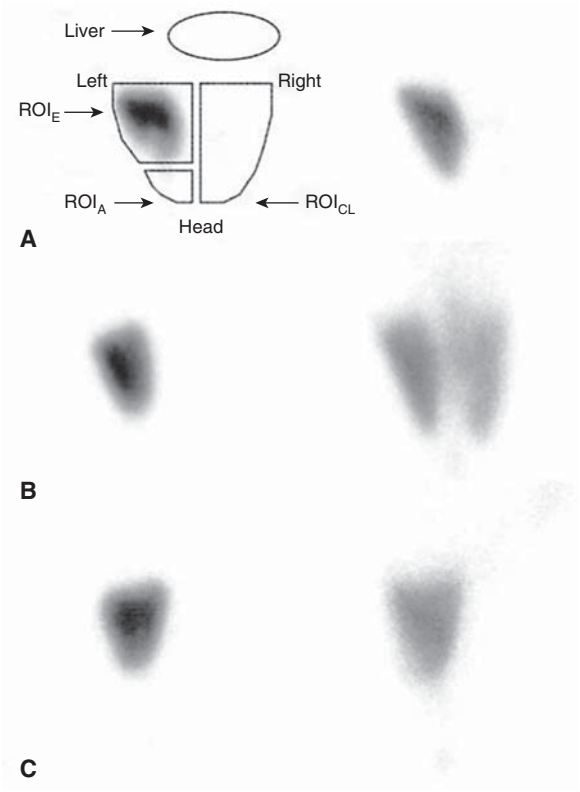

FIGURE 42-23 Scintigraphy images integrated over 15 minutes after instillation (t0 to t15; *left panels*) and the last 15 minutes of the experiment (t195 to t210; *right panels*). Regions of interest (*ROIs*) were drawn around initial focus of edema (ROI_E), the apex of the same lung (ROI_A), the contralateral lung (ROI_{CL}), and over the thorax. At baseline (*left panels*), all animals were ventilated with tidal volume 8 mL/kg and PEEP 2 cm H_2O and exhibited focalized localization of the tracer in the left lung. When the same ventilator settings were maintained during the experiment (**A**), the tracer remained remarkably confined in the initial zone; there was no contralateral and only slight homolateral dissemination. High-volume ventilation (pressure plateau [P_{PLAT}] = 30 cm H_2O) with no PEEP (**B**) induced strong homolateral and contralateral dispersion of the tracer and systemic leakage as attested by the decrease in overall activity. High-volume ventilation with 6 cm H_2O PEEP (**C**) induced systemic, but not contralateral, dissemination of the tracer. (Used, with permission, from de Prost et al.[91])

casting doubt on the usefulness of measuring LIP in order to prevent VILI.

The overall degree of lung distension resulting from the settings of both PEEP and tidal volume is a fundamental determinant of VILI. Although the exact physiologic significance of UIP is debated, it may indicate lung overstretching. Ventilation that takes place above UIP was found to be markedly deleterious (see Fig. 42-19).[83] Thus, determination of the volume at which the UIP is observed may help reduce the risk of VILI, because it indicates the maximum stretch that the lung can sustain without noticeable damage.[83] Analysis of the airway pressure–time curve during mechanical ventilation with constant flow has also proven useful in determining the stress applied to lungs. Indeed, an upward concavity of the pressure–time curve suggests that compliance decreases as tidal volume is delivered, with resulting high-volume stress.[135] Such a ventilation pattern was associated with histologic lung injury in an isolated, nonperfused, lavage model of acute lung injury[135] and with overdistension, as attested by computed tomography scan analysis, of the lungs of intact animals with saline lavage-induced lung injury.[136]

SURFACTANT

Numerous studies have been conducted on the effect of surfactant administration on gas exchange in experimental models of lung injury. In contrast, few experimental studies have specifically addressed the effect of surfactant administration during VILI. Verbrugge et al studied the effect of surfactant administration on lung function and alveolar permeability during 45 cm H_2O PIP ventilation in rats.[137] Alveolar permeability was significantly reduced in animals receiving 200 mg/kg of surfactant.[137] Exogenous surfactant prevented high-volume (20 mL/kg) lung injury in isolated rat lungs, but it did not affect the release of inflammatory cytokines by these lungs during ventilation.[138] In rats receiving lipopolysaccharide by tracheal instillation, however, surfactant pretreatment reduced decompartmentalization of TNF-α from the lungs to the systemic circulation during injurious mechanical ventilation.[139]

PERFLUOROCARBONS

Partial liquid ventilation[140] with perfluorocarbons was developed during the last decade as an alternative to conventional gas ventilation for the treatment of acute respiratory failure. Several investigators using different models of acute respiratory failure (surfactant depletion, oleic acid, hydrochloric acid, prematurity) have reported improvement in gas exchange, lung mechanics, and lung histology.[141] Although some investigators have shown a dose-dependent improvement in gas exchange with perflubron (LiquiVent) in a rabbit model of surfactant depletion,[142] others have highlighted the risk of barotrauma (namely pneumothorax) with the use of large volumes of perfluorocarbon combined with high PEEP or increased tidal volume.[143] Until recently, the effect of partial liquid ventilation on VILI has received little attention. Mechanical nonuniformity of diseased lungs may predispose lungs to VILI by overinflation of the more compliant (ventilatable), aerated zones.[105] Perfluorocarbon may reduce this nonuniformity by suppressing air–liquid interfaces and allowing reopening of collapsed or liquid-filled areas.

The effect of perfluorocarbon instillation on hyperinflation-induced lung injury during alveolar flooding was investigated in rats.[106] Saline was instilled into the trachea to mimic alveolar edema and reduce aerated lung volume. Alveolar flooding significantly aggravated VILI, as attested by an increase in capillary permeability alterations. Tracheal instillation of a low dose (3.3 mL/kg) of perflubron in these flooded lungs considerably reduced VILI and decreased permeability alterations (Fig. 42-24). Whereas instillation of saline alone raised LIP pressure to values as

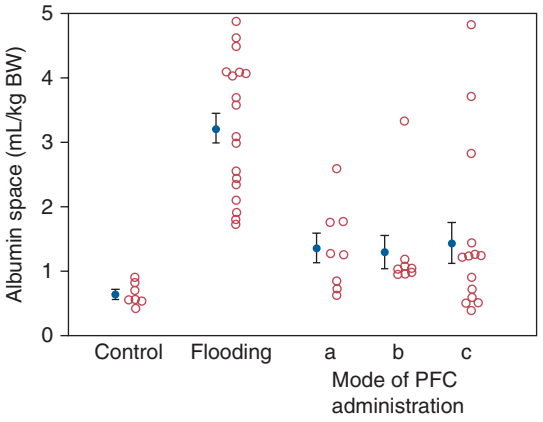

FIGURE 42-24 Effect of perflubron (LiquiVent) instillation on permeability pulmonary edema as assessed by the extravascular albumin distribution space in the lungs of rats ventilated with a tidal volume of 33 mL/kg BW. Flooding significantly increased albumin space ($p < 0.001$). Perflubron given as a bolus (*a*), by slow infusion before flooding (*b*), or as a bolus dose after flooding (*c*) resulted in a significant decrease in albumin space, the values of which remained higher than in controls ($p < 0.05$). *Closed circles with error bar* indicate means ± standard error of mean (SEM). *PFC*, perfluorocarbon. (Used, with permission, from Dreyfuss et al.[106])

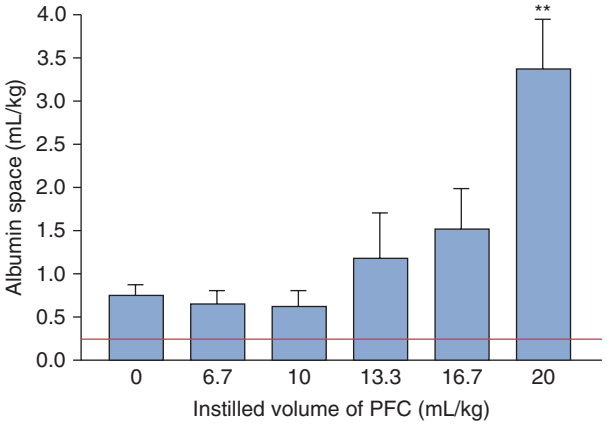

FIGURE 42-25 Dose–response effect of perflubron instillation on microvascular permeability assessed by the distribution space of albumin in the lung. Rats were ventilated with a tidal volume of 33 mL/kg BW. The albumin space value of control rats ventilated with a tidal volume of 7 mL/kg BW is represented by the *horizontal line*. Albumin space was three times higher after high-volume ventilation, in the absence of perflubron instillation. Lung injury was not aggravated by the instillation of 6.7 and 10 mL/kg perflubron, tended to increase with doses of 13.3 and 16.7 mL/kg, and increased significantly with 20 mL/kg perflubron. ** = $p < 0.01$; *PFC*, perfluorocarbon. (Used, with permission, from Ricard et al.[144])

high as 25 cm H_2O, and produced a significant increase in the end-inspiratory pressure, administration of perflubron significantly reduced LIP pressure and normalized end-inspiratory pressure.

To further investigate the effect of partial liquid ventilation on VILI with respect to the dosage of perfluorocarbon, intact animals ventilated with a high tidal volume (33 mL/kg BW) received increasing doses of perflubron (from 6 to 20 mL/kg).[144] Hyperinflation-induced pulmonary edema tended to decrease with doses of perflubron lower than 10 mL/kg as compared with animals not given perflubron. By contrast, ventilator-induced pulmonary edema was aggravated in animals given 13 and 16 mL/kg, and even more in animals given 20 mL/kg perflubron (Fig. 42-25). Large doses worsened volutrauma because they increased FRC, thus increasing end-inspiratory volume for the same tidal volume, and because they favored gas trapping in the distal lung, as demonstrated by computed tomography imaging.[144] Consistently, in rats with preinjured lungs (after ANTU administration) and subjected to ventilation with a high tidal volume (33 mL/kg BW), low and moderate doses of perflubron, but not larger doses (approximately 20 mL/kg), improved respiratory mechanics and ventilator-induced permeability alterations (Fig. 42-26).[145] These observations suggest that monitoring of end-inspiratory pressure might help detect the risk of volutrauma during partial liquid ventilation.

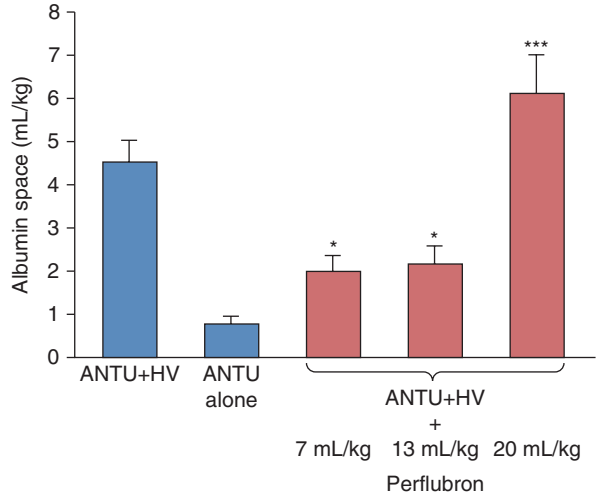

FIGURE 42-26 Dose–response effect of perflubron instillation on microvascular permeability assessed by the distribution space of albumin in lungs injured either by α-naphthylthiourea (*ANTU*) alone or combined with high tidal-volume ventilation (tidal volume 33 mL/kg BW; *ANTU+HV*). ANTU alone produced a mild permeability defect, which was considerably increased when combined with HV. This dramatic change in microvascular permeability was significantly reduced by doses of 7 and 13 mL/kg perflubron (* = $p < 0.05$). In contrast, animals that received 20 mL/kg perflubron had a further significant increase in microvascular permeability, as compared with animals that received ANTU+HV without perflubron instillation (*** = $p < 0.001$). PRONE POSITION

Prone position lessened the deleterious effect of high PIP ventilation with PEEP in dogs with previous oleic acid lung

injury;[146] similar benefit was shown in rabbits[147] and rats.[148] Prone position resulted in a more homogenous distribution of lung injury,[149] an observation that was not confirmed in other studies in rabbits or rats. These differences are probably a result of difference in lung size, with a larger lung increasing the influence of gravity. Indeed, computed tomography scans in rats did not disclose a gradient of lung inflation at end-expiration as in humans.[148] In rats, the beneficial effect of prone position was ascribed to a more homogenous distribution of tidal volume and thus of strain, because of the downward displacement of the diaphragm.[148] In a rat model of paraquat-induced acute lung injury, the prone position was consistently associated with a more homogeneous lung expression of type III procollagen than observed in the supine position.[150]

NOISY VENTILATION

Spontaneously breathing subjects show an intrinsic variability in tidal volume and respiratory frequency during normal ventilation.[151] It has been theorized that the respiratory system may work as a stochastic resonance system where the variability of input parameters leads to an increase in the surface area for gas exchange in the lungs, thus improving lung function.[152] In a model of endotoxin-induced acute lung injury in guinea pigs, variability of tidal volumes of some 10% to 60% above and below the mean combined with a respiratory frequency that kept minute ventilation constant significantly decreased lung elastance and improved oxygenation as compared to conventional ventilation.[153] After oleic acid-induced lung injury, pigs ventilated with a comparable strategy exhibited lower concentrations of IL-8 in tracheal aspirates than did pigs ventilated with a conventional strategy.[154] Recently, Spieth et al[155] studied the effects of variability of tidal volume (within 40% of mean) in a surfactant-depletion model of acute lung injury in pigs. Animals were ventilated with two different strategies for setting PEEP: the ARDS Network protocol and an open-lung approach where PEEP was set according to the minimal elastance of the respiratory system. Adding noisy ventilation to these settings not only improved oxygenation, but also decreased histologic damage.[155] Depending on the strategy with which it was combined, noisy ventilation likely improved VILI by distinct mechanisms. When combined with the ARDS Network protocol, noisy ventilation stabilized distal lung units and likely reduced their repetitive opening and closing. When combined with an open-lung approach, noisy ventilation generated lower peak airway pressures, thereby limiting the overdistension of nondependent lung regions. Further experimental studies are required to determine whether similar results would be obtained in less recruitable models of acute lung injury and after longer periods of mechanical ventilation.

Pharmacologic Interventions

The following observations show that a tremendous number of cell-signaling pathways are involved in the pathophysiology of VILI. Although it is probably illusory to believe that a single pharmacologic intervention might be beneficial in patients, the description of those pathways illustrates the complexity of the cellular mechanisms involved in VILI.[78]

MODULATION OF MICROVASCULAR PERMEABILITY

Blocking stretch-activated cation channels[52] and inhibiting phosphotyrosine kinase,[54] phosphodiesterase,[54] and calcium-dependent phospholipase A_2[71] reduced the pulmonary capillary permeability alterations caused by high PIP ventilation. Reducing myosin light-chain phosphorylation with adrenomedullin, an endogenous peptide belonging to the calcitonin gene-related peptide family, decreased lung vascular permeability and the accumulation of neutrophils in the lungs of mice subjected to high PIP ventilation.[156] These inhibitions suggest that stretch-induced calcium entry in lung cells and intracellular calcium signaling play an important role in the early response to high PIP ventilation. Indeed, the phosphorylation of myosin light chains by Ca^{2+}/calmodulin-dependent myosin light chain kinase leads to endothelial cell contraction, a key mechanism of VILI-induced endothelial barrier dysfunction.[157] Intravenous delivery of a myosin light-chain kinase inhibitor in a mouse model of VILI reduced lung microvascular permeability and neutrophilic infiltration.[158]

β-adrenergic agonist infusion reduced accumulation of plasma protein in the lungs of patient who survived an episode of ARDS,[159] suggesting that it might have lessened their microvascular permeability alterations. In a model of high PIP ventilation in rats, terbutaline administered intratracheally lessened both the increase in lung epithelial and endothelial permeability caused by VILI, whereas terbutaline administered intraperitoneally lessened only lung endothelial permeability (Fig. 42-27).[160] These results help

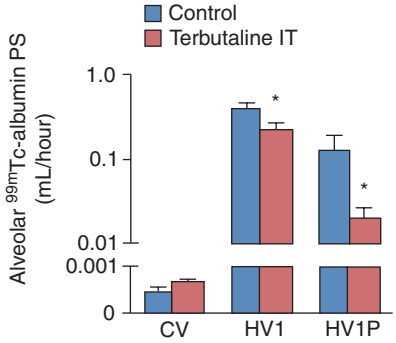

FIGURE 42-27 Alveolar ^{99m}Tc-albumin permeability surface-area product (*PS*), reflecting lung-epithelial permeability. PS was dramatically increased during high-volume ventilation using 30 cm H_2O PIP (*HV1*), as compared to conventional ventilation (*CV*). This effect was present even when positive end-expiratory pressure was applied (*HV1P*) and was decreased when terbutaline was administered intratracheally (*IT*). * = $p < 0.05$ when compared with the same ventilation modality. (Adapted, with permission, from de Prost et al.[160])

us understand the disappointing results of a trial that compared the intravenous administration of β-adrenergic agonists versus placebo in patients with ARDS.[161] In that study, gas exchanges and lung injury score remained unchanged despite a decrease in extravascular lung water, as measured by thermodilution. The findings suggest that airway delivery might be more efficient in preventing the increase in alveolocapillary barrier permeability during mechanical ventilation.

Inhibition of nitric oxide synthase[131,162] lessened ventilator-induced capillary permeability abnormalities. Inhibition of the endothelial isoform mitigated VILI via a decrease in the production of superoxide.[163] Recently, phosphoinositide 3-kinase-γ of resident lung cells was consistently shown to mediate alveolar edema induced by high-stress ventilation in part through an increase in nitric oxide production by endothelial cells.[164] Surprisingly, transgenic mice that overexpressed endothelial nitric oxide synthase exhibited less lung damage, lung water content, and neutrophil infiltration as compared to wild-type mice, suggesting that this isoform might also be protective from VILI in different conditions.[165] These discrepant results suggest that the mechanisms of VILI are equivocal and that more work is needed to determine the involvement of the nitric oxide pathway despite the fact that the ultrastructural abnormalities observed after high-volume ventilation[3] resemble those seen during increased endothelial nitric oxide production.[166]

MODULATION OF INFLAMMATION

Tremblay et al[76] examined the effects of different ventilator strategies on the level of several cytokines in bronchoalveolar lavage fluid of ex vivo, unperfused rat lungs ventilated with different end-expiratory pressures and tidal volumes. High tidal volume ventilation (40 mL/kg BW) with zero end-expiratory pressure resulted in the release of considerable amounts of TNF-α, IL-1β, IL-6, and MIP-2, a potent neutrophil chemoattractant and the rodent functional homolog of human IL-8 (Fig. 42-28). These results have not, however, been replicated by other groups using either the same ex vivo lung model.[78,167] In vivo studies of intact animals showed that high-volume mechanical ventilation, which produces a very severe pulmonary edema, does not induce lung release of TNF-α in rats.[167,168] Similarly, TNF-α release was not found in mice ventilated with a high PIP in vivo, although it was found in the perfusate of isolated lungs from the same strain.[30] Studies on TNF-α messenger RNA (mRNA) also yielded conflicting results. Takata et al[169] showed large increases in TNF-α mRNA in the intraalveolar

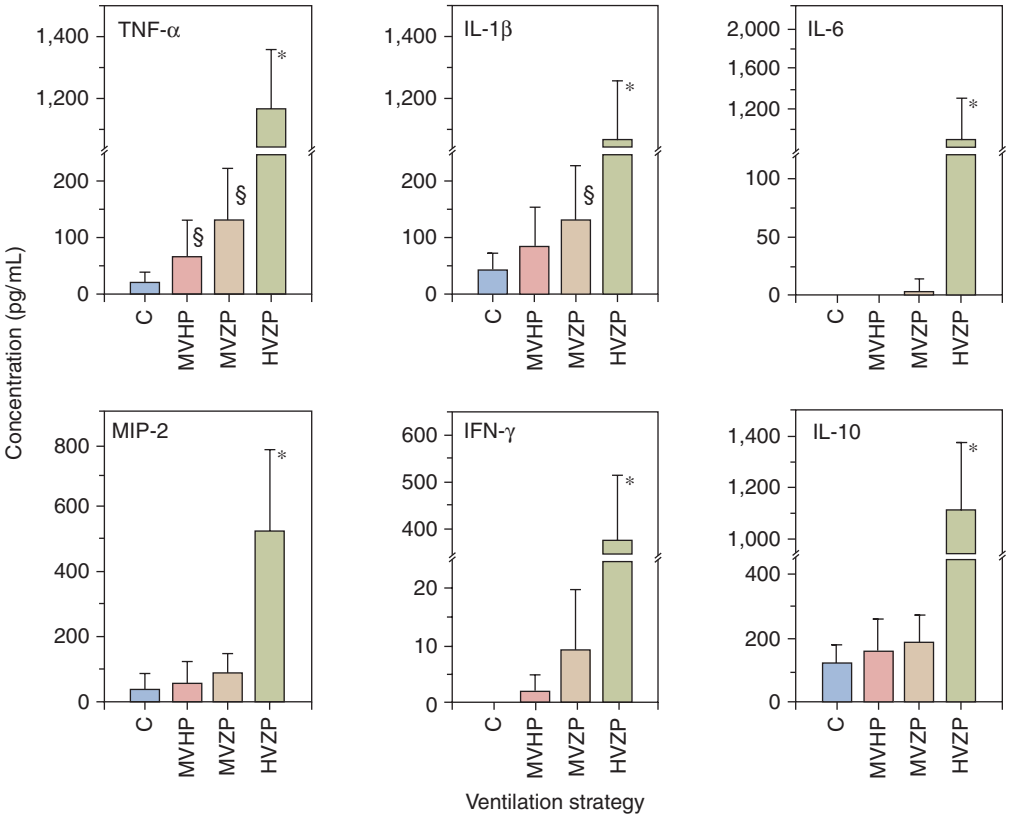

FIGURE 42-28 Effect of different ventilator strategies on cytokine concentrations in lung lavage of isolated unperfused rat lungs. Four ventilator settings were used: controls (*C* = normal tidal volume), moderate tidal volume + high PEEP (*MVHP*), moderate tidal volume + zero PEEP (*MVZP*), high tidal volume + zero PEEP (*HVZP*) resulting in the same end-inspiratory distension as MVHP. Major increases in cytokine concentrations were observed with HVZP. * = $p < 0.05$ vs all other groups; § = $p < 0.05$ vs controls. (Used, with permission, from Tremblay et al.[76])

cells of surfactant-depleted rabbits after 1 hour of conventional mechanical ventilation with peak inspiratory and end-expiratory pressures of 28 and 5 cm H_2O. Conversely, Imanaka et al found no increase in lung tissue TNF-α mRNA of rats ventilated with 45 cm H_2O PIP.[170] Administration of an anti–TNF-α antibody via the trachea, but not via the systemic circulation, lessened inflammation in lungs of mice subjected to high PIP ventilation.[132,171,172] Mice with knockout of the TNF receptor had less lung inflammation, but no less release of CXC chemokines, in bronchoalveolar lavage fluid.[30]

The only mediator that was consistently released by lungs subjected to high-volume ventilation[30,76,123,167,173] or in vitro in stretched lung cells, such as human alveolar macrophages[174] or cell lines such as A549 epithelial cells,[175] was the chemokine IL-8 or its rodent equivalent MIP-2. The release of MIP-2 may explain the recruitment of neutrophils that occurs during subacute VILI.[73,176,177] Leukocyte sequestration during injurious ventilation strategies seems to be the result of polymorphonuclear stiffening and mediated by L-selectin–dependent but CD18 (β_2-integrin)-independent mechanisms.[178] Belperio et al[173] showed that inhibition of the chemokine interaction with the CXCR2 receptor attenuates neutrophil sequestration and lung injury after 6 hours of high-volume ventilation in mice. Whether neutrophil recruitment alone is sufficient to produce VILI or merely accompanies mechanical injury continues to be debated.[78] Inhibition of MIP-2 activity by specific antibodies[179] of the MIP-2 receptor[173] reduced neutrophil infiltration and lung injury caused by high PIP ventilation.

Leukocyte activation, however, is an unlikely explanation for the major vascular leakage observed during high-inflation edema because the speed with which permeability and ultrastructural alterations develop[4] is not consistent with such a mechanism. Besides, the potent proinflammatory mediators, TNF-α and MIP-2, are unlikely to be involved in the acute lung injury consequent to high-volume ventilation[30] for two reasons. First, there was no correlation between the flux of albumin in alveolar spaces (as reflected by its concentration in bronchoalveolar lavage fluid) and MIP-2 (or IL-6) concentration in this fluid. Second, the authors did not detect TNF-α in bronchoalveolar fluid in any intact mouse model that developed pulmonary edema after lung overinflation and the absence of TNF-α receptors did not preclude the development of acute VILI.[30] These observations confirm that two different types of VILI exist: acute VILI that follows marked overexpansion, and subacute VILI in which inflammatory phenomena prevail. Recently, the use of genomic-intensive approaches allowed for the identification of VILI susceptibility candidate genes[180] and revealed that pre–B-cell colony-enhancing factor is a direct neutrophil chemotaxin and potentially a key pharmacologic target in VILI.[181]

The concept of biotrauma (i.e., the release of proinflammatory cytokines and mediators by lung parenchymal cells, alveolar macrophages, and neutrophils) led to the publication of a tremendous number of studies that tested the effect of modulating the imbalance between proinflammatory and antiinflammatory mediators in the lung. For instance, ventilation with high tidal volume of isolated mouse lungs for 1 hour resulted in nuclear factor-κB (NF-κB) activation, which was inhibited by dexamethasone.[182] Pretreatment of rats with NF-κB antibodies resulted in less permeability pulmonary edema, pathologic changes, and IL-1 expression in an isolated rat lung model of VILI.[183] Administration of an IL-1 receptor antagonist reduced lung albumin, elastase, and neutrophil counts in surfactant-depleted rabbits ventilated with hyperoxia and a high tidal volume[184] and decreased pulmonary edema, airspace neutrophils, and expression of nitric oxide synthase 2 and intercellular adhesion molecule 1 mRNA in rats ventilated with 30 mL/kg tidal volume.[185] In a rat model of VILI, Hoegl et al showed that the prophylactic inhalation of IL-22 before initiation of 45 cm H_2O PIP ventilation protected the lung against lung edema and improved survival.[186] This beneficial effect might be related to an increase in STAT3/SOCS3 expression in alveolar epithelial cells. In a rat model of VILI, prophylactic IL-10 inhalation mitigated the increase in MIP-2 and IL-1β in bronchoalveolar fluid and plasma, and increased animal survival time.[187]

Finally, other kinds of antiinflammatory interventions, such as the stimulation of the endogenous cholinergic pathway,[188] the administration of adenosine A_{2A} receptors agonists,[189] the inhalation of carbon monoxide,[190] and the inhibition of the cyclooxygenase[191] or lipooxygenase[192] showed beneficial effects in animal VILI models.

MODULATION OF HORMONAL AND METABOLIC PATHWAYS

The renin–angiotensin system is involved in lung inflammation during VILI, as attested by increased angiotensin II levels and angiotensinogen mRNA levels in bronchoalveolar lavage fluid of rats subjected to 4 hours of high PIP ventilation.[193] Angiotensin-converting enzyme II, which inactivates angiotensin II and is thus a negative regulator of the renin–angiotensin system, protects mice from acute lung injury related to acid aspiration or sepsis.[194] Moreover, pretreatment of animals with captopril attenuated lung injury and inflammation.[193,195] These protective effects might be related to a reduction in the angiotensin II-induced production of plasminogen activator inhibitor-1.[196]

Pretreatment with atorvastatin decreased alveolar capillary permeability and improved hemodynamics in an isolated rabbit lung model of VILI.[197] Muller et al confirmed these findings in an in vivo model of VILI in mice, showing that treatment with simvastatin limited lung endothelial injury and hyperpermeability, decreased lung neutrophilic infiltration, and improved oxygenation.[198] It remains unknown, however, whether these effects are related to the lipid-lowering properties of statins or to antiinflammatory, antioxidative, or nitric oxide synthesis regulatory properties.[196]

Lung-soluble mediators are pathogenic in VILI.[199] Indeed, isolated perfused mouse lungs ventilated with low tidal volumes but perfused with a perfusate derived from lungs previously ventilated with high tidal volumes develop a similar

decrease in compliance and an increase in lung water.[199] Several lipid-derived mediators have been identified as candidate mediators in VILI.[200] For instance, inhibition of cytosolic phospholipase A_2 mitigates the increase in capillary permeability induced by high PIP ventilation.[201] Finally, ceramides and other sphingolipids are essential constituents of plasma membranes and have been recognized as potential pharmacologic targets in the treatment of acute lung injury.[202] Whether this also applies to prevention or treatment of VILI is unknown.

Reversible induction of a suspended animation-like state (i.e., a hypometabolic state characterized by decreased heart rate, body temperature, and exhaled amounts of CO_2) obtained by the intravenous infusion of a hydrogen sulfide donor, reduced pulmonary inflammation and improved oxygenation in rodent models of VILI.[203,204]

Hypercapnia

Ventilator strategies consisting of a low tidal volume to lower the risk of VILI have a positive impact on survival in ARDS.[1] It has been proposed that the hypercapnic acidosis that accompanies a tidal volume reduction may reduce VILI.[205]

Extreme hypoventilation (with partial pressure of arterial carbon dioxide [Pa_{CO_2}] between 150 and 250 mm Hg) lessened lung injury in surfactant-depleted rabbits, suggesting a therapeutic role for high Pa_{CO_2}.[206] Studies on isolated rabbit lungs[205] found that hypercapnia lessened the acute (within 30 minutes) increase in endothelial permeability produced by high PIP ventilation. Other studies in rabbits ventilated for 4 hours showed that hypercapnic acidosis lessened neutrophil infiltration and lung injury when tidal volume was high,[207] and also reduced the increases in alveolar–arterial oxygen gradient and airway pressure at a clinically relevant tidal volume.[208] Two other in vivo studies, however, were unable to demonstrate a reduction by hypercapnia of the acute capillary permeability alterations caused by high tidal-volume ventilation in a rabbit model of surfactant depletion[209] or in intact rats.[210] The latter investigation concluded that hypercapnia probably has a greater influence on late inflammation-dependent phenomena than on acute stress failure.

Studies in isolated rat lungs, however, have shown that hypercapnia lessened lung weight gain and the decrease in compliance during high tidal-volume ventilation,[211] but the number of subpleural damaged cells, evaluated by confocal microscopy with a membrane impermeant fluorescent tracer, did not differ between normocapnic and hypercapnic lungs. Furthermore, compared to normocapnia, hypercapnia significantly reduced the probability of wound repair in A549 cell cultures.[211] These observations suggest that there is no strong correspondence between the occurrence of cell lesions and the physiologic response of the lung to stretch. They also suggest that the benefit from hypercapnia, if any, may be offset by alterations in the cellular reparation process.[49] This hypothesis was further confirmed by Caples et al in an isolated-perfused rat-lung model of VILI.[212] The buffering of hypercapnic acidosis decreased the rate of cell membrane wounding when lungs were exposed to an injurious ventilation strategy, which suggested the importance of pH-dependent mechanisms.

CLINICAL RELEVANCE

It is clear that microvascular lung injury and pulmonary edema during mechanical ventilation are not the consequences of "barotrauma," but rather of "volutrauma."[36] The main determinant of volutrauma seems to be end-inspiratory volume (the overall lung distension) rather than tidal volume or FRC (which is dependent on the level of PEEP).[92]

It is fascinating to see how the experimental concept of VILI was rapidly translated into a preoccupation of clinicians, as exemplified by the term *ventilator-associated lung injury*.[213] Although the validity of this concept could not be directly demonstrated in patients, it formed the rationale beneath all lung-protective strategies that aimed to reduce the risk of lung overinflation during ventilation of patients with ARDS. That the lungs in ARDS exhibit significant heterogeneity is well documented,[103,214] and ARDS is a condition that results in uneven distribution of ventilation. Gattinoni et al[103] demonstrated that ARDS lungs include healthy tissue, recruitable tissue, and diseased tissue unresponsive to pressure changes. Healthy units represent as little as 20% to 30% of total units.[103] These units can be viewed as "baby lung," another term for the "shrunken lung" described by Gibson and Pride in patients with lung fibrosis.[104] Thus, during conventional ventilator treatment in ARDS, the bulk of ventilation may be directed to healthy units, resulting in regional overdistension, especially when high PIP is required.

Ventilator strategies aimed at reducing the risk of overinflation, such as extracorporeal membrane oxygenation,[215] extracorporeal CO_2 removal,[216] and high-frequency oscillation[217] were proposed (see Chapters 19 to 21). These techniques are merely experimental (at least in adults) and require special devices and highly trained physicians and nurses. In addition, the lack of demonstrable benefit with extracorporeal CO_2 removal,[218] and the scarcity of data on high-frequency oscillation in adults,[219] preclude their acceptance in many centers. Emerging data, however, have generated renewed interest in these techniques.[220,221] It is beyond the scope of this chapter to discuss this issue extensively. Nevertheless, the complexity of these techniques is in striking contrast with the extraordinary simple lung-protective strategies that accompany permissive hypercapnia.[222] Although caution should be exercised when extrapolating experimental data to clinical situations as complex as infant respiratory distress syndrome or ARDS, the clinical relevance of available experimental data received resounding support with the publication of the ARDS Network study.[1] This study showed that simply reducing tidal volume from 12 mL/kg to 6 mL/kg resulted in a 22% reduction in mortality. The effectiveness of this strategy was attributed to a reduction of lung stress, as attested by markedly decreased airway plateau pressure.[223]

The demonstration, however, of a technique to prevent overdistension is difficult. Airway pressure monitoring is easy to perform but cannot completely eliminate the risk of VILI. For instance, application of a continuous distending pressure during high-frequency oscillation or extracorporeal CO_2 removal may be associated with a gradual increase in lung volume. If the increase in volume is the result of recruitment of previously closed lung units, it is likely to be beneficial, at least in terms of gas exchange, and will probably not cause additional lung damage. On the contrary, failure to recruit closed alveoli may result in overdistension of open alveoli.[224]

Because of the study protocol, the same reduction in tidal volume was employed in all patients allocated to the low tidal volume group in the ARDS Network trial.[1] It has, however, repeatedly been shown that the pressure and volume considered safe for some patients with ARDS may cause lung overdistension in others.[99,100,103,225] Conversely, arbitrary settings may result in an unnecessary reduction in tidal volume.[226] As discussed above, information from the inspiratory pressure–volume curve of the respiratory system may be used to tailor ventilator settings, especially when the significance of its particular characteristics (LIP, UIP) are better understood.[83]

Another question that cannot be answered at present is whether or not a threshold tidal volume exists below which experimental VILI or ventilator-associated lung injury in patients does not occur in previously injured lungs. If such a threshold exists, it is unnecessary to drastically reduce tidal volume in all patients as was done in the ARDS Network study,[1] especially in view of possible adverse effects that occur with too great a reduction in tidal volume.[226] In such conditions, staying within the so-called safe limits of plateau pressure[213,223] will be sufficient. In contrast, the absence of such a safe threshold was suggested in the ARDS Network study:[1] Mortality was lower in patients with reduced tidal volume independently of static compliance of the respiratory system at baseline. This observation suggests that low tidal volume was advantageous regardless of lung compliance.[1] Notwithstanding, the reduction of mortality by simply reducing end-inspiratory lung stress lends credence to the possibility that end-inspiratory lung volume is the main determinant of volutrauma (as contended at the beginning of this section). Indeed, it was recently suggested that higher tidal volume may be associated with the onset of acute lung injury[227] or ARDS[228] in patients ventilated for other causes of respiratory failure.

In contrast with the experimental and clinical demonstration of the importance of reducing lung stretch by reducing tidal volume, the clinical relevance of the concept of low lung-volume injury (discussed above) is less obvious. This is a crucial issue as it governs the level of PEEP that should be applied to reduce ventilator-associated lung injury. It is beyond the scope of this chapter to discuss in detail the clinical studies that evaluated this issue. It is worth noting, however, that three randomized, controlled trials did not show any difference in survival of patients with ARDS ventilated with higher or lower levels of PEEP.[229–231] Despite the conclusion of a meta-analysis of these three studies[232] that higher PEEP levels were associated with better survival in the patient with the most severe diseases, the best level of PEEP to apply when ventilating patients with ARDS is still unknown,[233,234] given the fact that ventilator protocols were markedly different between the three studies, with considerable heterogeneity in the values for plateau pressure in the high PEEP groups.

A recent study measuring lung metabolic activity (a surrogate of lung inflammation), using positron emission tomography with ^{18}F-fluorodeoxyglucose (^{18}F-FDG) in patients with ARDS showed that lung regions undergoing cyclic recruitment–derecruitment did not exhibit higher ^{18}F-FDG uptake than did regions that remained collapsed throughout the respiratory cycle.[235] Instead, ^{18}F-FDG uptake in normally aerated regions correlated with plateau pressure and regional volume expansion. Although these results should be interpreted cautiously because of the small number of patients involved and because pulmonary infection, a major confounding factor for the interpretation of lung inflammation, was often the cause of ARDS, they suggest that "volutrauma" rather than "atelectrauma" is a more significant contributor to lung inflammation in ventilated patients with ARDS.[235]

Improving lung mechanical properties so as to decrease the risk of ventilator-associated lung injury is another option that may combine with protective lung strategies. Two treatments were tested during clinical trials: surfactant administration and partial liquid ventilation. The failure of both strategies could have been predicted on physiologic and experimental grounds.

Administration of surfactant by aerosol[236] or tracheal instillation[237] was not associated with any survival advantage in the treatment of adult patients with ARDS. These treatments failed to improve oxygenation in one study[236] and achieved only mild improvement in another study[237] and were not associated with changes in lung mechanics.[237] It has been suggested that the treatments were not effective in preventing damage caused by lung overstretching or oxygen toxicity, either because the mode of administration was not optimal or because the particular type of surfactant was not physiologically effective in diseased lungs. In contrast, administration of a natural surfactant containing high levels of surfactant-specific protein B in a pediatric population with acute lung injury (premature infants were not included) was associated with increased survival.[238] Moreover, the oxygenation index (which takes into account both lung mechanical properties and oxygenation) was markedly improved.

The recent failure of a multicenter clinical trial of partial liquid ventilation with perflubron (a perfluorocarbon) during mechanical ventilation of adult patients with acute lung injury illustrates the clinical relevance of VILI.[239] The amount of administered perflubron was high and was associated with a high level of PEEP (>13 cm H_2O). Consequently, inspiratory pressure was higher in the patients who received perflubron than in controls. Not only was mortality higher (although not significantly) in patients receiving liquid ventilation, but the incidence of macroscopic barotrauma was also particularly high, more than double that in the controls

(17% vs. 6%). All these results were predictable from careful analysis of experimental studies, which showed increased incidence of barotrauma[143] and worsening of VILI[106,144,145] when both the amount of instilled perfluorocarbon and the pressures delivered by the respirator were high.

As already discussed, the literature on possible cytokine involvement during VILI contains many contradictions and inconsistencies.[78] Indeed, it is not surprising that the clinical correlate of such experimental findings is very vague. Ranieri et al[77] reported significant decreases in bronchoalveolar fluid and plasma concentrations of many inflammatory and antiinflammatory mediators in patients ventilated with a so-called lung-protective strategy (low tidal volume plus high PEEP). They suggested that nonprotective ventilation (high tidal volume plus low PEEP) was responsible for the inflammatory state. In contrast, Stuber et al[240] reported the release of mainly antiinflammatory mediators in the bronchoalveolar fluid and plasma of patients ventilated with a nonprotective modality.[241] Finally, very modest although significant decreases of plasma inflammatory cytokines were reported in patients of the low tidal-volume arm of ARDS Network study[1] compared with patients of the high tidal-volume arm.[242] The decrease, however, was trivial and very unlikely to have any clinical consequence. Thus, developing possible antiinflammatory therapy to prevent ventilator-associated lung injury based on these findings is speculative at best.

CONCLUSION

Considerable clinical progress has accrued from the extensive physiologic experimental research on VILI since its initial description by Webb and Tierney in 1974.[2] There is now widespread consensus on the need to ease the stress on diseased lungs during mechanical ventilation. The extent, however, to which tidal volume should be decreased, the level of PEEP that should be used, and how to identify lung overdistension in an individual patient remain largely unknown. A tremendous number of experimental studies aimed at exploring the pathophysiology of VILI and at identifying pharmacological targets for its prevention and treatment have been performed. None of those pharmacologic interventions, however, has proven beneficial in patients. The multiplicity of the pathways involved in VILI suggests that a single pharmacologic intervention is unlikely to impact on the outcome of patients.

VENTILATOR-INDUCED DIAPHRAGMATIC DYSFUNCTION

Theodoros Vassilakopoulos

Controlled mechanical ventilation (CMV) is a ventilator mode where the respiratory muscles are not contracting, and the ventilator takes full responsibility for inflating the respiratory system. Evidence accumulating over the past two decades has shown that CMV can induce dysfunction of the diaphragm, mainly consisting of atrophy, oxidative stress, and ultrastructural injury, resulting in decreased diaphragmatic contractility. This is called *ventilator-induced diaphragmatic dysfunction (VIDD)*.[1]

The frequency with which CMV is used cannot be determined with certainty. An international survey revealed that 13% of mechanically ventilated patients receive a neuromuscular blocker for 8% of the total days of ventilator support.[2] In these patients, full ventilator support is mandatory. Moreover, it was recently shown that the use of neuromuscular blockers during the first 2 days of ventilator support improves the survival of patients with severe acute respiratory distress syndrome,[3] a finding that may lead to increased use of CMV. Other patient groups not receiving neuromuscular blockers also receive full ventilator support, such as patients with traumatic brain injury, postoperative neurosurgical patients, comatose patients, patients with status epilepticus on barbiturate coma to suppress seizure activity, and so on. Thus, a considerable percentage of ventilated patients are at risk of developing VIDD.

The mechanisms of this dysfunction and the clinical relevance for mechanically ventilated patients is the subject of this chapter.

EVIDENCE FOR VENTILATOR-INDUCED DIAPHRAGM DYSFUNCTION IN HUMANS

The first human evidence for the existence of VIDD came from retrospective analysis of postmortem data obtained in neonates who received ventilatory assistance for 12 days or more immediately before death. This study revealed diffuse diaphragmatic myofiber atrophy (small myofibers with rounded outlines), not present in extradiaphragmatic muscles or diaphragms of infants ventilated for 7 days or less.[4]

Recently, direct evidence came from studies of brain-dead organ donors (with an intact circulation) who underwent CMV and who developed biopsy-proven atrophy[5,6] and decline in the contractility of their diaphragm.[6]

THE COMPONENTS OF VENTILATOR-INDUCED DIAPHRAGM DYSFUNCTION

Atrophy

Ventilator-induced atrophy[7] is usually measured by the reduction of the cross-sectional area of myocytes in histologic sections. Atrophy has been observed in both slow-twitch and fast-twitch human diaphragmatic fibers and is

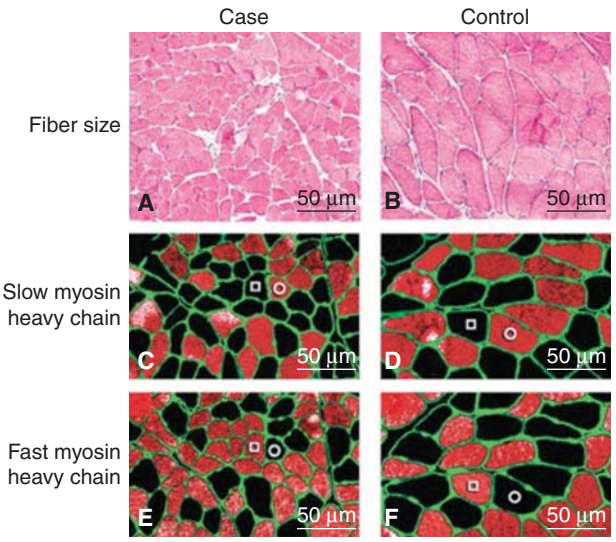

FIGURE 43-1 Atrophy in the human diaphragm after CMV. The slow-twitch and fast-twitch fibers in the case specimens (Panels **A, C,** and **E**) are smaller than those in the control diaphragms (Panels **B, D,** and **F**). Panels A and B (hematoxylin and eosin) show that neither inflammatory infiltrate nor necrosis is present in case or control specimens. The sections in Panels C and D were preincubated with NOQ7.5.4D antibody, which is specific for the slow myosin heavy chain, whereas sections in Panels E and F were preincubated with the MY-32 antibody, which reacts with all fast myosin heavy chains. In addition, in each section, all fibers are outlined by an antibody reactive to laminin. In each of the sections, fibers reacting with the antibody appear *orange-red*, whereas fibers not reacting with the antibody appear *black*. In Panels C, D, E, and F, a representative slow-twitch fiber is indicated by an *open circle* and a fast-twitch fiber by an *open square*. (Used, with permission, from Levine et al.[5])

quite significant (Fig. 43-1), its magnitude amounting to 40% to 50% after quite variable periods of CMV (range: 15 to 276 hours.)[5,6,8] Atrophy preferentially affects the diaphragm because it was not observed in the pectoralis major muscle of the same patients.[5] The longer the duration of CMV, the greater the observed atrophy (Fig. 43-2).[6]

Animal studies also suggest that atrophy is more pronounced in the diaphragm, which atrophies earlier than the peripheral skeletal muscles, which are also inactive during CMV.[9–11] Two days of CMV with positive end-expiratory pressure (PEEP) (2 cm H_2O) induced atrophy in rabbits,[12] whereas 3 days of CMV without PEEP were inadequate to

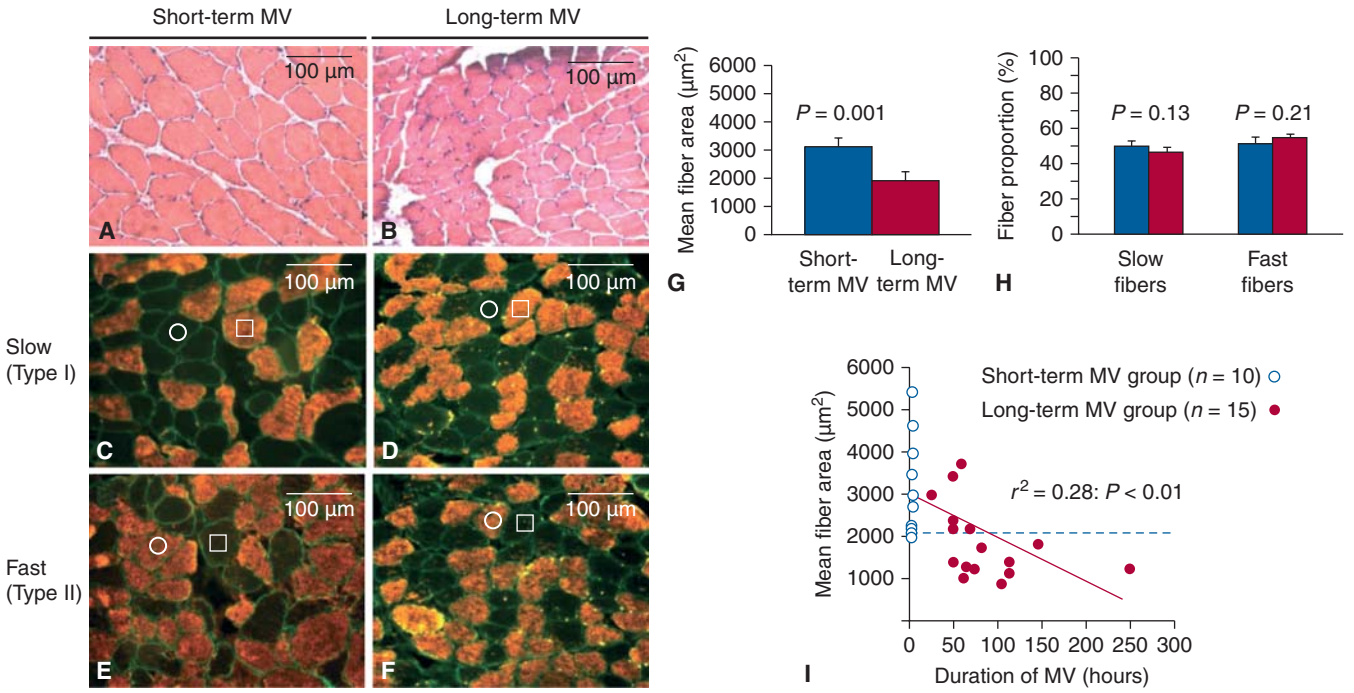

FIGURE 43-2 Relationship between duration of mechanical ventilation (MV) and diaphragmatic atrophy. Representative images of transverse frozen sections obtained from the diaphragms of the short-term MV (**A, C, E**) and long-term MV (**B, D, F**) groups are shown. The diaphragmatic sections are stained with hematoxylin and eosin (A, B) or with antibodies directed against slow (C, D) or fast (E, F) isoforms of myosin heavy chain. **C** to **F**. Serial sections, individual representative slow-twitch and fast-twitch fibers are marked by an *open square* and *circle*, respectively. **G** and **H.** Quantitative analyses of diaphragmatic fiber size (mean cross-sectional area) and fiber-type proportions in the two patient groups, respectively. **I.** The significant correlation between the degree of diaphragmatic atrophy and the duration of MV (*horizontal dashed line* indicates lowest value of fiber size measured in short-term MV group). (Used, with permission, from Jaber et al.[6])

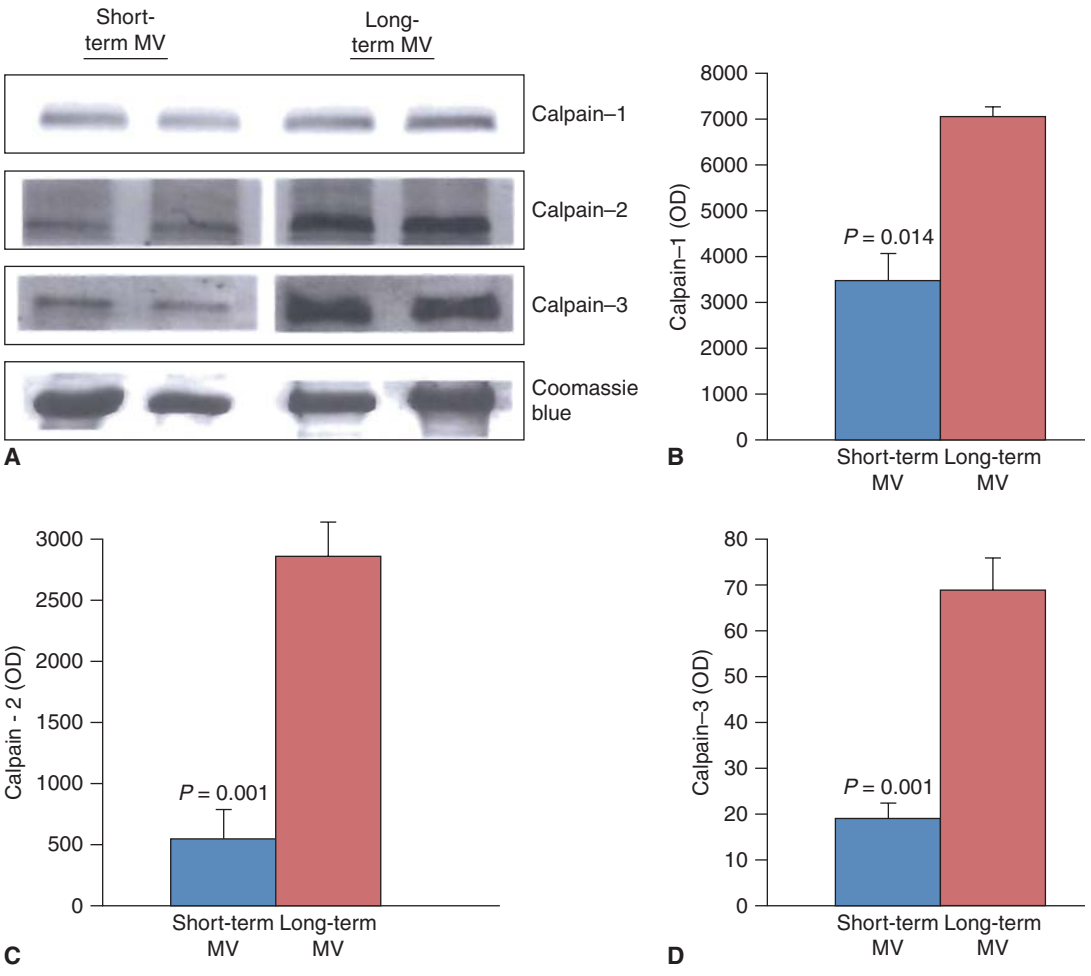

FIGURE 43-3 Expression of calpain isoforms in diaphragms of short-term and long-term mechanical ventilation (MV) groups. Representative immunoblots (**A**) and group mean quantification of protein levels measured in diaphragmatic tissues obtained from the short-term and long-term MV groups for calpain-1 (**B**), calpain-2 (**C**), and calpain-3 (**D**). (Used, with permission, from Jaber et al.[6])

induce atrophy[13] in the same species, which suggests that the rapidity of atrophy development might be augmented with use of PEEP. The increased lung volume at the end of expiration (with use of PEEP) places the passive diaphragm in a relatively shortened position and skeletal muscle atrophies faster when shortened.[14,15]

Atrophy can result from decreased protein synthesis, increased proteolysis, or both. Six hours of CMV in rats decreased the in vivo rate of mixed muscle protein synthesis (averaged for all muscle proteins) by 30% and the rate of myosin heavy-chain protein synthesis by 65%, both of which persisted throughout 18 hours of CMV.[16] In addition, 24 hours of CMV suppressed the messenger RNA levels of insulin-like growth factor-1, which stimulates protein synthesis.[17] Thus, CMV decreases protein synthesis in the diaphragm.

Increased proteolysis has been documented in diaphragmatic strips of animals subjected to 18 hours of CMV.[9] Mammalian cells have four different protein systems and organelles for proteolysis—the calpains,[6] the caspases,[5] the proteasome system,[5,8] and the autophagy-lysosomal system[8]—all of which are activated in the human diaphragm after CMV, a finding previously suggested by animal models.[9,18–20]

CALPAINS

Calpains, which are activated after CMV (Fig. 43-3), do not fully degrade, but only partially cleave proteins in vivo. This renders the proteins amenable to the proteasome.[7] The stimulus for calpain activation in not known, but calcium elevation in the cell is a prerequisite. The reduced (messenger RNA) levels of sarcoplasmatic reticulum calcium adenosine triphosphatase (ATPase; the enzyme that removes calcium from the sarcoplasm), secondary to 24 hours of CMV[21] in animal models may contribute to calpain activation.

CASPASES

Caspases are proteases that can degrade proteins and especially complexes of actin and myosin[18,22] and release

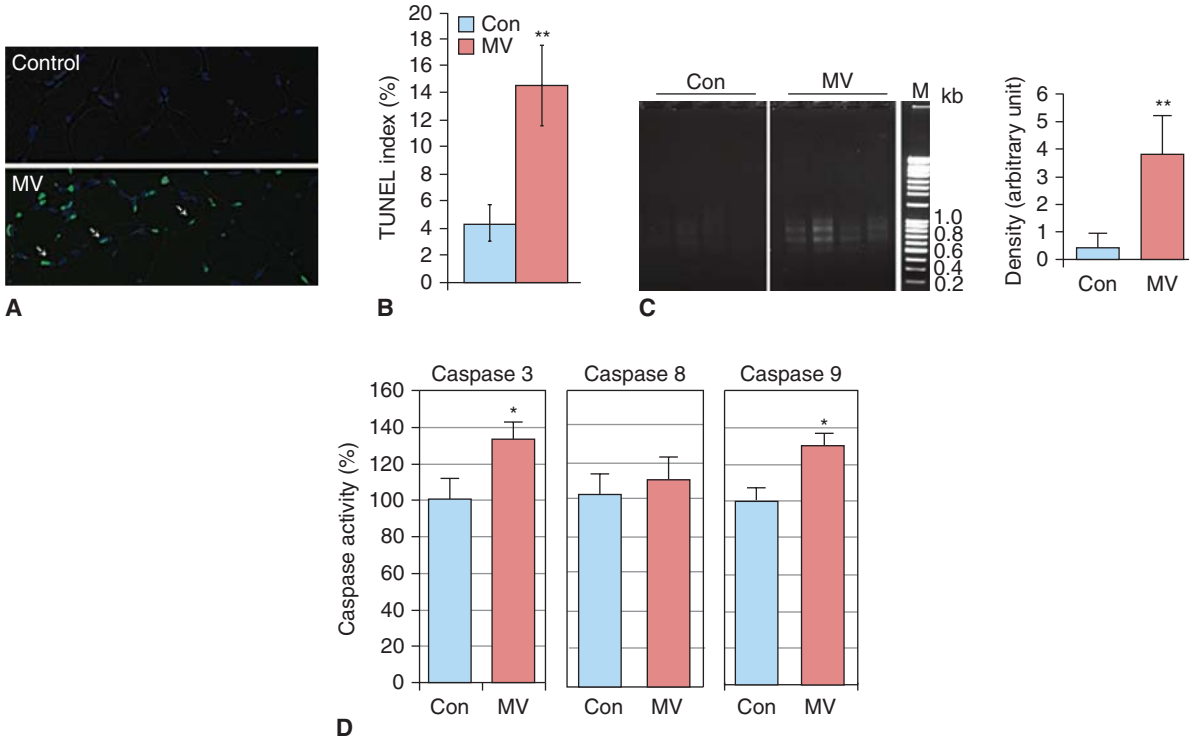

FIGURE 43-4 Apoptosis in the human diaphragm after CMV. CMV results in DNA fragmentation and activates caspases 3 and 9 in human diaphragm. **A.** TUNEL (TdT [terminal deoxynucleotidyl- transferase]-mediated [2′-deoxyuridine 5′-triphosphate]-biotin nick-end labeling) staining was performed on cryosections of control and ventilated human diaphragm. Fragmented genomic DNA was labeled with FITC (fluorescein isothiocyanate) conjugated dUTP (deoxyuridine triphosphate); positive signals appear *green*. Myonuclei are visualized by DAPI (4,6-diamidino-2-phenylindole) staining (*blue*). Note that the positive TUNEL staining signals (*green*) are localized in nuclei stained by DAPI (*blue*). **B.** TUNEL-positive nuclei were counted and normalized to total myonuclei; ratio is shown as the TUNEL index. Control (Con), $n = 9$; MV, $n = 10$. **C.** DNA fragmentation was measured by polymerase chain reaction (PCR)-based detection and visualized by electrophoresis in 2% agarose gel. Density of the PCR products was quantitated with Image J and normalized to the total DNA input. M, DNA markers. Control, $n = 5$; MV, $n = 8$. **D.** Caspase 3, 8 and 9 enzymatic activities from control and MV human diaphragm lysates were measured by fluorometric assay. Results are presented as relative fluorescence units after normalization to total protein amount. Control, $n = 7$; MV, $n = 9$. *, $P < 0.05$; **, $P < 0.01$. (Used, with permission, from Tang et al.[24])

them from the myofibrillar lattice. Upregulation of caspase-3 expression has been documented in the diaphragm secondary to CMV in both humans[5] and in animal models of VIDD.[19] Caspase-3 can be activated by oxidative stress, increased intracellular calcium, and increased calpain activity.[18]

In animal models of VIDD, the decreased volume of the cytoplasm (atrophy) was observed in the presence of decreased number of myonuclei (skeletal muscle cells are multinucleated cells and theoretically a single myonucleus can sustain the necessary gene expression for a limited area of the cytoplasm, a relationship known as the myonuclear domain[23]), so that the myonuclear domain remains constant.[19] This decrease in myonuclear content was mediated by a caspase-3 dependent increase in apoptosis, which was evident as early as 6 hours after the onset of CMV.[19] Both the apoptosis and atrophy were attenuated with caspase-3 inhibition.[19]

CMV-induced apoptosis has also been documented in the human diaphragm (Fig. 43-4).[24] The finding of elevated caspase 9, but not caspase 8, and elevated Bcl2-interacting mediator of cell death (Bim) (and its transcriptional variants), but not Fas or Fas Ligand, suggest that the intrinsic (mitochondrial), rather than the extrinsic apoptotic pathway, is the primary pathway that operates in CMV-induced apoptosis in the human diaphragm, resulting in caspase 3 activation and nuclear DNA fragmentation.[24] Complementary experiments, conducted in vitro, suggest that oxidative stress is a potential proximal activator of *all* of the pathways that have been implicated in VIDD, with mitochondrial dysfunction representing a central component of this cascade.[24] Bcl2-interacting mediator of cell death is probably an important mediator of the oxidative stress-induced activation of the intrinsic apoptotic pathway, and Fos, FoxO1, and Stat3 are the transcription factors that regulate its expression.[24]

AUTOPHAGY–LYSOSOME PATHWAY

The autophagy–lysosome pathway is also upregulated in the ventilated human diaphragm.[8] Autophagy (Greek for self-eating) is a catabolic pathway characterized by the formation

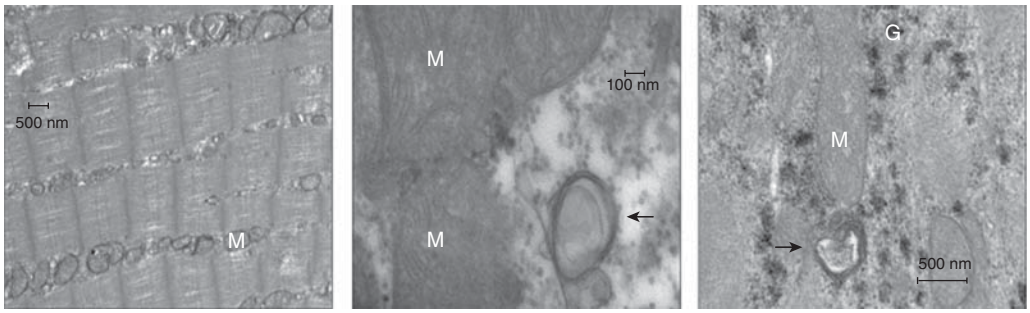

FIGURE 43-5 *Left panel.* Representative electron micrograph of a section of a diaphragm from a control subject showing normal ultrastructure and absence of autophagosomes. *Middle and right panels.* Representative electron micrographs of a section of a diaphragm from a brain-dead organ donor undergoing controlled mechanical ventilation. These sections show autophagosomes (*black arrows*) in close proximity to mitochondria (*M*). *G* indicates glycogen particles. (Used, with permission, from Hussain et al.[8])

of vesicles (autophagosomes) that engulf cytoplasmic organelles and proteins, which then fuse with lysosomes that degrade their contents. This process is a major mechanism for degrading long-lived proteins and organelles. Autophagy occurs at low basal levels to perform homeostatic functions, but can be rapidly upregulated when cells need to generate energy. Hussain et al[8] demonstrated that prolonged CMV triggers the appearance of autophagosomes (Fig. 43-5) and increases the expression of autophagy-related genes in the diaphragm (Fig. 43-6). This is associated with upregulation of the transcription factor FOXO-1. It should be emphasized that these changes are relatively specific to the diaphragm

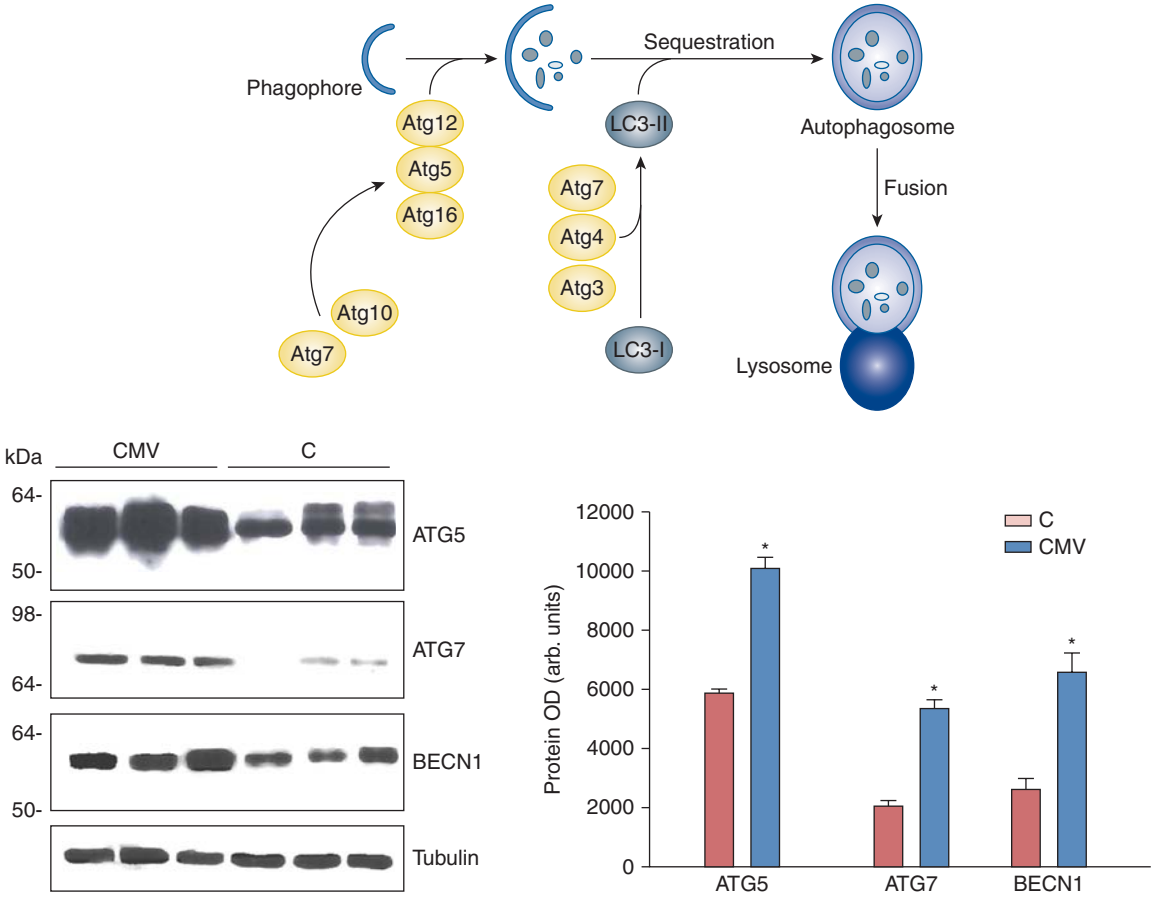

FIGURE 43-6 Autophagy-related genes in the human diaphragm after controlled mechanical ventilation (*CMV*). *Top.* Schematic cartoon of autophagosome assembly. *Left.* Representative immunoblots of BECN1, ATG5, and ATG7 in diaphragms of the control (*C*) and CMV groups. *Right.* Mean values of protein optical densities (*OD*) of BECN1, ATG5, and ATG7 in diaphragms of the C and CMV groups. *, $P < 0.05$ compared with control subjects; *Atg,* Autophagy related genes; *LC3-I, LC3-II,* microtubule-associated protein light chain-3 (LC3)-I or LC3-II; *BECN1,* beclin-1. (Used, with permission, from Vierstra et al.[72])

and are not observed to the same degree in the control limb muscle (quadriceps) of the same patients. Moreover, upregulation of the autophagy-related genes in the diaphragm increases with the time spent on CMV.[8]

PROTEASOME

The proteasome is a multisubunit, multicatalytic complex that exists in two major forms (Fig. 43-7): The core 20S proteasome can be free or bound to a pair of 19S regulators to form the 26S proteasome, which degrades (in an adenosine triphosphate [ATP]-dependent manner) proteins covalently bound to a polyubiquitin protein chain (ubiquitinated proteins). The binding of ubiquitin to protein substrates requires the ubiquitin-activating enzyme (E1), which utilizes ATP-derived energy to form a covalent link with a ubiquitin protein, followed by transfer of the active ubiquitin moiety to a ubiquitin-conjugating enzyme (E2), and finally transfer of this ubiquitin to the protein to be degraded via a ubiquitin ligase (E3) (Fig. 43-8). CMV increases the level of ubiquitin-protein conjugates in the diaphragm,[6,25] which are the substrates of the 26S proteasome (Fig. 43-9). Key enzymes involved in the function of ubiquitin-proteasome pathway are upregulated in the human diaphragm after CMV, such as the skeletal muscle specific ubiquitin ligases (E3 enzymes), muscle atrophy F-box (MAFbx/Atrogin-1), and muscle ring finger-1 (MuRF1),[5,8,25] as well as the E2 conjugases UBC2 and UBC4[8] (Fig. 43-10). The changes in the E3 ligases are relatively specific to the diaphragm and were not observed in the quadriceps (control limb muscle) of the same patients, which were also inactive (Fig. 43-10).[8]

Interestingly, the activity of the 20S proteasome is elevated in the human diaphragm after CMV.[25] The 20S proteasome is specialized in degrading proteins oxidized by reactive oxygen species. Oxidative damage of a protein results in its partial unfolding, exposing hidden hydrophobic residues.[26,27] Therefore, an oxidized protein does not need to be further modified by ubiquitin conjugation to confer a hydrophobic patch, nor does it require energy from ATP hydrolysis to unfold. It should, however, pointed out that the expression of various α subunits of the 20S proteasome was not increased in human diaphragms after CMV.[8]

Oxidative Stress

CMV is associated with augmented oxidative stress in the human diaphragm, as evidenced by the rise in protein

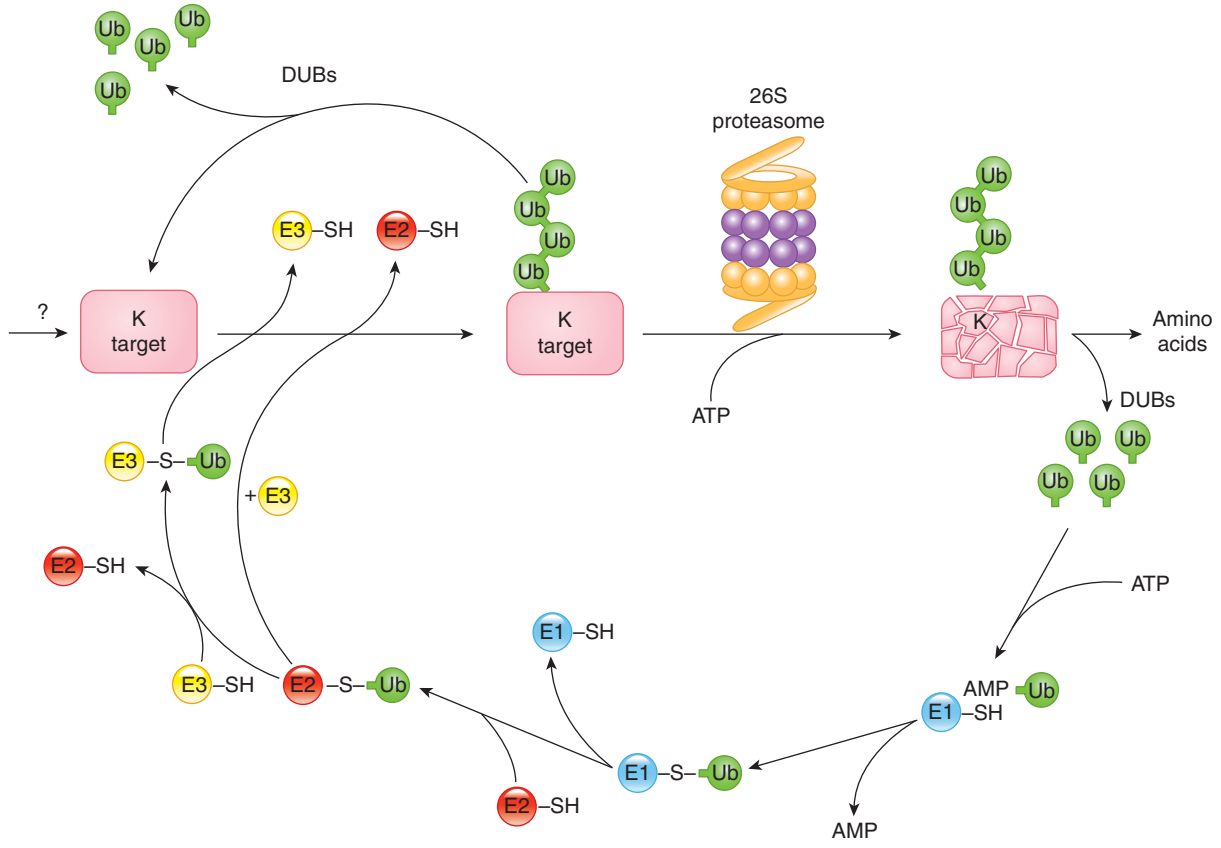

FIGURE 43-8 The ubiquitin–proteasome pathway of proteolysis. Proteins degraded by the ubiquitin–proteasome pathway are first conjugated to ubiquitin (*Ub*). The process of linking ubiquitin to lysine residues in proteins destined for degradation involves the activation of ubiquitin by the E1 enzyme in an adenosine triphosphate (*ATP*)-dependent reaction. Activated ubiquitin is transferred to an E2 carrier protein and then to the substrate protein, a reaction catalyzed by an E3 enzyme (E3 ligase). This process is repeated as multiple ubiquitin molecules are added to form a ubiquitin chain. Once a conjugate is assembled bearing a chain of multiple Ubs, it is either recognized by the 26S proteasome and degraded in an ATP-dependent process or the conjugate is disassembled by deubiquitinating enzymes (*DUBs*), releasing the ubiquitin and target intact. In ATP-dependent reactions, ubiquitin-conjugated proteins are recognized and bound by the 19S complex, which releases the ubiquitin chain and catalyzes the entry of the protein into the 20S core proteasome. Degradation occurs in the core proteasome, which contains multiple proteolytic sites within its two central rings. The ubiquitin is not degraded but is released and reused. *ADP*, adenosine diphosphate; *K*, lysine; *SH*, sulfhydryl. (Used, with permission, from Vierstra et al.[72])

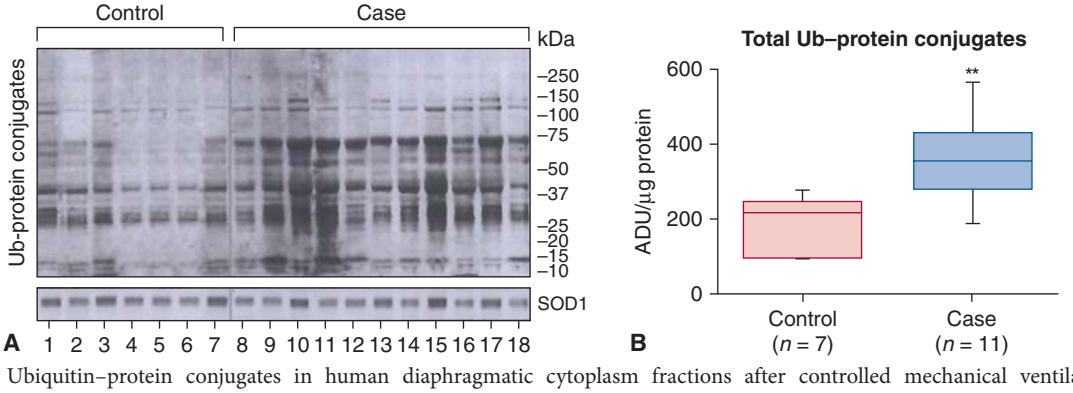

FIGURE 43-9 Ubiquitin–protein conjugates in human diaphragmatic cytoplasm fractions after controlled mechanical ventilation (CMV). **A.** Immunoblotting results for ubiquitin (*Ub*)–protein conjugates in seven control and eleven case specimens. The fact that the control diaphragms show ubiquitination of many bands is consistent with the concept that ubiquitination is a normal process for protein turnover. The superoxide dismutase (*SOD*) 1 protein-loading control did not differ between lanes. **B.** Case diaphragms exhibited approximately twice the amount of ubiquitinated proteins, suggesting that case diaphragms are exhibiting an upregulation of ubiquitination. **, $P < 0.01$; *ADU*, arbitrary density units. oxidation (elevated 4-hydroxy-2-nonenal [HNE]-protein adduct formation[8] and protein carbonylation,[8,24] as well as the increased levels of superoxides documented by dihydroethidium staining.[24] Animal models of VIDD have also documented other indices of oxidative stress, such as lipid peroxidation (elevated 8-isoprostane,[9] total lipid hydroperoxides,[28,29] and thiobarbituric reactive substance content[30]), and have provided direct evidence of oxidative stress by the increased emissions of dichlorofluorescein (a molecule that fluorescences upon reacting with reactive oxygen species within cells) when diaphragmatic strips from CMV-treated animals are incubated in vitro with the dye.[31] Animal models of VIDD suggest that the onset of oxidative injury is rapid, occurring within 6 hours after the institution of CMV in rats[28] and is long lasting, being present after 3 days of CMV in piglets.[30] The mechanism(s) of oxidative stress generation remain elusive. Interestingly, the messenger RNA levels of both nuclear-encoded cytochrome C oxidase IV and the mitochondria-encoded cytochrome C oxidases I, II, and III are reduced in the diaphragm after CMV. These observations indicate the presence of a functional impairment of the coupling between electron donors and acceptors as well as mitochondrial energy production,[24] and point to the mitochondria as potential sources of oxidative-stress generation in VIDD. The initial oxidative stress may result from the sudden change in the functional status of the diaphragm as it switches from continuous, intermittent contraction to passive rest (as occurs with CMV). Because noncontracting muscle fibers do not require major mitochondrial energy production, this altered functional status may place a "brake" on normal mitochondrial function. This may, in turn, cause mitochondrial reactive oxygen species accumulation and eventual leak.[24]

The response of antioxidant enzymes in the diaphragm to CMV is controversial. Consistent with a mitochondrial role in this oxidative stress, the mitochondria-resident antioxidant gene, superoxide dismutase-2 (SOD 2), is significantly induced in the human diaphragm after CMV, whereas cytosolic superoxide dismutase-1 (SOD 1) is not.[24] Glutathione levels are reduced in the diaphragm, but this may simply be the result of oxidative-stress development.[5]

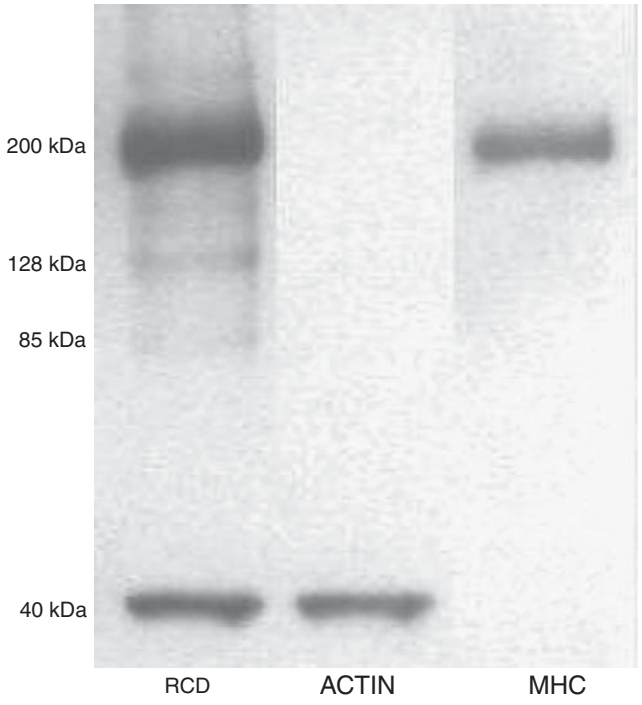

FIGURE 43-11 Illustration of Western blots using monoclonal antibodies to identify oxidized proteins with molecular masses of approximately 200 to 40 kDa. *Left lane*. Reactive carbonyl derivatives (*RCD*), which are the footprints of protein modifications induced by oxidative stress in insoluble proteins isolated from the diaphragm of an animal exposed to controlled mechanical ventilation (CMV) for 18 hours. *Middle* and *Right lanes*. the same membrane stripped of the 2,4-dinitrophyenylhydrazone antibody (the antibody recognizing RCD was removed) and then sequentially re-probed with monoclonal antibodies specific for rat skeletal muscle actin and all myosin heavy chain (*MHC*) isoforms. (Used, with permission, from Zergeroglu et al.[28])

Oxidative stress can modify proteins involved in energetics, excitation–contraction coupling, intracellular calcium regulation, and force generation.[32] In humans[8] and in animal models of VIDD,[28] diaphragmatic protein oxidation was evident in proteins with molecular masses of about 40 and 200 kDa. These findings raise the possibility that actin (40 kDa) and/or myosin (200 kDa) undergo oxidative modification during CMV (Fig. 43-11), which is expected to compromise diaphragmatic contractility. This intriguing possibility awaits confirmation by more specific identification of the modified proteins. Interestingly, decreased levels of both myosin heavy chains and α-actin were documented in human diaphragms after CMV.[25]

Oxidative stress, and especially 4-hydroxy-2-nonenal (produced in the diaphragm under conditions such as sepsis, resistive breathing,[33] and CMV[8]), can reduce the activity of plasma membrane calcium ATPase.[34] This would retard calcium removal from the diaphragmatic myofibers and contribute to calcium accumulation and calpain activation.[18] Oxidative stress could injure various intracellular structures-organelles, activate proteolysis (especially through the 20S proteasome), and induce apoptosis.[24]

Structural Injury

CMV leads to a significant increase in the prevalence of ultrastructural abnormalities in the human diaphragm, consisting of disruption of the normal myofibrillar organization with enlarged spaces containing disorganized sarcomeric material (Fig. 43-12). The longer the duration of CMV, the greater the degree of injury in the human diaphragm.[6] Animal models of VIDD have also documented structural abnormalities of different subcellular components of diaphragmatic myofibers, progressively developing after 2 to 3 days of CMV in rabbits.[13,35,36] The changes consisted of disrupted myofibrils, increased numbers of lipid vacuoles in the sarcoplasm, and abnormally small mitochondria containing focal membrane disruptions. Similar alterations were observed in the external intercostal muscles of ventilated animals,[36] but not in hindlimb muscles.[13] The structural abnormalities have detrimental effects on diaphragmatic contractility. The number of abnormal myofibrils is inversely related to the force output of the diaphragm.[13] The mechanisms of injury have not been elucidated, but may involve activation of calpains, which have the ability to degrade several sarcomeric proteins, and direct cellular injury secondary to augmented oxidative stress.[37]

Diaphragmatic Force and Endurance

MEASUREMENTS IN HUMANS

A major problem in documenting whether VIDD compromises diaphragmatic contractility in humans is the difficulty in accurately evaluating respiratory muscle function in critically ill patients undergoing mechanical ventilation, especially because these patients show variable levels of cooperation. An alternative, although technically demanding, approach is to obtain simultaneous recordings of esophageal (Pes) and gastric (Pga) pressures (their difference being transdiaphragmatic pressure [Pdi]), during bilateral magnetic phrenic nerve stimulation.[38,39]

The magnitude of the negative deflection in tracheal pressure (Ptr) during twitch stimulation of the phrenic nerves against an occluded airway can be used as a surrogate of Pdi in intubated patients,[39,40] and has the major advantage of not requiring the placement of esophageal and gastric balloon catheters. Jaber et al performed serial measurements of twitch Ptr in critically ill patients who were ventilated for approximately 1 week. Twitch Ptr decreased progressively during the period of CMV, with a mean reduction of 32 ± 6% at 6 days (Fig. 43-13).[6] These data provide the best available evidence for the occurrence of contractile dysfunction as a component of VIDD in humans.

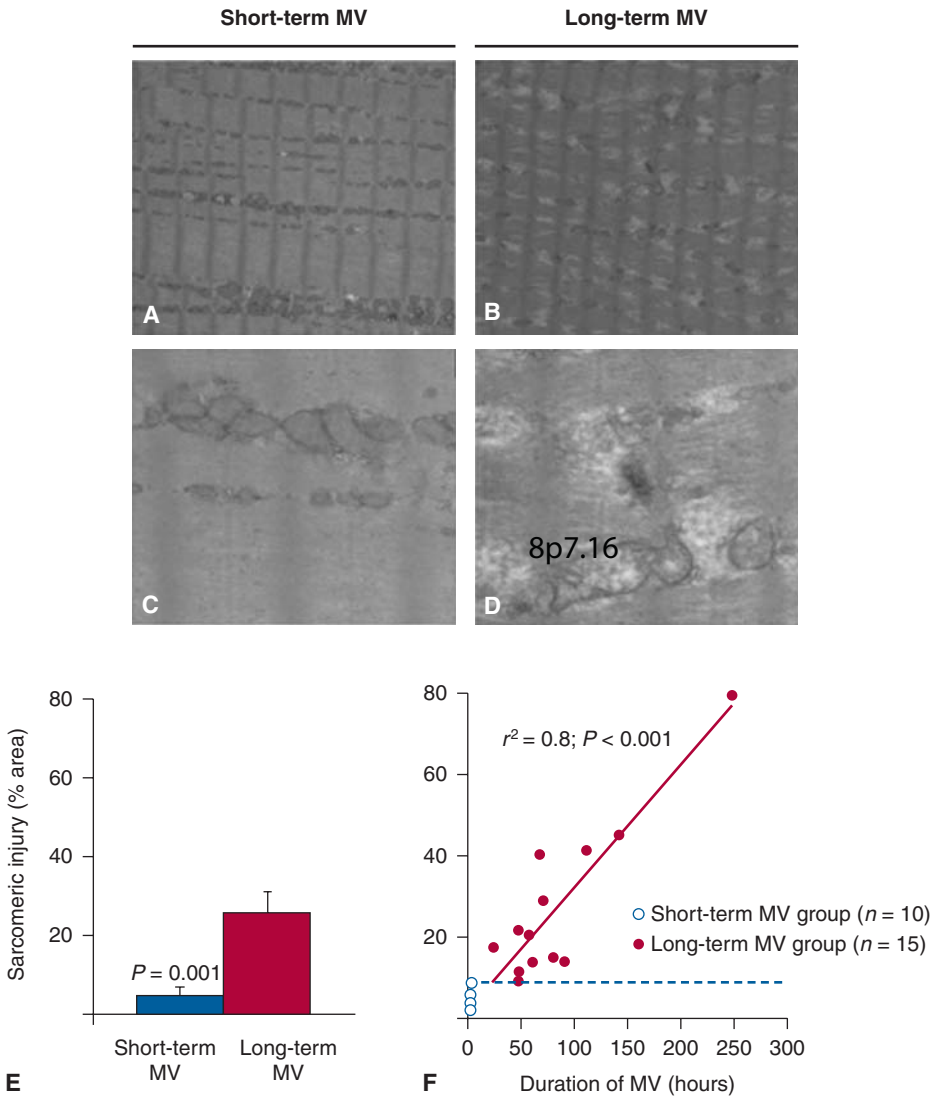

FIGURE 43-12 Relationship between duration of mechanical ventilation (*MV*) and diaphragmatic injury. Representative electron microscopy images of longitudinal ultrathin sections obtained from the diaphragms of the short-term MV (**A** and **C**) and long-term MV (**B** and **D**) groups are shown, at both low (A and B) and high (C and D) magnitude amplification. Note the disorganization of sarcomeric structure, which is only present in the long-term MV group images. **E.** Quantitative analysis of the prevalence of these findings in the two groups. **F.** Significant correlation between the degree of diaphragmatic injury and the duration of MV (*horizontal dashed line* indicates highest value of injury measured in short-term MV group). (Used, with permission, from Jaber et al.[6])

Several intriguing indirect data support this finding. Twitch Pdi elicited by magnetic stimulation of the phrenic nerves was reduced in mechanically ventilated patients[39] and in patients ready to undergo weaning trials,[38] as compared to normal subjects. Recently, Hermans et al[41] assessed diaphragmatic force production in twenty-five mechanically ventilated intensive care unit patients using cervical magnetic stimulation of the phrenic nerves in a prospective single-center study. Seven patients were evaluated more than once during their intensive care unit stay. A longer duration of mechanical ventilation was associated with more severe diaphragmatic force loss, irrespective of the ventilator mode used. Impairment of diaphragmatic force was also correlated with the amount of sedation the patients received. The authors, however, were unable to determine whether sedative use is an independent risk factor for diaphragmatic weakness in ventilated patients or simply a marker of more prolonged periods of mechanical ventilation. It should be emphasized that the above observations are not specific evidence for the presence of VIDD, because other factors can lead to muscle weakness in the intensive care unit and modes other than CMV were used. Nevertheless, VIDD may have contributed to the reduction in diaphragmatic contractility in the patients who received full ventilator support (CMV).

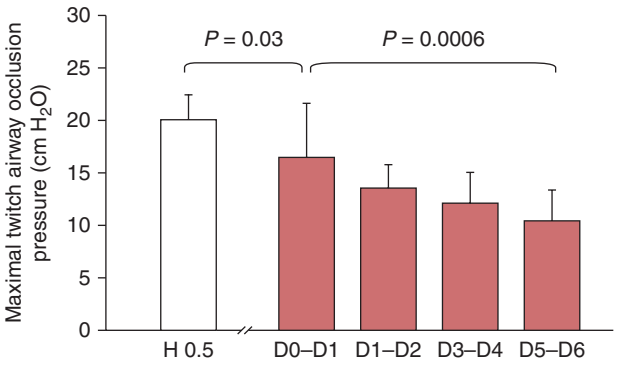

FIGURE 43-13 Relationship between duration of mechanical ventilation (MV) and diaphragmatic function. Maximal twitch airway occlusion pressure generated by magnetic stimulation of the phrenic nerves at different time points in short-term MV (*open bar*; $n = 6$) and long-term MV (*solid bars*; $n = 6$) groups. *D*, number of days of MV; *H*, number of hours of MV. FIGURE 43-14 Neural and neuromuscular transmission to the diaphragm during experimental VIDD. The evoked compound muscle action potential (CMAP) tracings of the diaphragm upon electrical stimulation of the phrenic nerves in vivo from one piglet on days 1, 3, and 5 of CMV, respectively. The time from the stimulus to the onset of CMAP (latency) does not change after 3 to 5 days of CMV, whereas the amplitude of CMAP is progressively reduced. This indicates that the neural and neuromuscular transmission are not affected when VIDD develops and that the contractile dysfunction resides within the diaphragmatic myofibers. (Used, with permission, from Radell et al.[43])

MEASUREMENTS IN INTACT ANIMALS

CMV leads to decreased diaphragmatic force generating capacity in various animal species. In the intact diaphragm studied in vivo, Pdi generation upon phrenic nerve stimulation declines at all stimulation frequencies (20 to 100 Hz).[13,30,42,43] The decline ensues early (1 day in rabbits,[13] 3 days in piglets[30,43]) and is progressive: Pdi decreasing to 63% of the control value after 1 day of CMV and to 49% of the control value after 3 days of CMV in rabbits.[13] Within a few days (3 days in rabbits, 3 to 5 days in piglets, 11 days in baboons), the pressure-generating capacity of the diaphragm declines by 35% to 50%. The endurance of the diaphragm is also compromised.[42]

The decrease in force-generating capacity that ensues with CMV is not caused by changes in lung volume[30] or abdominal compliance.[42,43] Neural and neuromuscular transmission remain intact as evidenced by the lack of change in phrenic nerve conduction (latency) and stable response to repetitive stimulation of the phrenic nerve (Fig. 43-14).[43] In contrast, the compound muscle action potential declines progressively, suggesting that excitation–contraction coupling or membrane depolarization may be involved (Fig. 43-14).[43] Thus, the CMV-induced impairment in diaphragmatic force-generating capacity appears to reside within the myofibers.

IN VITRO MEASUREMENTS

The isometric (both twitch and tetanic) tension development by isolated diaphragmatic strips in vitro[10–12,43,44] confirm the in vivo findings and suggest that the decline in contractility is an early (12 hours) and progressive phenomenon,[44] the isometric force declining by 30% to 50% after 1 to 3 days of CMV in rats. The effects of CMV on diaphragm in vitro fatigability are controversial.

Drugs and Ventilator-Induced Diaphragm Dysfunction

All information regarding the role of drugs in the development of VIDD comes from animal models. Anesthetics can be excluded as causes of VIDD because studies that used appropriate controls (to the extent feasible, viz., a group of anesthetized spontaneously breathing animals) concluded that the decreased contractility was the result of mechanical ventilation per se (and not anesthetic use).[13]

Neuromuscular blockers[11,42] cannot solely account for the decreased contractility secondary to CMV, because decreased contractility was also observed in studies that did not use these drugs.[13,44] Nevertheless, the effects of 24 hours of CMV and aminosteroidal neuromuscular blockers (rocuronium) are synergistic in depressing diaphragmatic contractility, in inducing atrophy of type IIx/b fibers, and in upregulating the ubiquitin ligase (E3) muscle ring finger-1 (MuRF1) (but not the E3 muscle atrophy F-box/Atrogin-1)[29]—a synergism not observed with different doses of benzylisoquinoline neuromuscular blockers (cisatracurium).[45]

CLINICAL RELEVANCE

Clinical Context

VIDD should be suspected in patients who fail to wean after a period of CMV. The weaning failure is related to respiratory muscle weakness. Other causes of respiratory

muscle weakness should be ruled out,[46] although several may coexist with VIDD.

Ventilator-Induced Diaphragm Dysfunction Prevention

VENTILATOR STRATEGY

Because data in humans are lacking, suggestions are based on animal models and speculations. The time spent in CMV must be curtailed to the extent possible, especially in older individuals, because the effects of aging and CMV are additive.[47] Although CMV induced similar losses (24%) in diaphragmatic isometric tension in both young and old animals, the combined effects of aging and CMV resulted in a 34% decrement in diaphragmatic isometric tension as compared to young control animals.

When feasible, partial support modes should be used. Partial support modes can be used in conditions traditionally considered as indications for CMV, such as acute lung injury and/or acute respiratory distress syndrome[48,49] although complete CMV with the use of neuromuscular blockers in the first 48 hours of severe acute respiratory distress syndrome may be beneficial.[3] In a rabbit animal model, assisted (flow-triggered pressure limited) ventilation from the onset of ventilator support resulted in attenuation of the force loss induced by CMV (Fig. 43-15).[50] Similarly, adaptive support ventilation was able to prevent any deleterious effect of mechanical ventilation on the piglet diaphragm.[51] Thus, it stands to reason that preserving diaphragmatic contractions during mechanical ventilation should attenuate the force loss induced by CMV, although other forms of partial ventilator support (pressure support, synchronized intermittent mandatory ventilation) have not been experimentally tested. Pressure support was able to prevent increased proteolysis in the diaphragm when compared to CMV, although its effects on contractility were not reported.[52] It should be stressed that these suggestions originate from studies in healthy animals. The extent to which these same phenomena occur in critically ill patients with various diseases is not known. During sepsis in rats, albeit of short duration (4 hours), CMV protected the diaphragm against injury,[53] which raises the question about the effects of CMV on the diaphragm of septic (not healthy) humans.

Assisted modes or even noninvasive ventilation in hypercapnic patients with chronic obstructive pulmonary disease[54–56] is an alternative to the use of CMV in weaning-failure patients[57]—a strategy based on the premise that respiratory muscle fatigue (requiring rest to recover) is the cause of weaning failure.[58,59] Fatigue is expected to occur because the load that the respiratory muscles of weaning-failure patients is increased to the level that would predictably produce fatigue of the respiratory muscles[60] if patients were allowed to continue spontaneous breathing without ventilator assistance. Evidence, however, does not support the existence of low-frequency fatigue (the type of fatigue that is long-lasting, taking more than 24 hours to recover) in patients who fail to wean despite the excessive respiratory muscle load.[38] This is because physicians typically terminate a weaning trial and place a patient back on the ventilator before low-frequency fatigue has had time to develop. Thus, no reason exists to completely unload the respiratory muscles with CMV for fatigue reversal when weaning is typically terminated.[57]

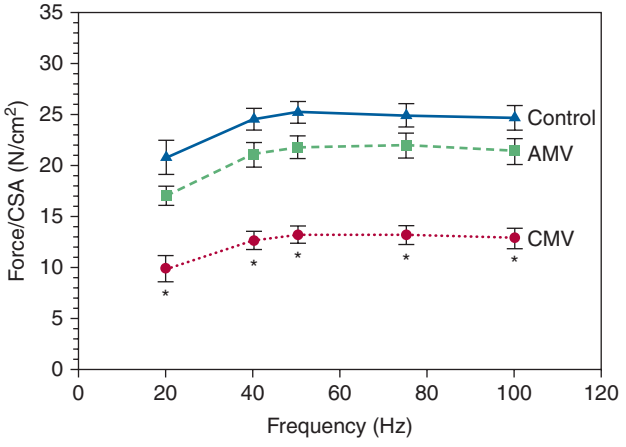

FIGURE 43-15 Diaphragmatic tetanic force at various stimulation frequencies in control, assisted mechanical ventilation (*AMV*), and controlled mechanical ventilation (*CMV*) in rabbits. Values are mean ± SE (standard error). *, $p < 0.01$, CMV versus control and AMV; *CSA*, cross-sectional area. (Used, with permission, from Sassoon et al.[50])

INTERMITTENT DIAPHRAGMATIC CONTRACTIONS

When CMV is inevitable, short periods of diaphragmatic activity have been suggested as preventive countermeasure. This could be achieved with either phrenic nerve stimulation or short periods of intermittent spontaneous breathing. As little as 30 minutes of pacing of one hemidiaphragm each day attenuated atrophy in this hemidiaphragm during prolonged CMV in a tetraplegic patient compared to the nonpaced hemidiaphragm.[61] In rats subjected to 24 hours of CMV, either 5 or 60 minutes of spontaneous breathing every 6 hours did not preserve diaphragmatic force. Rats receiving CMV developed reduced cross-sectional areas of type I and type IIx/b diaphragmatic fibers, which was not observed in intermittently spontaneously breathing rats, yet no difference was observed in the cross-sectional areas between the CMV and intermittently spontaneously breathing rats.[62] Whether more frequent or longer intervals of spontaneous breathing might be more effective in preventing VIDD awaits experimental proof.

PHARMACOLOGIC APPROACHES

Antioxidant supplementation could decrease oxidative stress and thus could attenuate VIDD. Accordingly, when

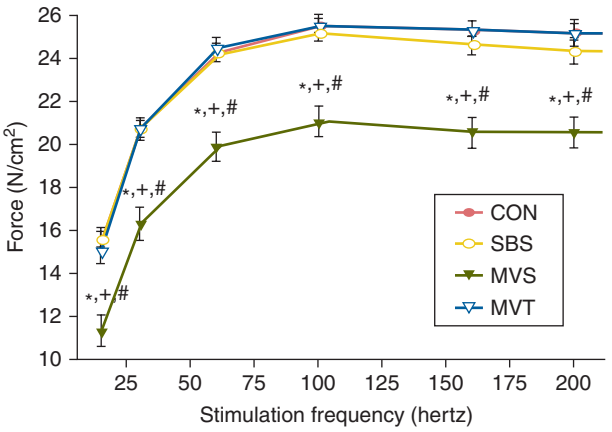

FIGURE 43-16 Force-frequency curves of in vitro diaphragm strips from control (*CON*), spontaneously breathing (*SBS*), mechanical ventilation (*MVS*), and mechanical ventilation animals receiving Trolox (*MVT*). Values represent means ± SEM (standard error of mean). *, Significantly different from CON group, $p < 0.05$; +, significantly different from SBS group, $p < 0.05$; #, significantly different from MVT group, $p < 0.05$. (Used, with permission, from Betters et al.[63])

rats were administered the antioxidant Trolox (6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid, a water-soluble analog of vitamin E) (Fig. 43-16) or apocynin (a nicotinamide adenine dinucleotide phosphate oxidase inhibitor with antioxidant properties) from the onset of CMV, its detrimental effects on contractility and proteolysis were prevented.[63,64]

A similar approach is adopted by nature itself! Various dormant animals immobilized for prolonged periods of time prevent muscle atrophy through a decrease in metabolic rate that reduces reactive oxygen species formation, and a concomitant rise in antioxidant enzymes.[65,66] Interestingly, a combination of vitamins E and C administered to critically ill surgical (mostly trauma) patients was effective in reducing the duration of mechanical ventilation as compared to nonsupplemented patients.[67] It is tempting to speculate that part of this beneficial effect was mediated by preventing VIDD. Thus, when CMV is used, concurrent administration of antioxidants seems justified and a meta-analysis suggests that they are beneficial in critical care patients.[68]

Administration of leupeptin (an inhibitor of lysosomal proteases and calpain) at the beginning of CMV prevented the development of diaphragmatic contractile dysfunction and atrophy[20] in experimental animals. This raises the possibility of future clinical trials of protease inhibitors in patients to prevent VIDD.

Recovery from Ventilator-Induced Diaphragm Dysfunction

There is no established or experimentally tested therapy for VIDD. Theoretically, resumption of spontaneous breathing would retrain the respiratory muscles, yet the time course of recovery of normal function is unknown. A major concern is that diaphragmatic disuse associated with CMV would increase its susceptibility to subsequent contraction-induced injury once respiratory efforts are resumed, similar to other skeletal muscles.[69] Rats receiving 24 hours of CMV exhibited a 26% decline in maximal specific diaphragmatic force with no apparent injury to the cell membrane or evidence of inflammation.[70] Resumption of spontaneous breathing for 2 hours did not exacerbate contractile dysfunction in these rats or induce membrane injury or macrophage invasion.[70] Reloading, however, was associated with increased myeloperoxidase activity and neutrophil infiltration in the diaphragm, which is expected to cause injury at a later time point, if reloading were continued.[70] Further studies are needed to elucidate the recovery response of the diaphragm that has developed VIDD as spontaneous respiratory muscle activity is resumed.

IMPORTANT UNKNOWNS

All data on animal models of VIDD have been obtained in previously healthy animals. Human data also have been obtained in brain-dead organ donors who did not have severe infections. Thus, the extent to which the deleterious effects of CMV on diaphragmatic function and biology occur in critically ill patients is unknown.

Modes of partial ventilation support attenuate the deleterious effects of CMV in animal models of VIDD. Whether this is also the case in humans is a clinically important question. Furthermore, the actual amount of assist necessary to prevent VIDD is also unknown.

Pharmacologic approaches used successfully to prevent VIDD in animal models have not been tested in human trials. Thus, no drugs has demonstrated clinical efficacy in the prevention or treatment of human VIDD.

Once VIDD is suspected, the best approach is to reload the diaphragm with abrupt or gradual reduction in the level of ventilator assistance, although the optimal rate of assist reduction is not known.

THE FUTURE

Microarray analysis has identified 354 differentially expressed gene products in the diaphragms of animals subjected to CMV compared to control animals.[71] Intense research is required to unravel the mechanisms of VIDD. Animal models can be used to study the effects of CMV on the diaphragm of a critically ill organism, and to determine the best approach to reload the diaphragm once VIDD has developed. Clinical trials of different ventilator strategies (different levels of assist) and of pharmacotherapy to prevent VIDD should be designed and conducted. Finally, pharmacologic approaches for VIDD recovery are the next logical step of research in the field.

SUMMARY AND CONCLUSION

Over the last two decades researchers have discovered that mechanical ventilation can damage the previously normal respiratory muscles. CMV imposes a unique form of skeletal muscle disuse: The diaphragm is simultaneously unloaded, electrically quiescent, and phasically shortened by cyclical lung inflation or tonically shortened when PEEP is used. The respiratory muscles are not some inert mechanical pump that can be replaced cavalierly by the ventilator. The respiratory muscles should remain as active as possible because they are plastic and vulnerable.

BAROTRAUMA AND BRONCHOPLEURAL FISTULA

Andrew M. Luks
David J. Pierson

This chapter considers the possible origins of extraalveolar air in ventilated patients and then reviews the manifestations and most frequent clinical settings of its various forms. After a discussion of general principles of management and a review of reported therapeutic approaches, it presents logical steps for prevention in susceptible patients and points out important gaps in the existing evidence base pertaining to this important topic. Although all the clinical forms of barotrauma are touched upon, most attention is devoted to those that pose a threat to life.

Only overt extraalveolar air is covered in this chapter. The reader is referred to Chapter 42 for a discussion of lung damage at the tissue or subcellular level related to mechanical lung distension and the application of positive pressure to the airways. Because data from laboratory studies are covered extensively in that discussion, this chapter deals primarily with barotrauma as a complication in patients, referring mainly to the adult clinical literature. As will be apparent, although the latter is replete with anecdotes and observational reports, this focus primarily on human data means that the evidence base in terms of prospective studies and "hard data" available to the clinician is remarkably limited. Spontaneous pneumothorax and other forms of extraalveolar air encountered in patients who are not intubated or receiving mechanical ventilation are not dealt with extensively here, nor is decompression-related barotrauma or bronchopleural fistula complicating lung resection.

DEFINITIONS

Pneumothorax, subcutaneous emphysema, and other clinical forms of extraalveolar air occurring in association with mechanical ventilation are commonly referred to as *barotrauma*. This term is doubly unfortunate, *trauma* connoting iatrogenic injury and *baro* implying that it is pressure, rather than volume, shear force, or some other factor that produces it. In fact, these implications of both roots of the word are probably incorrect, and the expression *ventilator-associated extraalveolar air* would be technically more appropriate. Similarly, the term *bronchopleural air leak* would be more accurate than *bronchopleural fistula*, because of the implications of inflammation and suppuration associated with the word *fistula* in surgical and other settings. Like *barotrauma*,

however, the latter is so ingrained in clinical usage that change is unlikely, and the more familiar terms are used in this chapter, as elsewhere in this book.

Although extraalveolar air appearing during ventilator support may not be caused by the ventilator itself, the expression *ventilator-induced lung injury* would seem as applicable to clinical barotrauma as to parenchymal damage associated with mechanical stretch and overdistension. Again, however, owing more to convention than to logical etymology, the term *ventilator-induced lung injury* is generally reserved for the latter, in this book and in the broader literature.

Usually, barotrauma in mechanically ventilated patients is automatically assumed to be a complication of mechanical ventilation. As with nosocomial pneumonia, however, ventilatory muscle dysfunction, and most of the other adverse developments to which ventilated patients are prone, whether the ventilator per se is responsible is usually unclear, because patients ill enough to require endotracheal intubation, supplemental oxygen, positive-pressure ventilation, and management in an intensive care unit (ICU) tend to have numerous other predispositions to such complications. Each of these things would be better thought of as complications *associated with*, rather than *of*, mechanical ventilation.[1,2]

TABLE 44-1: POSSIBLE ORIGINS OF EXTRAALVEOLAR AIR

Upper respiratory tract
Fractures of facial bones, mandible, etc.
Other traumatic mucosal disruption
Dental extractions and other oral surgical procedures
Intrathoracic airways
Airway rupture or laceration in blunt or penetrating chest trauma
Complications of intubation or airway instrumentation
Foreign body in upper or lower airways
Bronchoscopy-related procedures (e.g., transbronchial biopsy, bronchial brushing, or transbronchial needle aspiration)
Lung parenchyma
Penetrating trauma
Surgical procedures
Diagnostic procedures as above
Thoracentesis
Percutaneous needle aspiration or biopsy
Alveolar rupture
Gastrointestinal tract
Perforation of esophagus or abdominal viscus
Infection with gas-producing organisms
Pleural empyema
Acute mediastinitis
Necrotizing fasciitis or other soft-tissue infection
Exogenous source (air from outside the body)
Penetrating trauma
Thoracentesis or closed pleural biopsy
Surgical procedures (e.g., chest tube insertion, tracheotomy, or mediastinoscopy)

PATHOPHYSIOLOGY

Mechanism of Alveolar Disruption

Barotrauma in a patient receiving positive-pressure ventilation has a number of potential causes (Table 44-1).[3] Most often extraalveolar air during mechanical ventilation results from overdistension of alveoli and rupture of their walls down a pressure gradient from airspace into bronchovascular sheath, as illustrated in Figure 44-1.[4] This mechanism was worked out many years ago in elegant animal experiments by C.C. and M.T. Macklin:[5,6] "…pulmonic interstitial emphysema and its sequelae—air in the mediastinum, peritoneal cavity, subcutaneous tissues, and pleural cavity—are present in many conditions; differing widely in their cause, their clinical manifestations and their seriousness. All of these conditions, however, have a single common factor, a gradient of pressure between the alveoli and vessel sheath, and hence an opportunity for air to gain access to the interstitial tissues of the lung."[6]

According to the work of the Macklins,[5,6] the basic requirement for alveolar rupture is the presence of a pressure gradient between the alveoli and their surrounding structures. Interalveolar walls are probably not susceptible to such pressure gradients, as they are very thin and the pressures between adjacent alveoli are probably equal. Any sudden increase in alveolar pressure (or presumably a fall in perivascular interstitial pressure), however, may establish a gradient sufficiently large to disrupt alveolar walls at their bases (see Fig. 44-1), introducing air into the pulmonary interstitium. Alveolar overdistension would tend to thin and stretch the alveolar membranes, facilitating rupture once the pressure gradient was established. This mechanism can readily be understood in the case of extraalveolar air following sudden deceleration injury, such as falling into water from a height,[7] but it likely is the main means of alveolar rupture in the majority of other clinical settings as well.[3,4,8]

Spread of extraalveolar air via bronchovascular sheaths after alveolar rupture was dramatically demonstrated by Jamadar et al when pneumomediastinum developed in a patient undergoing liquid ventilation.[9] After the liquid medium was removed from the bronchial tree and alveoli, computed tomography of the chest demonstrated persistence of the radiopaque perfluorocarbon fluid in the bronchovascular sheaths, confirming the mechanism elucidated a half-century earlier by the Macklins.

Other Possible Sources of Extraalveolar Air

Beyond clinical barotrauma that occurs as a direct complication of mechanical ventilation, it is important to be cognizant of other possible sources not related to the ventilator itself (Table 44-2).[3,8] Distinguishing these causes from barotrauma secondary to mechanical ventilation itself may be challenging in some circumstances, particularly when adequate clinical history is lacking. Pneumothorax appearing within the first few hours following initiation

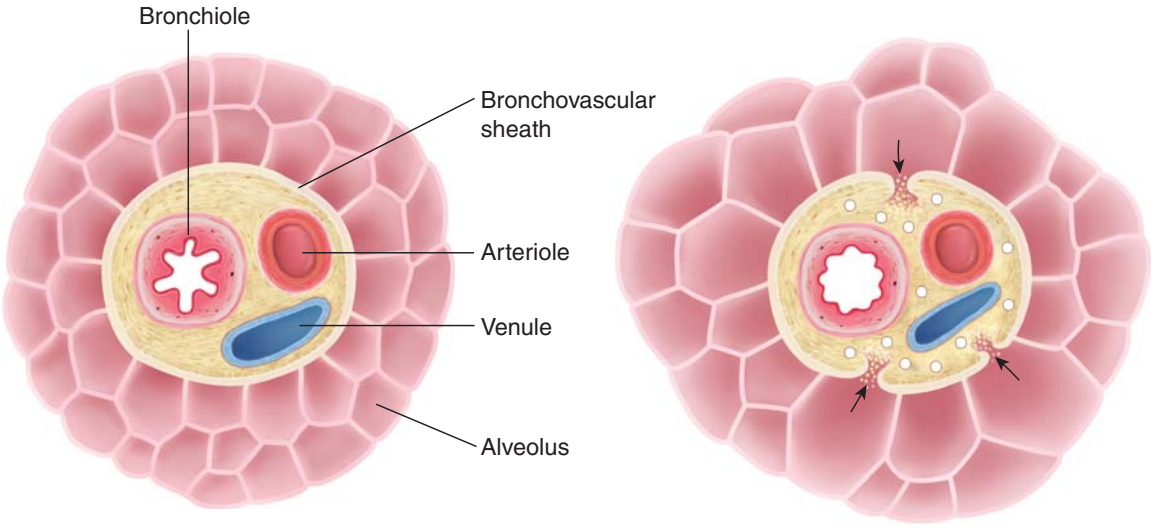

FIGURE 44-1 Mechanism of alveolar rupture during mechanical ventilation. Pressures between adjacent alveoli equalize rapidly, but, especially in the presence of high alveolar volume, increased alveolar pressure, in comparison with that in the adjacent bronchovascular sheath, establishes a pressure gradient that may result in rupture of the alveolar wall, allowing passage of air into the interstitial tissue of the bronchovascular sheath. (Used, with permission, from Maunder et al.[4])

of mechanical ventilation may be the result of previous trauma, overinflation during manual ventilation, or procedures such as central line attempts before intubation. Even in patients already receiving ventilator support, the appearance of extraalveolar air may represent "pseudobarotrauma"—external trauma to the lung from attempts at placing central venous access or various endoscopic procedures—rather than "spontaneous" alveolar rupture.

TABLE 44-2: POSSIBLE MECHANISMS FOR "BAROTRAUMA" IN MECHANICALLY VENTILATED PATIENTS

- Airway disruption or alveolar rupture before initiation of ventilatory support
  - Trauma (penetrating or blunt)
  - Resuscitation (mouth-to-mouth or manual ventilation)
  - Airway laceration or perforation during intubation attempts
  - Attempted central line placement (e.g., via the internal jugular or subclavian route)
  - Biopsy or surgical procedure
- Direct laceration of visceral pleura or airway during mechanical ventilation ("pseudobarotrauma")
  - Central line placement
  - Thoracentesis or chest tube placement
  - Transbronchial biopsy or bronchial brushing
- "Spontaneous" alveolar rupture
  - Manifestation of a primary disease process
  - Complication of ventilator-associated pneumonia or sepsis
  - Inadvertent alveolar overdistension (e.g., right main bronchus intubation or manual ventilation)
  - Related to ventilator management per se (e.g., tidal volume, positive end-expiratory pressure, recruitment maneuvers, or breath-stacking)

Air originating in the upper respiratory tract can dissect downward from the head and neck and produce subcutaneous emphysema, pneumomediastinum, and conceivably even pneumothorax. During mechanical ventilation, this could occur in the presence of negative intrathoracic pressure, as with vigorous efforts against a partially occluded airway or in severe patient–ventilator dyssynchrony. Reported causes of pneumomediastinum from air dissection from above include facial or mandibular fractures,[10] retropharyngeal abscess,[11] and dental extractions, particularly if these involve the lower molar teeth and air-turbine drilling.[12]

Mediastinal air and other barotrauma can also originate in the intrathoracic airways, as after blunt or penetrating chest trauma,[13,14] as a complication of bronchoscopic procedures, during percutaneous dilatational tracheotomy,[15] or from perforation by a foreign body. Injury to the upper airway or laceration of the posterior membranous trachea may occur during attempted endotracheal intubation, particularly when a stylet is used, and this has been associated with clinical barotrauma in numerous reports.[16–20]

Endoscopic procedures[21–23] and other interventions may rupture or perforate the esophagus, providing access for air into the mediastinum. In many instances, but not always, signs of mediastinitis accompany the appearance of pneumomediastinum following esophageal procedures.[8] Air in the mediastinum is also a characteristic feature of Boerhaave syndrome,[24] and the typical history of vigorous retching after a large meal may be absent.

Most often the origin of clinical barotrauma is the lung parenchyma, but even then the mechanism may be other than "spontaneous" alveolar rupture. Other possibilities include penetrating trauma that lacerates pulmonary tissue, surgical procedures involving the intrathoracic structures, bronchoscopic procedures, and transthoracic needle

aspiration. When acute mediastinitis or pleural empyema involves gas-producing organisms, palpable or radiographically detectable extraalveolar air may result; gas arising from soft-tissue infections such as clostridial gangrene may also be confused with barotrauma.

Finally, exogenous air may find its way into the pleural space, subcutaneous tissues, or mediastinum. Most commonly this occurs during or following thoracentesis, chest tube insertion, tracheotomy,[25] or mediastinoscopy. Rarely, air may enter the soft tissues following cutaneous injury to an extremity[26] or elsewhere in the body, producing subcutaneous emphysema that could be confused with barotrauma.

Airway Pressure versus Alveolar Distension

For many years, a primary goal of mechanical ventilation was to limit peak airway pressures, based on the belief that high peak airway pressures were a primary mediator of barotrauma.[27–31] The desire to avoid high peak airway pressures was a main driver in the introduction of pressure-targeted modes of ventilation and the different forms of high-frequency ventilation.[3] As discussed in Chapter 42, however, a large body of evidence now supports the conclusion that it is excessive volume, not airway pressure per se, and especially not peak airway pressure measured outside the patient, that primarily determines the occurrence and severity of ventilator-induced lung injury.

Peak airway pressure during mechanical ventilation can be influenced by a number of factors (Table 44-3), most of which do not affect (or reflect) alveolar volume. This can readily be understood by envisioning the various potential sources for high peak airway pressure as sensed at the ventilator's manometer. Increased resistance to airflow in the ventilator circuit or endotracheal tube, or in the patient's conducting airways, will be reflected in an increased peak inspiratory airway pressure. Likewise, an increase in chest wall pressure, as with coughing, chest strapping, or massive generalized edema, will increase peak airway pressure without increasing transalveolar pressure or alveolar volume. Even increased pressure at the alveolar level should not cause disruption of alveolar walls unless this pressure is unevenly distributed between adjacent alveoli or between alveoli and the adjoining bronchovascular sheath.

This conclusion becomes obvious when one considers the common activities that markedly raise peak airway pressure without causing alveolar rupture.[3] Normal persons routinely generate peak airway pressures up to 200 cm H_2O or more during a cough or sneeze.[32] In a study of fifty-six normal male subjects ranging in age from 6 to 64 years, Cook et al[33] found their mean individual maximum peak expiratory airway pressures to be 237 ± 45 cm H_2O. In that study, the subjects sustained these pressures for at least 1 to 2 seconds, and even longer periods of sustained high peak airway pressures can be maintained during the Valsalva maneuver, during which pressures as high as 200 torr (286 cm H_2O) have been documented.[34] Airway pressures well above 100 cm H_2O are routinely achieved and held by trumpet players[35] without causing barotrauma. Alveolar rupture is extremely rare in wind instrument players, as it is in glass blowers, weight lifters, and other healthy people after coughing, sneezing, or straining.[3,36]

TABLE 44-3: POSSIBLE CAUSES OF HIGH PEAK AIRWAY PRESSURE DURING MECHANICAL VENTILATION

High inspiratory flow (increases proximally measured peak airway pressure at any given total airway resistance)
High resistance in the ventilator circuit or endotracheal tube
Inspissated secretions
Smaller-than-usual endotracheal or tracheostomy tube
Kinking
Obstructed distal orifice
High resistance in the patient's airways
Bronchospasm
Secretions
Airway edema
Neoplasm, stenosis, or foreign body in trachea or main bronchus
Alveolar overdistension
Decreased compliance of the lung parenchyma
High pleural or transthoracic pressure
Coughing
Agitation, shivering, or seizures
Splinting as a consequence of chest wall pain
Pneumothorax or pleural effusion
Ascites or abdominal packs or binding
Head-down position
Bandages, casts, or restraints
Other causes of intraabdominal hypertension or reduced chest wall compliance

In addition, for any given airway resistance, varying inspiratory flow will also vary the pressure developed as a given volume is delivered to a patient's lungs, but will not affect end-inspiratory alveolar pressure. For any given volume-targeted inspiratory waveform, shortening inspiratory time will increase peak airway pressure but will not affect overall lung distension if the set tidal volume is unchanged; in fact, higher proximal airway pressures will decrease delivered alveolar volume because of increased compressed volume in the tubing. Conversely, increasing inspiratory time will lower peak airway pressure but could even increase alveolar distension over a series of breaths if insufficient time were provided for complete exhalation, resulting in air-trapping and endogenous positive end-expiratory pressure (auto-PEEP).

It should be remembered that peak inspiratory pressure can also be increased as a result of problems with respiratory system compliance such as low pulmonary parenchymal compliance caused by acute respiratory distress syndrome (ARDS) or pulmonary edema, chest wall problems such as circumferential burns or chest wall edema, and abdominal distension. Such situations will be reflected in an elevated plateau pressure. If this value is high relative to the pressure outside the lung parenchyma—a question

that can be sorted out using esophageal manometry[37]—the transpulmonary pressure difference will be high and the patient may be at increased risk for barotrauma. High plateau pressures in the setting of increased extrapulmonary pressure, on the other hand, will be associated with a small transpulmonary pressure difference and a lower risk of alveolar rupture.

The Importance of Ventilator Mode and Other Settings

To date, no studies have definitively established that the particular ventilator mode or other ventilator settings such as tidal volume or PEEP affect the incidence of barotrauma. The lack of effect secondary to tidal volume in conventional volume-control ventilation can best be seen by comparing the incidence of barotrauma in the era before and after the widespread adoption of lung-protective ventilation in patients with ARDS. In six large series published between 1974 and 1983, including data from 2980 mechanically ventilated patients, the incidence of detectable extraalveolar air ranged from 4% to 11%, with most in the range of 5% to 7%.[28,30,38–41] Although some patients with acute lung injury and ARDS were included in these series, barotrauma was not specifically examined in those conditions. As Tables 44-4 and 44-5 demonstrate, the incidence of barotrauma has not declined significantly since lung-protective ventilation became a part of clinical practice, despite a general impression that this complication is now encountered less frequently than in the past.[42]

In trials comparing low and high tidal-volume strategies,[43–48] as well as trials in which both arms were managed with lower tidal volumes,[49–53] the incidence of barotrauma does not differ significantly from that documented in earlier periods. Further support for a lack of a role for tidal volume comes from studies that examined risk factors for the incidence of barotrauma, which revealed that tidal volume had no significant effect.[47,54,55]

It is not clear whether other, less commonly used modes of ventilation affect the incidence of barotrauma. Several studies on the use of high-frequency oscillatory ventilation in acute respiratory failure, for example,[56–58] have documented incidence rates of pneumothorax or barotrauma of 8% to 9%, although a retrospective review of high-frequency oscillatory ventilation use at three centers in Toronto documented a much higher incidence rate of 21.8%.[59] A randomized trial comparing airway pressure release ventilation to conventional volume-targeted lung-protective ventilation, in patients with acute respiratory failure following trauma, found no difference in the incidence of barotrauma with the two approaches.[60]

The use of noninvasive ventilation has increased substantially in recent years, particularly for the management of acute exacerbations of chronic obstructive pulmonary disease. One report suggests the incidence of barotrauma is less than 5% with this modality,[61] but, overall, less data are available on this question compared to the other support modalities.

By increasing alveolar distension, increased levels of PEEP might be expected to cause more barotrauma. As with tidal volume, however, no studies have established a strong relationship in this regard. Eisner et al[62] examined 718 patients enrolled in the ARDS Network clinical trials and found that higher levels of PEEP correlated with increased likelihood of developing clinical barotrauma during the first 4 days

(relative hazard: 1.5), although the 95% confidence interval included 1 (0.98 to 2.3). More recently, two large randomized studies[49,51] comparing the use of high and low PEEP strategies in patients with ARDS ventilated at low tidal volumes (≤6 mL/kg predicted body weight) showed no significant differences in the incidence of barotrauma. Even if data did suggest an association between PEEP and increased risk of barotrauma, this finding could be interpreted in two ways: either higher levels of PEEP predispose to barotrauma, or sicker patients (who require higher levels of PEEP) are more likely to develop barotrauma.

End-inspiratory plateau pressure is another variable that could affect alveolar distension and, therefore, the risk of barotrauma, but consistent evidence of such a link is also lacking. Boussarsar et al[54] reviewed the findings of eleven studies (2270 patients) that reported the incidence of barotrauma in patients with ARDS and noted that end-inspiratory plateau pressure was the only ventilator management-related variable that correlated statistically with the occurrence of barotrauma. In an international study of 5183 mechanically ventilated adult patients with a wide variety of diagnoses, however, Anzueto et al[63] found no correlation between any ventilator setting or pressure measurement and the development of barotrauma; several recent large randomized trials of ventilator management in ARDS in which plateau pressures were different between the two arms of the study showed no differences in barotrauma incidence (see Table 44-5).[43,51,52] One reason why plateau pressure may not be convincingly related to the risk of barotrauma may be because plateau pressure represents the difference between pressure in the airways and the atmosphere and, hence, total respiratory system compliance, whereas the risk of barotrauma is more a function of the pressure difference between the alveoli and bronchovascular sheath. Plateau pressure may be high but if this is caused by factors outside the lungs, such as increased abdominal distension or chest wall edema, the elevated pressures may not lead to alveolar rupture.

THE IMPORTANCE OF PROPER MANUAL (BAG) VENTILATION

A circumstance in which tidal volumes and airway pressures are delivered substantially above desirable levels is manual (bag) ventilation, an adjunctive ventilation method used immediately following intubation, during cardiopulmonary resuscitation, in association with airway suctioning, and chest physiotherapy, and during patient transport.[64] The volumes delivered and the pressures generated are typically not monitored and can vary substantially, depending on the size of the operator's hands, whether one hand or two is used, and other factors. Tidal volumes during manual ventilation ranged between 838 mL and 1674 mL in one study, with a mean value of 170% of the ventilator's set tidal volume.[65] In a bench study, in which experienced respiratory therapists performed manual ventilation on a lung model to simulate ventilating a 70-kg patient, delivered tidal volumes varied from 400 mL to more than 1000 mL, with airway pressures

sometimes exceeding 100 cm H_2O.[66] Indeed, the development of clinical barotrauma during manual ventilation has been reported several times.[67–69]

The Importance of the Underlying Disease Process

The occurrence of alveolar rupture during mechanical ventilation is influenced markedly by the presence and nature of underlying lung pathology. Barotrauma is rare in patients with normal lungs—for example, in routine postoperative ventilation[39] or in paralytic states such as high cervical spinal cord injury or Guillain-Barré syndrome. In contrast, barotrauma is more common in patients with underlying obstructive or restrictive lung disease.[42,63] In an observational cohort study of 5183 patients who underwent mechanical ventilation for more than 12 hours in 361 ICUs in twenty countries,[70] barotrauma was observed in 154 patients (2.9%).[63] The incidence of barotrauma, defined as pulmonary interstitial emphysema, pneumothorax, pneumomediastinum, pneumoperitoneum, or subcutaneous emphysema, was 2.9% in patients with chronic obstructive pulmonary disease, 4.2% in pneumonia, 6.3% in asthma, 6.5% in ARDS, and 10.0% in chronic interstitial lung disease.[63] Logistic regression analysis identified the last three of these conditions as independent risk factors for development of barotrauma. An earlier analysis by Gammon et al[71] of 168 consecutive patients who underwent mechanical ventilation at one center found with multivariate analysis that of all variables examined, only the presence of ARDS correlated with development of pneumothorax.

The Spread of Extraalveolar Air Once Alveolar Rupture Occurs

Because pressures in the interstitium and bronchovascular sheath tend to be slightly less than those in the alveoli at peak lung inflation, there is a tendency for air to move into these areas once the alveolar walls are disrupted.[4–6] Although this is also accepted as the mechanism of the spread of extraalveolar air in spontaneously breathing patients, it is particularly facilitated by positive-pressure ventilation, especially when large tidal volumes are used. Figure 44-2 depicts the possible routes of spread once air leaves the alveolus. Except for systemic air embolism, which is uncommon, and pulmonary interstitial emphysema, the common pathway for all the clinical forms of barotrauma is pneumomediastinum.[8] Once in the mediastinum, air follows the path of least resistance and may rupture through the delicate mediastinal fascia and overlying pleura into the pleural space. Why this occurs in some patients and not in others may be determined by local pleural scarring in some cases, but is usually not readily apparent.

The spread of extraalveolar air to a wide variety of locations in the body can be understood through reference to the fascial planes of the neck, mediastinum, and retroperitoneum, as shown in Figure 44-3.[4] Three distinct cervical

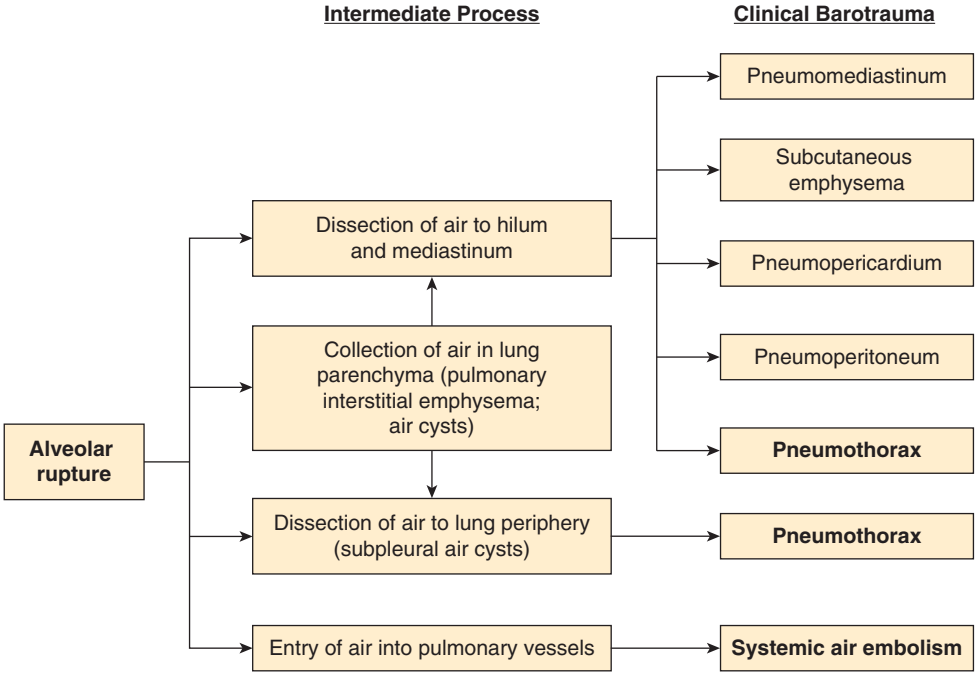

FIGURE 44-2 Pathogenesis of the various forms of barotrauma, with those of greatest clinical importance in bold type. In addition to being associated with use of mechanical ventilation, pneumothorax can also occur as a result of puncture or laceration of the visceral pleura during central line placement or other procedures or traumatic injuries such as rib fractures.

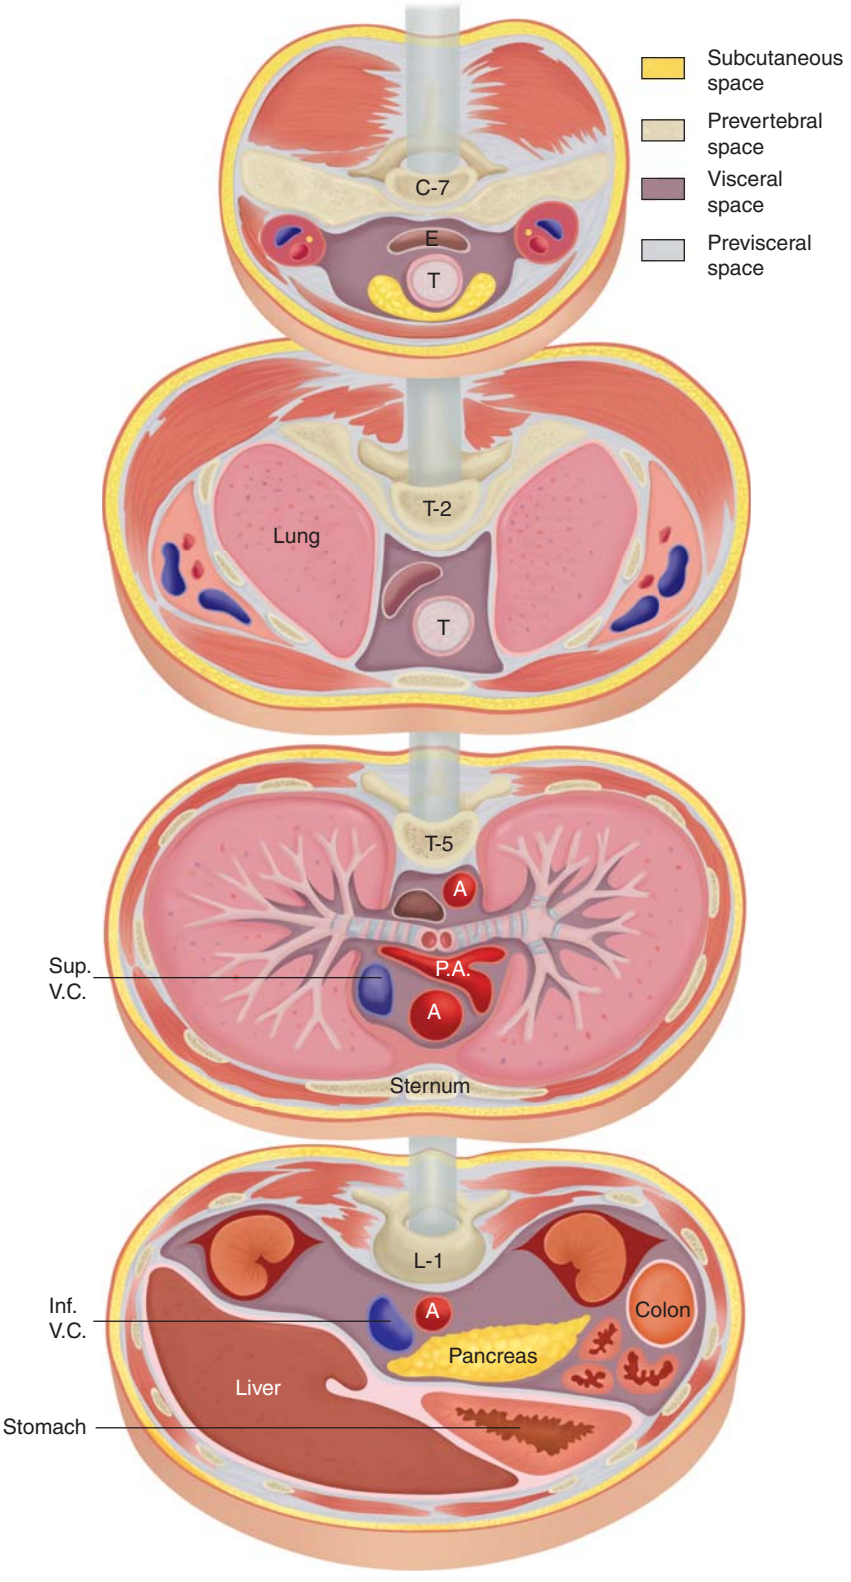

FIGURE 44-3 Fascial planes of the neck, mediastinum, and retroperitoneum, as depicted at the levels of C-7, T-2, T-5, and L-1, respectively. Because the soft-tissue compartments are continuous, air can dissect into a wide variety of anatomic locations. (Adapted, with permission, from Maunder et al.[4])
Abbreviations: A, aorta; E, esophagus; inf.V.C., inferior vena cava; P.A., pulmonary artery; Sup.V.C., superior vena cava; T, trachea.

compartments exist—a previsceral space lying between the deep cervical fascia and the pretracheal fascia, a visceral space lying between the pretracheal fascia and the prevertebral fascia, and a prevertebral space situated behind the prevertebral fascia. These cervical compartments continue via the mediastinum through the thorax and trunk, providing the potential for the spread of air into the retroperitoneal space.

Air may continue to leave the airways, as shown in Figure 44-1, so long as the alveolar rent is large enough and a sufficient pressure gradient exists. If this path of least resistance leads up the mediastinum and into the soft tissues of the neck and upper chest, subcutaneous emphysema may become massive, spreading extensively over the body. Occasionally the pressure gradient and local anatomy favor passage of air into the retroperitoneal space, from which it decompresses into the peritoneum,[72–76] causing massive abdominal distension. When the extraalveolar air has reached the pleural cavity, the resultant pneumothorax may rapidly increase with successive positive-pressure breaths. Air readily leaves the torn alveolus and passes into the pleural space, but cannot return between inspirations because of the collapsibility of the lung and mediastinum. A ball-valve mechanism is created and fatal tension pneumothorax can rapidly result. Figure 44-4 depicts examples of the various forms of barotrauma that can result from these mechanisms.

Bronchopleural Fistula

After evacuation of a pneumothorax via tube thoracostomy, air may continue to leak into the pleural space and via external suction into the pleural collection device. Such a bronchopleural air leak tends to be perpetuated by the very measures often required to reinflate the collapsed lung and to maintain gas exchange in patients with severe acute respiratory failure. Once a rent exists at either the alveolar or visceral pleural level, the higher the pressure gradient between airways and pleural space, the greater will be the tendency of the bronchopleural fistula to leak. It therefore stands to reason that management should focus on decreasing airway pressure and minimizing pleural suction. As discussed later (see the section Management: Bronchopleural Fistula), however, little experimental evidence is at hand to support this hypothesis, and the management needs of critically ill patients often prevent the realization of these goals.

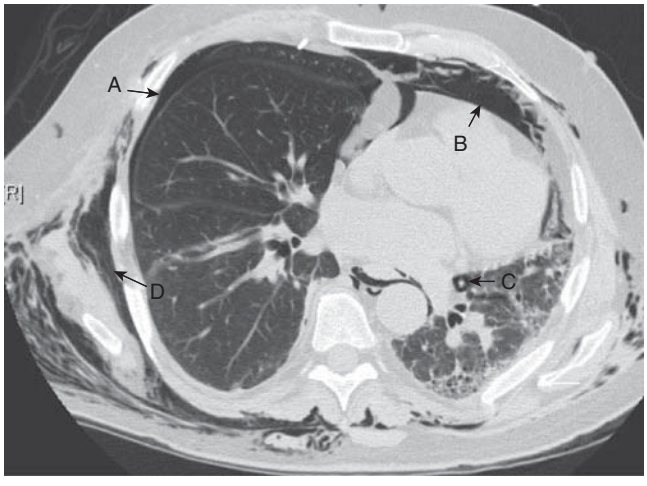

FIGURE 44-4 Computed tomography image through midchest showing multiple manifestations of pulmonary barotrauma in the same patient including: (**A**) pneumothorax; (**B**) pneumomediastinum; (**C**) pulmonary interstitial emphysema represented by a halo of air surrounding a vascular structure; and (**D**) subcutaneous emphysema.

CLINICAL MANIFESTATIONS

The different clinical forms of barotrauma shown in the right-hand column in Figure 44-2 vary considerably in their clinical manifestations, relative frequency, and potential for doing harm to the patient. Table 44-6 lists the nine categories of extraalveolar air that are discussed in the remainder of this chapter, and shows their relative frequency in ventilated patients, along with their relative seriousness and potential threat to life. With few data from prospective studies of the incidence of the different forms of barotrauma across the broad range of patients managed on mechanical ventilation, the frequencies listed in Table 44-6 are based on the our clinical experience and what little information can be gleaned from the literature. Tension pneumothorax and systemic air embolism are always potentially fatal events. Beyond these, however, the effects of barotrauma on survival, organ dysfunction, ICU stay, and other outcomes, separate from those of the underlying disease, are largely unknown.

Pulmonary Interstitial Emphysema and Cystic Dilation

Air in the interstitium of the lung can be identified at autopsy in patients who die with clinical barotrauma associated

TABLE 44-6: CLINICAL FORMS OF BAROTRAUMA DURING MECHANICAL VENTILATION

with positive-pressure ventilation, and is easily demonstrated using computed tomography (CT) scanning (see C in Fig. 44-4).[77–79] With appropriate technique pulmonary interstitial emphysema may also sometimes be detected on plain radiographs of the chest, and be present without other signs of extraalveolar air.[80,81] A variety of patterns have been described.[81] Parenchymal stippling, thought to represent multiple small pulmonary vessels and their air-distended vascular sheaths in cross section, has been referred to as a "salt-and-pepper" pattern.[80] Air dissection within the pulmonary interstitium is believed responsible for lucent mottling,[81] with small cyst-like lucencies that may increase progressively in size on successive films. Other signs of pulmonary interstitial emphysema include lucent streaks, believed to be produced by air dissecting toward the hilum along the course of larger pulmonary vessels, and perivascular halos in the perihilar regions of the lung, representing such air collections seen end-on. All these signs are most readily seen in the presence of diffuse pulmonary consolidation or atelectasis, which increases the radiographic contrast between parenchyma and extraalveolar air.

Although it is well-defined pathophysiologically (see Figs. 44-1 and 44-2), pulmonary interstitial emphysema in mechanically ventilated adult patients has doubtful practical clinical importance, primarily because of the realities of bedside imaging in the ICU. Several older studies described pulmonary interstitial emphysema in critically ill patients,[30,31,82–84] and in some instances it has been shown to precede the development of pneumothorax. The subtle changes identifying this entity, however, are beyond the resolution of most bedside radiologic tools. In one study attempting to elucidate the patterns and risk factors for barotrauma in ventilated patients, the investigators abandoned their initial plan to determine whether pulmonary interstitial emphysema precedes pneumothorax because they could not reliably or reproducibly detect the former.[85] In our experience, the degree of resolution and interexposure consistency required to detect and follow this radiographic finding are beyond the capabilities of most portable X-ray units, that must frequently shoot through bandages and bedding, with suboptimal positioning and patients who cannot hold still or take a deep breath.

Intrapulmonary cystlike air collections in patients with ARDS have been recognized with increased frequency since the use of CT in such patients became commonplace. The early studies of Maunder et al[86] and Gattinoni et al[87] demonstrated the heterogeneous nature of lung involvement in ARDS, and especially late in the course of this disorder large collections of free air within the pulmonary parenchyma are common (Fig. 44-5). Pneumothorax also seems to be common in this setting, although no study published to date has documented this observation objectively.

Small subpleural air collections, also identified on CT scans occur frequently during the course of ARDS.[88] These collections probably represent centrifugal dissection of air through the interstitium to the visceral pleura, and are the likely source for pleural air in some patients.

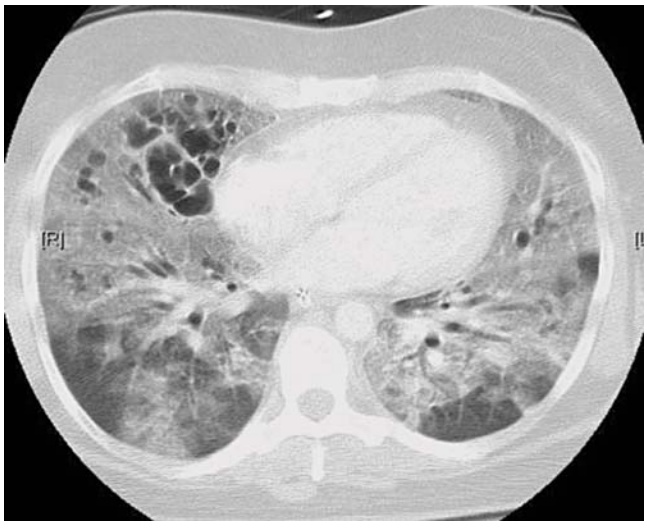

FIGURE 44-5 CT image through the midchest in a patient with ARDS receiving mechanical ventilation with PEEP. Parenchymal involvement is markedly inhomogeneous, with relatively normal areas in the dependent lung zones, widespread ground glass opacities in both lungs and intraparenchymal cystic air collections, primarily in the anterior portions of the right lung.

Pneumomediastinum

The mechanisms for alveolar rupture and the spread of air to the mediastinum illustrated in Figures 44-1 and 44-2 apply to spontaneously breathing, nonintubated patients as well as to those receiving mechanical ventilation.[8] In the former, symptoms referable to pneumomediastinum are frequent and characteristic. Stabbing precordial chest pain is the most common complaint,[89–91] occurring in 80% to 90% of patients.[4,92] "Hamman's crunch," a crunching or clicking sound best heard over the retrosternal area synchronous with cardiac systole,[93] can be detected in many patients who present with spontaneous pneumomediastinum. It is not specific, however, and may occur in patients with spontaneous pneumothorax without evidence of pneumomediastinum.[94]

Symptoms may be unobtainable from an intubated, critically ill patient, however, and the physical findings characteristic of pneumomediastinum may be hard to detect amid the hubbub of the ICU. Most often, pneumomediastinum is first detected radiologically, usually as an incidental finding. The most common appearance is a radiolucent area paralleling the left-heart border. This is readily detected in the presence of fluid density in the adjacent lung tissue, as with pneumonia or pulmonary edema. A thin, vertically oriented white line representing the mediastinal pleura may be seen when the pneumomediastinum is bordered by normal lung parenchyma. Once detected, a pneumomediastinum can often be traced cephalad beyond the hilum and into the neck. Other radiographic findings include highlighting of the aortic knob, which is surrounded by more lucent gas density than usual, and the "continuous diaphragm sign" described by Levin (Fig. 44-6).[95] Many patients with

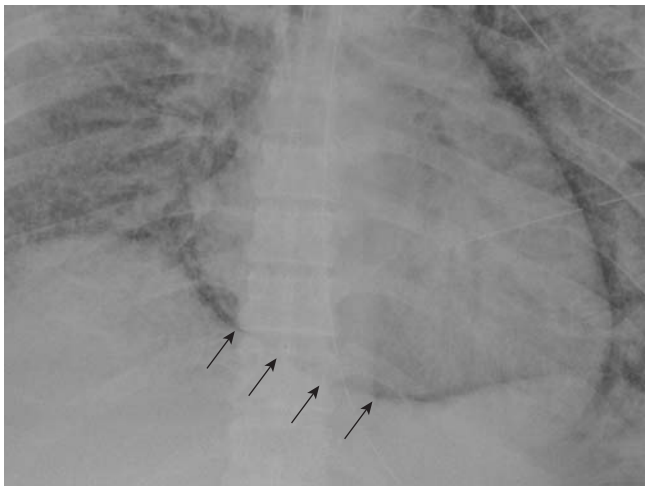

FIGURE 44-6 The "continuous diaphragm sign" of pneumomediastinum in a patient with barotrauma complicating ARDS. An unbroken radiolucent line denoted by the *arrows* extends from one hemidiaphragm to the other, rendering the inferior heart border clearly visible.

ventilator-associated pneumomediastinum also develop subcutaneous emphysema, which is typically more obvious radiographically.

Pneumomediastinum is frequently the first sign of barotrauma, and a substantial number of cases go on to development of pneumothorax. In one retrospective study,[85] thirty-four of 139 intubated patients had radiographic signs of barotrauma at some point in their ICU course. Pneumomediastinum was the initial manifestation in twenty-four of the thirty-four patients, and a pneumothorax was subsequently diagnosed in ten (42%).

Pneumopericardium

Dissection of air into the pericardium can follow alveolar rupture, and pneumopericardium may occasionally be the only sign of barotrauma. Long known as a complication of respiratory distress syndrome in neonates, it has been reported in adults as well,[96,97] particularly following blunt chest trauma,[98,99] and complicating severe bacterial pneumonia.[100,101] Although hemodynamically significant pneumopericardium in ventilated adults is not generally considered likely, presumably because the adult pericardium communicates less readily with the rest of the mediastinum than is the case in neonates, one group[96] reviewed eighty-one previously published cases and found 37% of them to have been hemodynamically significant. Several patients in this series were said to have required emergency pericardiocentesis. Adding to the uncertainty about the frequency and clinical importance of pneumopericardium in ventilated adult patients is the difficulty often encountered by portable radiographic devices to distinguish air in the pericardium from the much more common finding of pneumomediastinum.

Subcutaneous Emphysema

Although subcutaneous emphysema is commonly observed both radiographically and on physical examination around chest tube insertion sites, most often this form of barotrauma is encountered in the neck and upper anterior chest as it is vented from the superior mediastinum. When present in only small amounts, subcutaneous air produces the typical findings of crepitance on palpation. If the leak continues, as may be seen in severe ARDS when excessive tidal volumes and high inflation pressures are used, obvious distortion of the neck and anterior chest wall can be seen, and palpation shows a characteristic "pneumatic sponginess" as the skin and subcutaneous tissues are depressed to touch the underlying ribs. Air is commonly noted outlining the pectoralis musculature on routine chest radiology; chest CT reveals the spread of air throughout the soft tissues and in all fascial planes (Fig. 44-7).

From the neck and chest wall the air can spread literally everywhere in the body, collecting especially in areas with loose subcutaneous tissue, such as the upper arms and axillae and the abdominal wall. Periorbital accumulation may become extensive enough to force the eyelids shut. Radiographic studies obtained for other reasons in patients with widespread subcutaneous emphysema may reveal air in a variety of unexpected locations (Fig. 44-8).

Although it may be uncomfortable for the patient and distressing to the caregivers at the bedside, subcutaneous emphysema is nearly always clinically benign. Air in the subcutaneous tissues or dissecting along deeper fascial planes poses little if any direct threat to the adjacent tissues. The air tends to collect in areas with loose connecting tissue, whose blood supply is not compromised by the stretching and other distortion. Like pneumomediastinum, this form of barotrauma serves mainly as an indicator rather than constituting a management problem per se. It signifies the presence of a substantial air leak, and should alert the

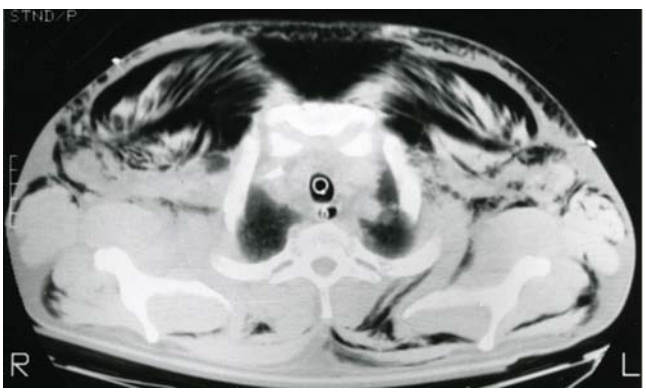

FIGURE 44-7 Example of widespread subcutaneous emphysema in a patient with barotrauma complicating ventilator management in severe ARDS. CT image through the shoulders, at the most cephalad extension of the lung apices, showing air widely dispersed under the skin and outlining the musculature.

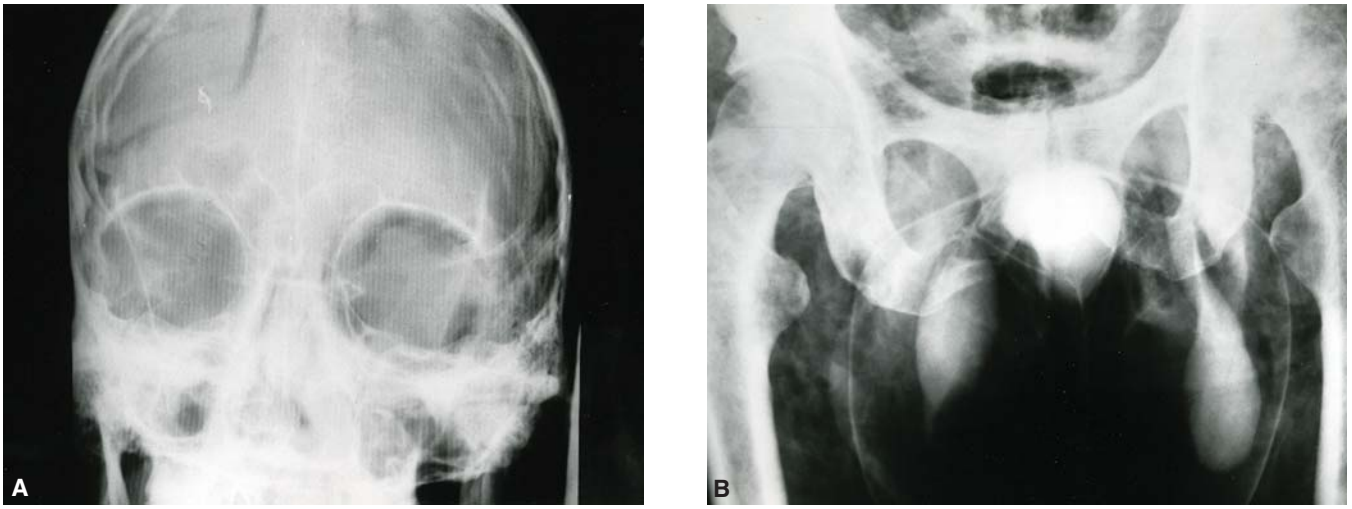

FIGURE 44-8 Examples of widespread subcutaneous emphysema in patients with barotrauma complicating ventilator management in severe ARDS. **A.** A bedside skull film showing air beneath the scalp on the left and in the orbit surrounding the ocular globe. clinician to the possibility of pneumothorax, but therapy for the subcutaneous air itself is seldom indicated. Airway compromise[102] hemodynamic collapse,[103] and manifestations of abdominal compartment syndrome,[17] have been reported in the context of large-airway disruptions and the use of high inflation pressures, although these instances are rare.

Pneumoperitoneum

Figure 44-3 shows how air from the lung that reaches the mediastinum can spread to the retroperitoneal space and thence into the peritoneum itself. The appearance of free air in the peritoneal cavity in a patient receiving mechanical ventilation[74] poses a diagnostic dilemma, even when subcutaneous emphysema and other signs of the wide spread of extraalveolar air are present. Avoidance of an exploratory laparotomy or other invasive procedure may be exceedingly difficult in such circumstances. Determining the partial pressure of oxygen (P_{O_2}) of aspirated peritoneal gas has been reported as a means of differentiating pneumoperitoneum from a ruptured abdominal viscus from air dissecting into the peritoneum under positive-pressure ventilation after alveolar rupture,[104] although the accuracy of this procedure has not been validated by others.

Although rare, accumulation of air in the peritoneum as a result of barotrauma during positive-pressure ventilation can cause or contribute to increased intraabdominal pressure[72] and, conceivably, abdominal compartment syndrome. Generally, however, air in the retroperitoneal and peritoneal spaces poses no intrinsic threat to health, and produces no physical signs other than subcutaneous emphysema and abdominal distension. In exceptional instances, air from ventilator-associated barotrauma can even dissect into the scrotum (see Fig. 44-8B) presumably via the peritoneum.

Systemic Air Embolism

Systemic air embolism may occur more commonly as a manifestation of barotrauma during mechanical ventilation than has previously been believed. Marini and Culver[105] describe the cases of two young adult patients with ARDS, necrotizing pneumonia, and prior pneumothoraces, in whom enlarging intraparenchymal air cysts and pulmonary interstitial emphysema were noted. While in a semi-upright position, each of these patients developed sudden neurologic events (facial twitching, hemiparesis, and seizures), evidence of acute myocardial injury, and focal livedo reticularis over the shoulder and anterior chest. Focal angioedema of the face subsequently developed. No other explanation for these events could be found, and in each patient there was evidence for recurrent episodes of air embolism. One patient survived without long-term sequelae; the other died of refractory hypoxemia and hypotension. Other cases of fatal air embolism as a manifestation of barotrauma have been reported.[106,107] In one instance, a patient being ventilated with PEEP for ARDS was found at postmortem examination to have air in the coronary and cerebral circulations, as well as in the pulmonary veins.[107]

Morris et al[108] reported the occurrence of venous air embolism via the inferior vena cava, as detected with transesophageal echocardiography, in three surgical patients, two with ARDS and one with multiple trauma. One 26-year-old patient developed an acute myocardial infarction on the thirteenth day of ARDS, while on 30 cm H_2O of PEEP, and transesophageal echocardiography revealed continuous bubbling of air in the inferior vena cava. In the other two patients transesophageal echocardiography revealed inferior vena cava bubbles without prior clinical signs of systemic air embolism. Each of these patients had had previous evidence for extraalveolar air, and the authors postulated that the

bubbling originated from subcutaneous or intraperitoneal air that gained entry into the splanchnic venous system.

Several cases of cerebral air embolism have been seen in association with mechanical ventilation in patients with traumatic lung contusion.[109,110] In several reports, gas bubbling has been observed in the left atrium and left ventricle (but not on the right side) during ventilation with large tidal volumes and PEEP, with cessation during apnea and disappearance or diminution when lower tidal volumes and PEEP were used.[110,111] Cerebral air embolism has also been reported as a feature of barotrauma in patients receiving noninvasive ventilation via face mask.[112,113]

In some patients, once alveolar rupture occurs during mechanical ventilation, decompression into the bronchovascular sheath by the mechanism described by Macklin[5,6] may fail to occur, allowing pulmonary interstitial air to accumulate under pressure as tension air cysts.[88] Development of such cysts has been observed to precede the appearance of tension pneumothorax in several instances.[88,114] In ARDS, Marini and Culver[105] postulate that, in the presence of such intraparenchymal air collections, the strong retractive tendency of the infiltrated parenchyma may tether open vascular channels that have been disrupted by inflammation or shear stress, allowing entry of air.

Systemic air embolism should be considered when patients receiving positive-pressure ventilation (especially for ARDS or with high levels of PEEP) develop unexplained agitation, changed mental status, focal neurologic findings, seizures, or disturbances in cardiac rhythm. The finding of focal livedo reticularis, particularly over the neck, shoulder, or anterior chest wall, should raise the strong suspicion of this complication, as should the occurrence of focal angioedema of the face or neck.

Pneumothorax

Pneumothorax in patients receiving positive-pressure ventilation manifests in three ways. Commonly it is first detected on a routine chest radiograph without clinical signs. The findings may be subtle. Typical radiographic signs of pneumothorax, such as a rim of lucency without lung markings completely surrounding the lung, demarcated by the visceral pleura and denser lung tissue, may be absent. Often the only indication of free pleural air is an increase in overall lucency in one hemithorax or one area of the lung, particularly the lower zone (Fig. 44-9). In some cases the deep sulcus sign, (Fig. 44-10) seen when radiographs are taken with the patient in the supine position, is the only clue to the presence of the pneumothorax. Physical signs of pneumothorax (diminished chest wall excursion, increased percussion resonance, and diminished breath sounds) can rarely, if ever, be detected in a patient who does not have a tension pneumothorax.

The second presentation for pneumothorax in the ventilated patient is with a change in laboratory or bedside monitoring findings, but without an obvious change in the patient's clinical state. Worsening oxygenation,[115] an increase in peak inspiratory airway pressure with accompanying rise in the plateau pressure, or a fall in lung–chest wall compliance may signal the development of a pneumothorax that has affected pulmonary function but has not yet become hemodynamically significant.

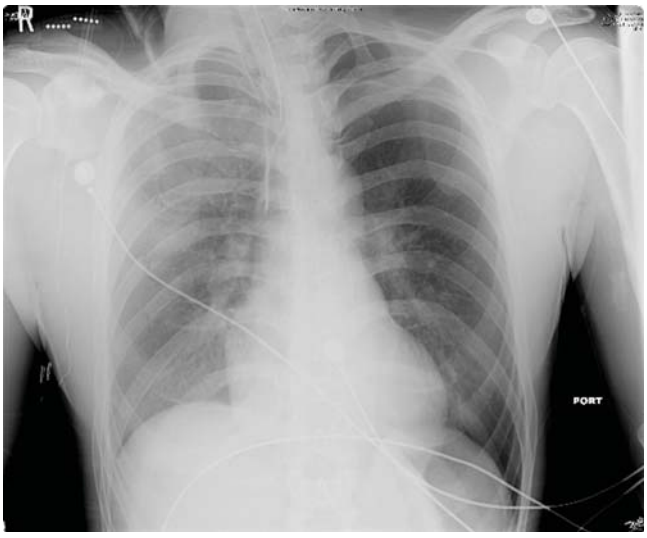

FIGURE 44-9 Loculated left-sided anterior pneumothorax in a patient receiving mechanical ventilation. Lung markings are present throughout the left hemithorax and there is no visible air laterally between the parietal and visceral pleurae. With anterior pneumothorax the only signs may be an increase in overall lucency in one hemithorax, typically confined to the lower lung field, and an increase in the clarity of the left-heart border.

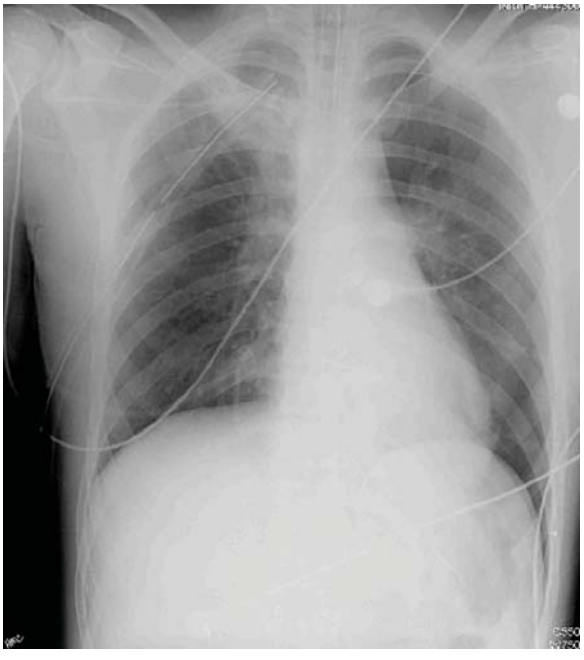

FIGURE 44-10 The deep-sulcus sign in a patient receiving mechanical ventilation in the supine position following trauma. The costophrenic sulcus on the left is substantially deeper than the sulcus on the right. There is no visible air laterally between the parietal and visceral pleurae on the left. The patient already has a chest tube on the right side from a pneumothorax detected on that side at the time of admission.

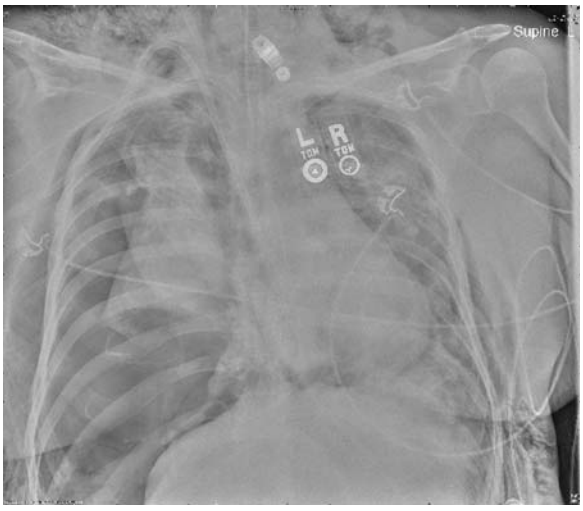

FIGURE 44-11 Tension pneumothorax in a patient receiving mechanical ventilation for ARDS. There is a large pneumothorax on the right with associated collapse of the right lung and shift of the heart and mediastinal structures toward the left side of the chest. A smaller left pneumothorax is also present. Although features of chest radiographs, including shift of the mediastinal structures, are strongly suggestive of the diagnosis of tension pneumothorax, the diagnosis is typically made clinically at the bedside before chest radiography is performed.

Tension pneumothorax is the third presentation (Fig. 44-11). This is primarily a bedside diagnosis, in that the complication is defined better by its adverse effects on cardiovascular function than by its radiographic characteristics. The latter include mediastinal displacement away from the pneumothorax, reversal of the diaphragmatic curve, and overall enlargement of the affected hemithorax, but these signs can occur in the absence of adverse physiologic effects, and the physiologic effects of pleural tension may be present without them. Most commonly the patient with tension pneumothorax presents with agitation and respiratory distress, hypotension, and other signs of cardiovascular collapse. Although tension pneumothorax is uncommon in spontaneously breathing patients, even in the presence of total lung collapse, the clinician should assume that every radiographically detected pneumothorax in a patient on mechanical ventilation can rapidly accumulate under tension.

Tables 44-7 and 44-8 list a number of clinical settings in which acute pneumothorax should be suspected or anticipated in the ventilated patient.

Bronchopleural Fistula

The presence of a bronchopleural air leak following insertion of a chest tube could potentially create several important clinical problems (Table 44-9). Unfortunately, relatively little is known about the natural history of this entity, and few data exist to substantiate the individual points in the table.

Bronchopleural fistula is a relatively uncommon complication, even in institutions managing large numbers of patients with ARDS and other forms of acute respiratory failure. Of 1700 patients ventilated during a 4-year period at a major trauma center in the early 1980s, thirty-nine (2%) developed a bronchopleural air leak that persisted at least 24 hours after chest tube insertion.[116] Postsurgical leaks, such as bronchial stump breakdown, were not included in this series. The leak varied in size in these patients from only intermittent bubbling into the chest drainage device to 900 mL/breath. Despite this, refractory hypercapnia causing arterial pH <7.30 occurred in only two patients, suggesting that inability to excrete CO_2 is very uncommon when bronchopleural fistula occurs as a complication during ventilator management.

Bronchopleural fistula occurred in two distinct settings in this study.[116] It was either the result of direct lung injury (e.g., blunt chest trauma or instrumentation) occurring

TABLE 44-7: WHEN TO SUSPECT A PNEUMOTHORAX IN THE VENTILATED PATIENT

Clinical change in patient's status
Sudden or progressive increase in inspiratory peak or plateau airway pressure
Hypotension or cardiovascular collapse
Sudden onset of agitation and respiratory distress ("fighting the ventilator")
Suggestive findings on chest radiograph
General increase in volume of one hemithorax
Deep sulcus sign: downward displacement of costophrenic angle and/or hemidiaphragm
Increase in relative radiolucency of one lung or part of one lung

TABLE 44-8: CLINICAL SITUATIONS SUGGESTIVE OF A HIGH RISK OF PNEUMOTHORAX

Use of large tidal volumes (e.g., >8 to 10 mL/kg) in patients with acute lung injury or underlying chronic pulmonary disease
Use of high levels of PEEP (e.g., >15 cm H_2O)
High peak airway pressure (e.g., >50 to 60 cm H_2O), especially if increasing on the same inspiratory flow settings
Acute respiratory distress syndrome (ARDS), especially late in its course (e.g., 2 to 3 weeks)
Severe underlying obstructive lung disease (COPD, asthma)
Severe bullous lung disease (e.g., idiopathic congenital giant bullous emphysema)
Pulmonary infection complicating ARDS
Pulmonary parenchymal disease accompanied by cystic changes (e.g., *Pneumocystis jiroveci* pneumonia, lymphangioleiomyomatosis, cystic fibrosis)
Presence of pulmonary interstitial emphysema or pneumomediastinum, and especially their new development on serial chest radiographs, suggesting alveolar rupture and increased likelihood of spread to pleural space

Abbreviations: ARDS, acute respiratory distress syndrome; *COPD*, chronic obstructive pulmonary disease; *PEEP*, positive end-expiratory pressure.

TABLE 44-9: POTENTIAL ADVERSE EFFECTS OF BRONCHOPLEURAL FISTULA IN THE VENTILATED PATIENT

Effect	Problems	Comment
Incomplete lung expansion	Atelectasis Worsened ventilation–perfusion mismatching ?Failure of leak to close	Occurs mainly with very large leaks (e.g., tracheobronchial injury) or with underlying restrictive lung disease
Loss of effective tidal volume	Incomplete expansion of other lung areas Worsened ventilation–perfusion mismatching	Attempts to compensate with increased delivered tidal volume may increase leak and exacerbate problem
Inability to remove CO_2	Acute respiratory acidosis	Unusual; life-threatening academia rare
Loss of positive end-expiratory pressure	Incomplete lung expansion Hypoxemia	May not be correctable in presence of large or multiple leaks
Pleural space infection	Infected secretions from airways pass through pleural space	Increases morbidity and ?mortality rates; ?additional source for sepsis
Factitious ventilator triggering	Ineffective ventilation	Caused by transmission of negative pressure from chest tube to central airways

within 24 hours of the onset of mechanical ventilation, or a manifestation of spontaneous alveolar rupture considerably later in the clinical course. In the latter circumstance, most often seen in patients with ARDS, bronchopleural fistula first developed a mean of 13 days after the onset of positive-pressure ventilation. This case series, reported in the context of ventilator management three decades ago, remains the only published study of the incidence of persistent bronchopleural air leak as a feature of barotrauma.

As discussed earlier for barotrauma in general, it is not known whether bronchopleural fistula as a complication of ventilator support has become less common with the use of lung-protective ventilation. Likewise, the effect of this complication on patient outcomes remains unknown. Development of a bronchopleural fistula appears to identify patients as having a poor prognosis, but whether the fistula plays an independent role remains to be established.[116,117]

MANAGEMENT

General Principles

Of the clinical forms of barotrauma (see Table 44-6), pneumothorax and systemic air embolism present a threat to the life of the patient and thus require immediate treatment. All of the others should be considered primarily as signs, either of the severity of the pulmonary disease or of the possibility of inappropriate ventilator management. Extraalveolar air is not easily recognized at the bedside except in the case of subcutaneous emphysema and tension pneumothorax. Nevertheless, there is often a temptation to initiate therapy directed at the barotrauma itself. More important, however, is therapy of the underlying primary disease. Certain ventilator adjustments, though, are appropriate in order to reduce the likelihood of further damage. These should include reducing PEEP, tidal volume, and minute ventilation to the lowest values compatible with acceptable patient support, and consideration of lung-protective ventilation and permissive hypercapnia as discussed elsewhere in this volume for reducing the likelihood of lung damage.

Pulmonary Interstitial Emphysema and Cystic Dilation

As mentioned earlier (see the section Clinical Manifestations), although pulmonary interstitial emphysema is an important intermediate step between alveolar disruption and clinical barotrauma, it is difficult to detect reliably on either physical exam or portable radiography obtained in the ICU. With the increasing use of CT in patients with ARDS and other settings of acute respiratory failure, however, these forms of barotrauma are increasingly recognized. Along with intraparenchymal air cyst formation, pulmonary interstitial emphysema is an important sign that alveolar overdistension is occurring, and that tension pneumothorax and other forms of barotrauma are more likely to occur. Their recognition is an indication to monitor the patient closely, and to modify the ventilator settings to reduce alveolar overdistension if this is clinically feasible. Aside from these measures, however, there is no specific treatment for these phenomena. Although CT-guided percutaneous catheter drainage of intraparenchymal air cysts has been reported,[118] documentation of the clinical necessity of this is scant.

Subcutaneous Emphysema

In the great majority of cases, subcutaneous emphysema requires no treatment other than to treat the underlying lung pathology so that the leak will cease. Rarely, accumulation of massive amounts of air in the chest and abdominal walls can be physiologically important and require surgical decompression.[119,120] Most accounts of such intervention provide

little to convince the reader that the air was compromising vital organ function. If the air leak is massive and continuous, however, as can be seen in tracheal perforation as a complication of attempted intubation, urgent intervention may be warranted. In such instances, circulatory compromise, oliguria, and other manifestations of the abdominal compartment syndrome (such as increased bladder pressure) should be evident, and should improve dramatically upon release of the subcutaneous air.[17]

Pneumoperitoneum

Continued air leak resulting in massive spread of extraalveolar air during positive-pressure ventilation can lead to accumulation of air in many soft-tissue spaces. This air poses no threat to the tissues themselves, although in the case of pneumoperitoneum it can cause diagnostic confusion. Critically ill patients with barotrauma are also susceptible to perforating stress ulcers, mesenteric ischemia, and other potential causes of free air in the peritoneal cavity, particularly if they have experienced a period of hypotension. Even in the presence of widespread subcutaneous emphysema and other forms of extraalveolar air, it may not be possible to exclude a surgical abdomen without laparotomy. One report documented the use of measured oxygen tension in the gas aspirated from the peritoneal cavity,[104] but this has yet to be confirmed by other investigators. Aside from the need to exclude an abdominal emergency unrelated to barotrauma, the presence of free air in the retroperitoneal tissue planes or peritoneal cavity generally poses no danger to the patient, and will be resorbed once the need for positive-pressure ventilation diminishes.

Systemic Air Embolism

The diagnosis of systemic air embolism is based on the clinical setting rather than on any specific test. Demonstration of air bubbles in the left atrium or left ventricle by echocardiography is highly suggestive of ongoing extraalveolar air entry, but CT and magnetic resonance imaging have not proven to be helpful in this condition.

No therapy is convincingly effective. Although hyperbaric oxygen therapy is often recommended, its efficacy has not been shown in controlled trials. Traditionally, it has been recommended that patients with air embolism be placed in the left lateral decubitus position to move the air collection out of the right ventricular outflow tract; evidence supporting this recommendation, however, is lacking and data from several animal studies suggest it may not be effective at improving patient hemodynamics.[121–123] Administration of high concentrations of oxygen in order to raise partial pressure of arterial oxygen (Pa_{O2}) and hasten bubble absorption has also been recommended,[122,124] while reductions in PEEP, tidal volume, and minute ventilation should be carried out, if feasible, so as to reduce the likelihood of further air entry into the vasculature.

Pneumothorax

Because of the threat of tension pneumothorax, chest tube drainage is advisable anytime free pleural air is detected during positive-pressure ventilation. There is little reported experience in this setting with the small catheter drainage sets often used for treating uncomplicated primary spontaneous pneumothorax, and the use of a larger, standard chest tube and drainage system is advisable. The routine application of suction (e.g., 20 cm H_2O) is customary in the United States, although this is not the case in all areas of the world; chest tube suction should be applied or increased if the lung does not fully reinflate, although, as noted earlier, application of suction may perpetuate a bronchopleural fistula by maintaining a large gradient between the airways and pleural space. Once the lung is fully inflated and there is no residual air leak, the tube is placed to water seal and removed, usually after an additional day. No evidence supports the use of "prophylactic" thoracostomy tubes in patients at high risk for pneumothorax.

Bronchopleural Fistula

DIAGNOSIS AND QUANTITATION OF AIR LEAK

In pneumothorax, once a chest tube is inserted and external suction applied, air is evacuated from the pleural space, as shown by bubbling through the water seal of the chest drainage device. If there is no persistent communication between the airways and the pleural space, this bubbling will cease once the lung is fully reinflated. Air may continue to leak into the pleural space for minutes to a few hours, but in most instances this soon stops. When it does not, and the bubbling continues for 24 hours or more, a bronchopleural air leak (bronchopleural fistula) is present. Most such leaks are small—a few bubbles through the water seal in synchrony with the inspiratory phase of the ventilator—although they may reach several hundred milliliters per breath.

Although precise quantitation of the air leak is rarely needed for clinical management, several methods for doing this have been described. The leaked volume can be estimated by subtracting the expired from the inspired tidal volume as long as the leak exceeds 100 to 200 mL/breath and the measurements are made at the same point in the ventilator circuit to avoid error secondary to compression in the inspiratory limb. Other techniques have been described in the literature but they are more difficult to set up, have lower overall clinical utility, and are, as a result, better suited for research purposes.[125,126]

Although it is seldom necessary to quantitate the leak precisely for patient management, it is sometimes useful to determine whether the gas leaking into the pleural drainage unit originates in the patient's airways or from the room, as may occur around the chest tube insertion site or with breaks in the circuit between the patient and the drainage unit. Removal of the chest tube is unwise in the presence of a bronchopleural air leak, but may be indicated if there is an external leak, because the same circuit break that introduces

air may also permit ingress of contaminating organisms. Most leaks from the patient's airways vary with the respiratory cycle, and stop or diminish during exhalation when intrathoracic pressure is lower. A more definitive test is to withdraw a sample of leaked gas from the connecting tubing under sterile conditions and to pass it through a capnometer; except in cases of proximal bronchial disruption, gas from the patient's airways will contain CO_2, whereas air from the room will not.

Bishop et al[127] collected leaked gas in nine patients with bronchopleural fistulas complicating ARDS. Total delivered minute ventilation in these patients ranged from 16.6 to 42.6 L/min (mean: 23.9 L/min), with 4% to 53% of each tidal volume lost through the fistula (mean: 25%). As the proportion of total minute ventilation lost through the leak increased, so did the fraction of the patients' total CO_2 production that exited through the chest tube.[127] In several patients, more CO_2 was excreted through the chest tube than through the endotracheal tube. Thus, at least in ARDS, gas leaked through a bronchopleural fistula has participated in gas exchange and is similar to gas exiting via the trachea.[127] This observation is consistent with the finding that unmanageable CO_2 retention is unusual in bronchopleural fistula,[116] and suggests that respiratory acidosis in most patients with such a fistula is a manifestation of the severity of their underlying lung disease rather than of the air leak per se.

Measurements of oxygen consumption, CO_2 production, respiratory quotient, and resting energy expenditure can be erroneous in patients with significant bronchopleural air leaks because of the CO_2 lost through the chest tube.[128] Accurate measurement of CO_2 production in patients with ARDS requires collection of the leaked gas, although dead-space-to-tidal-volume ratio can be determined using the usual technique of endotracheally expired gas collection, because the proportion of CO_2 excreted via trachea and fistula are approximately equal.[128]

GENERAL MEASURES

In general, management of the patient with a bronchopleural fistula is the same as if the fistula were not there, provided that a functioning chest tube and a pleural drainage system are in place. Table 44-10 lists a number of commonsense measures that should be taken to diminish the magnitude of the leak and the probability of further pulmonary parenchymal damage.

Weaning the patient from positive-pressure ventilation altogether would be optimal from the standpoint of decreasing the leak. When this is not feasible, a ventilator strategy should be selected that minimizes both minute ventilation and mean intrathoracic pressure. Respiratory alkalosis should be avoided, and consideration should be given to permissive hypercapnia in patients with very low lung–chest wall compliance and high minute ventilation requirements. Because the "lost" volume participates in gas exchange, delivered tidal volume should not be increased beyond a certain point to "chase" the air leak.

TABLE 44-10: PRINCIPLES OF VENTILATOR MANAGEMENT IN THE PATIENT WITH A BRONCHOPLEURAL FISTULA

- Use the lowest number of mechanical breaths that permits acceptable alveolar ventilation (reduce both mean airway pressure and number of high-pressure breaths)
  - Wean the patient completely if possible
  - Partial ventilatory support may be preferable to total ventilatory support (e.g., pressure-support ventilation)
  - Avoid or correct respiratory alkalosis (to minimize minute ventilation)
- Limit effective (returned) tidal volume to 6 to 8 mL/kg or less
- Minimize inspiratory time
  - Keep inspiration-to-expiration ratio low (e.g., 1:2)
  - Use high inspiratory flow (e.g., 70 to 100 L/min)
  - Avoid end-inspiratory pause and inverse-ratio ventilation
  - Use low-compressible-volume ventilator circuit to minimize delivered tidal volume
- Minimize both dialed-in and endogenous positive end-expiratory pressure
- Use the least amount of chest tube suction that maintains lung inflation
- Explore positional differences; avoid placing the patient in positions that exacerbate leak
- Treat bronchospasm and other causes of expiratory airflow obstruction
- Consider specific or unconventional measures (e.g., independent lung ventilation, endobronchial measures) if the patient remains unstable or develops clinically harmful, uncorrectable respiratory acidosis despite the above measures
- Treat the underlying cause of respiratory failure, maintaining nutritional and other support, with the goal of discontinuing mechanical ventilation as soon as possible

Positive end-expiratory pressure (both dialed-in and endogenous) and pulmonary hyperinflation should be minimized. In a study using older-generation ICU ventilators and circuits, the use of high inspiratory flows and low-compressible-volume, low-compliance ventilator tubing independently and additively decreased auto-PEEP,[129] although whether these measures are necessary with current-generation ventilators and circuits is uncertain. High inspiration-to-expiration ratios and end-inspiratory hold should be avoided. Vigorous therapy for bronchospasm and obstructing airway secretions should be pursued.

SPECIFIC MEASURES

As stated previously, the role of a bronchopleural fistula in the overall prognosis of acute respiratory failure has not been established, and available data suggest that the great majority of such fistulae have little impact on gas exchange. Of all the clinical forms of barotrauma, however, this is the one that has been the subject of the most published reports of novel approaches to therapy. Most of the literature consists of descriptions of techniques for decreasing the size of the leak, and available clinical reports consist almost exclusively of anecdotal descriptions of immediate and short-term

physiologic changes that lack both longer-term outcome data and convincing evidence that "conventional" ventilator management had been inadequate. The subjects of most of these reports have been critically ill patients, many of whom have died in spite of the short-term physiologic improvements documented under the reported intervention.

Several reports have described the use of independent lung ventilation via double-lumen endotracheal tube and two ventilators in patients with bronchopleural fistula.[130–136] The reported experience with this strategy is limited to about ten patients, although the technique has no doubt been used in other unpublished cases. As with the use of this ventilator technique in other settings, improved gas exchange has generally been achieved, but in nearly all the reported cases, the necessity of switching to this complicated and expensive technique is unconvincingly described, a problem shared with many of the other strategies described further below. Placement and maintenance of a double-lumen endotracheal tube in a critically ill patient require considerable expertise, and the small lumens of these tubes make bronchial hygiene difficult in patients with significant secretions.

Many older reports documented the use of high-frequency jet ventilation (HFJV) in bronchopleural fistula,[137–143] but enthusiasm has waned and there are few new reports of the use of this technique in the last two decades or more.[144,145] Clinical experience with HFJV in patients without underlying lung disease, as in traumatic bronchial disruption or during tracheobronchial surgery, has generally been positive.[143,146] When bronchopleural fistula, however, occurs as a manifestation of barotrauma complicating severe diffuse pulmonary disease, both short-term and outcome results have been discouraging. In one study of seven patients with severe ARDS and large air leaks, when HFJV was adjusted to provide the same mean airway pressures as resulted from conventional ventilation, oxygenation and/or effective alveolar ventilation deteriorated in every patient, and the size of the leak increased in five of seven patients.[147] Because of this experience, the use of HFJV as treatment for bronchopleural fistula complicating severe acute respiratory failure has been abandoned in the authors' institution. High-frequency oscillatory ventilation has been reported in two cases of bronchopleural fistula,[148] but whether this technique offers any advantage over adjustments in conventional ventilation remains to be seen.

Several approaches have been reported for decreasing the size of the air leak through manipulation of the pleural drainage system.[149–152] The total patient population in which these approaches have been reported is very small, and no new reports of their successful use have appeared in more than 20 years. Their application becomes progressively more difficult as the number of chest tubes increases in a given patient, and incomplete lung expansion on the side of the leak is a common problem.

Commercial chest drainage units vary considerably in their ability to handle air leaks. In one bench study, the maximum leak flow that four widely used commercial chest drainage units could accommodate varied from 5.8 to 35.5 L/min.[153] In a subsequent study using an animal model of bronchopleural fistula, two older but commonly used devices became ineffective at leak flows as low as 4 to 5 L/min because of increased resistance.[154] A freestanding suction pump independent of wall suction (Emerson suction pump) consistently demonstrated the highest capacity to evacuate leaked air in these studies, and when flow through a bronchopleural fistula exceeds 4 to 5 L/min the use of such a device is recommended. We are unaware of studies evaluating the performance of the current generation of pleural drainage systems with respect to evacuating large air leaks.

Several approaches have been reported for plugging or otherwise sealing bronchopleural air leaks using the flexible or rigid bronchoscope,[144,155–165] including the use of endobronchial one-way valves[166,167] and expandable stents.[168] Very few of the patients comprising these case reports and small series, however, have had bronchopleural fistulas in the setting of ventilator-associated barotrauma.[156,162,163] Most of the reported experience is with bronchopleural fistulas following lung resection.[169]

Although it is tempting to think that the ultimate therapy for bronchopleural fistula would be direct surgical closure, this is seldom possible for technical reasons in settings other than acute traumatic tracheobronchial disruption. If the fistula is localized and associated with a necrotizing pneumonia, resection of the affected lobe may be feasible. A bronchopleural air leak following lung biopsy or other procedure, in a patient without pneumonia or acute respiratory failure, may be amenable to surgical repair by thoracoscopy or thoracotomy. In most instances of barotrauma, however, the air leak is a manifestation of the severity of the underlying pulmonary disease, and direct suture or cautery of the leak or leaks is simply not technically possible.

The clinician seeking the best way to manage a patient with bronchopleural fistula complicating positive-pressure ventilation is poorly served by the existing experimental literature, which consists largely of technical descriptions and anecdotal reports of immediate changes in leak size and arterial blood-gas values, and is virtually devoid of evidence that the therapies described affect patient outcome. There is an understandable desire to intervene when something so obvious as a bronchopleural fistula develops during the course of ARDS or other form of severe acute respiratory failure. Yet, except for the unusual circumstance of inability to reinflate the affected lung, evidence for harm by the air leak per se is strikingly lacking, and all the reported techniques for diminishing it have the potential for serious harm to the patient.

The clinician should approach any unconventional therapeutic measure with caution, realizing that it constitutes experimental, unproven, and potentially harmful therapy for a condition that may be more a sign of an adverse prognosis than its mechanism. Table 44-11 summarizes a number of principles for the approach to managing patients with bronchopleural fistula complicating severe acute respiratory failure, taken mainly from clinical experience in an area whose scientific basis remains woefully inadequate.

TABLE 44-11: EIGHT GENERAL OBSERVATIONS ABOUT MANAGING BRONCHOPLEURAL FISTULA IN THE PATIENTS WITH ACUTE RESPIRATORY DISTRESS SYNDROME

1. Bronchopleural fistula in the patient with ARDS is a manifestation of the severity of the underlying disease, perhaps initiated or exacerbated by its management, that will not resolve until the ARDS resolves or improves.
2. Bronchopleural fistula in ARDS is physiologically significant in only a minority of cases (perhaps 10%), even in the presence of hypercapnia.
3. Reducing the leak size per se typically has little effect on gas exchange as measured by arterial blood gases.
4. Measures directed at decreasing the size of the leak will generally prove unsuccessful until the underlying lung injury improves.
5. When the ARDS improves, the bronchopleural fistula will nearly always improve without specific therapy.
6. None of the specific measures (e.g., high-frequency ventilation, bronchoscopic interventions, etc.) discussed in the text has been shown to affect patient outcome.
7. Patients almost never die *of* bronchopleural fistula. They die *with* bronchopleural fistula, usually *of* multiple organ failure and occasionally of gas exchange failure because of ARDS.
8. Careful attention to general management principles (Table 44-10) is more important than any specific measure to decrease the leak.

Abbreviation: ARDS, acute respiratory distress syndrome.

PREVENTION

The degree to which all forms of clinical barotrauma are iatrogenic, as a result of how ventilator support is used in severe respiratory failure rather than primarily of the underlying pathology, remains unclear. Nonetheless, from the material discussed in this chapter several general principles emerge that are reasonable if not scientifically proven to reduce the likelihood of barotrauma during mechanical ventilation. Table 44-12 summarizes these principles.

The large (e.g., 12 mL/kg) tidal volumes traditionally used in ventilating adult patients originated many years ago in studies of individuals with normal lungs who were undergoing anesthesia. These tidal volumes are inappropriate for patients with diffuse lung disease, either restrictive (e.g., ARDS) or obstructive (e.g., chronic obstructive pulmonary disease or severe asthma). For such patients considerably smaller tidal volumes (e.g., 6 mL/kg, proportioned to predicted body weight) should be used, especially when PEEP is present with its attendant risk for local or overall pulmonary hyperinflation. Other patients should be ventilated with tidal volumes not exceeding 8 to 10 mL/kg predicted body weight.

PEEP, whether externally applied or endogenous, increases the likelihood of pulmonary hyperinflation, particularly when the lungs are heterogeneously involved, as is now recognized to be the case in ARDS. Insofar as hyperinflation predisposes to alveolar disruption, PEEP should be used cautiously in ARDS, and auto-PEEP should be sought in all ventilated patients and minimized when present. Because of the increased propensity of patients with ARDS to develop barotrauma late in the course of this disorder, and the apparent association of alveolar rupture with ongoing pulmonary infection and inflammation, scrupulous attention to infection control measures in all aspects of the care of such patients seems especially important.

TABLE 44-12: PRACTICAL MEASURES TO REDUCE THE LIKELIHOOD OF BAROTRAUMA DURING MECHANICAL VENTILATION

- Use small tidal volumes (6 mL or less per kilogram predicted body weight) and other aspects of lung-protective ventilation in patients with ARDS or obstructive lung disease, particularly in the presence of PEEP (dialed-in or endogenous)
- Avoid hyperventilation except where deliberately employed for specific indications
- Use PEEP cautiously in patients at increased risk for alveolar rupture, including those with:
  - ARDS
  - Any unilateral, patchy, or cavitary lung disease
  - Nosocomial pneumonia or sepsis
  - Obstructive lung disease (e.g., COPD or asthma)
  - Cystic lung disease (cystic fibrosis, *Pneumocystis jiroveci* pneumonia, lymphangioleiomyomatosis)
- Monitor respiratory system compliance as PEEP is applied or increased; decrease PEEP if compliance falls with increasing levels
- Monitor all ventilated patients for auto-PEEP; take specific measures to reduce auto-PEEP if its presence could be harmful to the patient:
  - Reduced minute ventilation, with normocapnia or hypercapnia
  - High inspiratory flow (e.g., 70 to 100 L/min)
  - Low-compressible-volume, low-compliance ventilator circuit
- Use extreme care in high-risk patients when placing subclavian or internal jugular lines or performing thoracentesis. Where available, use ultrasound guidance
- Take special care to avoid nosocomial pneumonia:
  - Practice good hand cleansing and other infection control techniques
  - Avoid circuit interruption

Abbreviations: ARDS, acute respiratory distress syndrome; *COPD*, chronic obstructive pulmonary disease; *PEEP*, positive end-expiratory pressure.

IMPORTANT UNKNOWNS

Surprisingly little is known about barotrauma complicating mechanical ventilation in terms of pathogenesis, clinical implications, optimum management, and prevention. The literature on this topic consists mainly of anecdotal observations and reports of interventions, the latter generally incompletely documented and at best with short-term physiologic endpoints. Although tension pneumothorax, air embolism, and, rarely, pneumomediastinum and subcutaneous emphysema, produce potential threats to life, whether the other forms of barotrauma discussed in this chapter

exert independent effects on morbidity, mortality, or the natural history of acute respiratory failure is not known. Even bronchopleural fistula, one of the more dramatic forms of clinical barotrauma, has not been shown to affect any patient-relevant outcome. The trend toward use of smaller tidal volumes, particularly in patients with acute lung injury or obstructive lung disease, would be expected to reduce the incidence of barotrauma, although to date the available data has not shown this to be the case.

THE FUTURE

If the use of lower inflating pressures and distending volumes during mechanical ventilation, which is becoming widespread largely as a result of the demonstration that such measures reduce mortality in patients with acute lung injury, also reduces the risk of alveolar disruption, then clinical barotrauma should become less frequent. The lack of evidence that special devices or unconventional approaches to ventilator support reduce the incidence of barotrauma or hasten its resolution once present may lead to their being used less often in patient management, which may lessen costs and the risk for attendant complications. In view of the lack of evidence that specific measures impact the severity or natural course of barotrauma, focusing on prevention through less injurious ventilatory support and better general care during critical illness is likely to be more beneficial than the continued search for specific interventions for its management.

SUMMARY AND CONCLUSION

Part of a spectrum of complications occurring during mechanical ventilation that includes ventilator-induced lung injury, extraalveolar air can be the result of alveolar disruption from overdistension or be caused by several other mechanisms. As a possible result of the ventilator settings used, barotrauma is always of clinical concern. Among its several clinical forms, however, those of greatest importance are systemic gas embolism and pneumothorax, as these can be fatal. Rarely, pneumopericardium and subcutaneous emphysema can also create a threat to life, and pneumoperitoneum poses a dilemma with respect to the possibility of a ruptured abdominal viscus. Bronchopleural fistula is an indicator of pathology that needs attention, but is usually not physiologically important and seldom requires specific measures targeted at the leak site. Barotrauma from alveolar rupture tends to occur in severely ill patients, and whether this complication independently contributes to mortality or morbidity remains unknown. Prevention of barotrauma, and management once it occurs, consist primarily of practicing sound general ventilator management, including limiting distending volumes and static airway pressures, to stop or reduce the passage of air into the bronchovascular sheaths and elsewhere.

OXYGEN TOXICITY

Robert F. Lodato

The importance of the physiology and toxicology of oxygen (O_2) breathing have increased in recent years. The past 25 years have witnessed a remarkable upsurge of knowledge and interest in "oxidative stress" throughout all of biology. The use of O_2 continues to grow, from critically ill to ambulatory patients and even to recreational use at "oxygen bars."[1] Recent advances in patient care have refocused attention on the optimum use of O_2. For example, currently, strategies to protect the lung from mechanical injury during mechanical ventilation emphasize the use of lower tidal volumes. But such strategies may impair gas exchange, resulting in higher requirements for inspired O_2 fraction (FI_{O_2}).[2]

Lavoisier initially characterized O_2 as "highly respirable air"[3] and "vital air" before eventually giving it the name "principle oxygine" (acidifying principle) in 1777. He took the name from the Greek roots "oxy" (acid) and "gen" (to form), because initially O_2 was incorrectly believed to be the essential principle in the formation of acids.[4] Normobaric hyperoxia may be defined as an inspired O_2 tension, PI_{O_2}, between 160 and 760 torr (i.e., between 0.21 and 1.0 atmosphere [atm] of pressure), whereas hyperbaric hyperoxia denotes that PI_{O_2} is greater than 760 torr.

J.B.S. Haldane[5] and others[6] speculated, and it is now generally accepted, that life on earth began anaerobically when the earth's atmosphere was virtually devoid of O_2. Gilbert[6] postulated that in this primordial reducing atmosphere, the first living cells used hydrogen, diffusing into the cell from the environment, as an energy source (e.g., metabolizing carbohydrates to methane and water). Gilbert[6] speculated further that because hydrogen would also reduce essential cellular constituents and thereby poison the cell, these early cells also had to develop antihydrogen defenses and actively transport hydrogen ions out of the cell. As the atmosphere was transformed from a reducing to an oxidizing one, O_2 replaced hydrogen as an energy source. Therefore, to avoid O_2 poisoning, cells then had to develop antioxygen and antioxidant defenses. These observations emphasize that as an energy source for cells, O_2 has a dual effect: It is both life promoting and life destroying. This dual nature of O_2 (Fig. 45-1) was noted by Priestley in 1775 shortly after his discovery of O_2: "though pure [oxygen] might be very useful as a medicine, … as a candle burns out much faster in [oxygen] … so we might … *live out too fast*."[7] Indeed, even at ambient concentrations, O_2 is now considered to play a role in the natural process of aging.[8–10] In 1777, Scheele, who independently

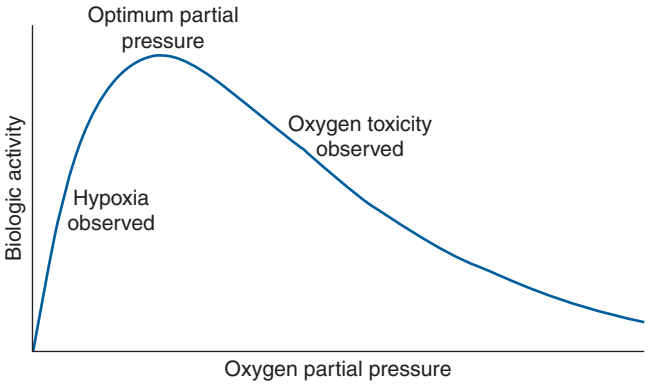

FIGURE 45-1 Dual effect of oxygen on biologic activity. (Used, with permission, from Gilbert.[8])

discovered O_2, noted along with Priestley that O_2 is toxic to plants. In 1785, Lavoisier, who first recognized the vital role of O_2 in the equivalent processes of respiration and combustion, commented explicitly on the dual nature of O_2: "when there is an excess of vital air [oxygen], the animal only undergoes a severe illness; when it is lacking, death is almost instantaneous."[6] In experiments carried out with Laplace, he described right-heart and pulmonary congestion in guinea pigs that died in O_2 under a bell jar before the O_2 was used up.[11,12]

In 1873, Paul Bert became the first to systematically study O_2 toxicity.[11] He documented the toxicity of O_2, particularly the lethality of hyperbaric hyperoxia, in all forms of life from mammals to viruses. He concluded that "no living thing is exempt from damage that can be produced by oxygen."[13] Grand mal seizures are the most notorious toxic effect of hyperbaric hyperoxia and have been referred to as the "Paul Bert effect."[11] J.B.S. Haldane experienced such seizures himself.[11] The pathophysiologic effects of hyperbaric hyperoxia have been reviewed elsewhere.[11,13–18] This chapter focuses on the effects of normobaric hyperoxia.

RESPIRATORY EFFECTS OF OXYGEN BREATHING

The best known and most studied effects of normobaric hyperoxia concern the respiratory system. Lavoisier was the first to note changes in the lungs of animals that died from hyperoxia, "…the lung was very flaccid, but bright red, even on the outside, and highly congested with blood…."[19] In 1899, J. Lorrain Smith became the first to systematically study the pulmonary pathology of normobaric hyperoxia, specifically, a 4-day exposure to a FI_{O_2} of 0.74 to 0.80 in mammals. The diffuse intense lung damage from O_2 toxicity described by Smith, and many others since, has been named the "Lorrain Smith effect."[11]

The symptoms and physiologic changes in healthy human volunteers associated with normobaric hyperoxia are the subject of several reviews.[11,13,16,17,20–30] Table 45-1 lists the respiratory effects of O_2 breathing.

TABLE 45-1: RESPIRATORY EFFECTS OF OXYGEN BREATHING (NORMOBARIC HYPEROXIA)

Depression of respiration
Stimulation of respiration
Pulmonary vasodilation; ventilation–perfusion mismatching
Hypercapnia
Absorption atelectasis
Acute tracheobronchitis; decreased mucociliary clearance
Diffuse alveolar damage; adult respiratory distress syndrome
Bronchopulmonary dysplasia

Respiratory Depression and Stimulation, Pulmonary Vasodilation, and Hypercapnia

The depression in respiratory drive is primarily related to decreased stimulation of the hypoxia-sensitive chemoreceptors in the carotid and aortic bodies. These chemoreceptors are the only known O_2 sensors that initiate chemoreflexes.[31,32] Dejours et al showed that the O_2 chemoreceptor drive of respiration, which may account for 10% to 15% of resting ventilation, disappears above an alveolar partial pressure of oxygen (P_{O_2}) of 170 torr, corresponding to a PI_{O_2} of 230 torr, or an FI_{O_2} of 0.30.[16] When O_2 breathing is suddenly initiated, the normal response is twofold.[21,33,34] First, there is a nearly immediate, precipitous decrease in ventilation, whose nadir occurs within 20 to 30 seconds (Fig. 45-2), followed by a gradual return to and slightly above baseline (Fig. 45-3). The acute transient depression is mediated by the arterial chemoreceptor reflexes and may be taken as an index of the level of chemoreceptor activity present during normoxia.[33,35] The subacute mild sustained ventilatory stimulation appears to be secondary to an indirect effect of hyperoxia on the respiratory centers in the brainstem. That is, hyperoxia causes an increase in tissue carbon dioxide tension (P_{CO_2}) secondary to the Haldane effect, or Christian-Douglas-Haldane effect[36] (the increase in blood P_{CO_2}, at a fixed CO_2 content, caused by the release of hemoglobin-bound hydrogen ions and CO_2, bound as carbamino compounds, that occurs on the oxygenation of hemoglobin). Ironically, in one of the earliest reports (1921) of this hyperoxia-induced mild hyperventilation, Dautrebande and Haldane[37] proposed that hyperoxic vasoconstriction of the central nervous system vasculature produces tissue hypercapnia, which, in turn, directly stimulates the respiratory center.

In normal subjects the mild respiratory stimulation induced in the steady state by hyperoxia results in a mild hyperventilation and a mild decrease in partial pressure of arterial carbon dioxide (Pa_{CO_2}) by a few millimeters of mercury, which, in turn, limits the degree of hyperventilation. But in the presence of inspired CO_2, the paradoxical respiratory stimulant effect of O_2 is much more obvious, as noted as early as 1918 by Yamada.[38] When the normally modest fall in Pa_{CO_2} is prevented, (isocapnic) hyperoxia produces a dramatic increase in ventilation (see Fig. 45-3),[39–41] by 21%

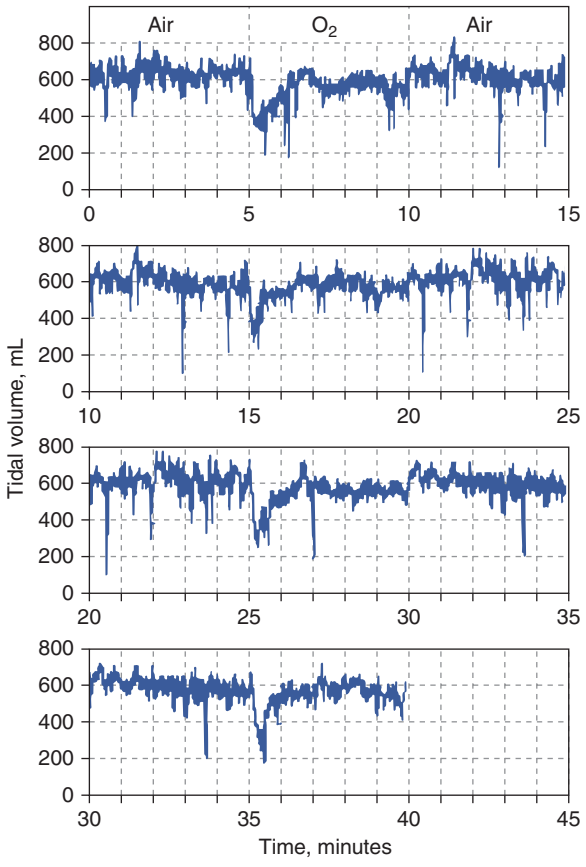

FIGURE 45-2 Acute depression of respiration by normobaric hyperoxia illustrated in a healthy conscious dog breathing from a mask as the inspired gas was alternated between air and O_2 every 5 minutes for 40 minutes. At the onset of each period of O_2 breathing, the continuous record of tidal volume shows a precipitous fall to a mean value of 54% of the normoxia baseline. This decrease in tidal volume is evident by 10 seconds and reaches a nadir at approximately 18 seconds. It is transient, and despite continued hyperoxia, it has returned nearly to baseline by 1.5 minutes. The record is plotted such that the normoxia data at the end of each 15-minute period are repeated on the next line as the beginning of the next 15-minute period to emphasize the repeating, cyclic nature of the alterations in inspired gas and to demonstrate more clearly the response pattern of tidal volume to hyperoxia. (Used, with permission, from Lodato and Jubran.[33])

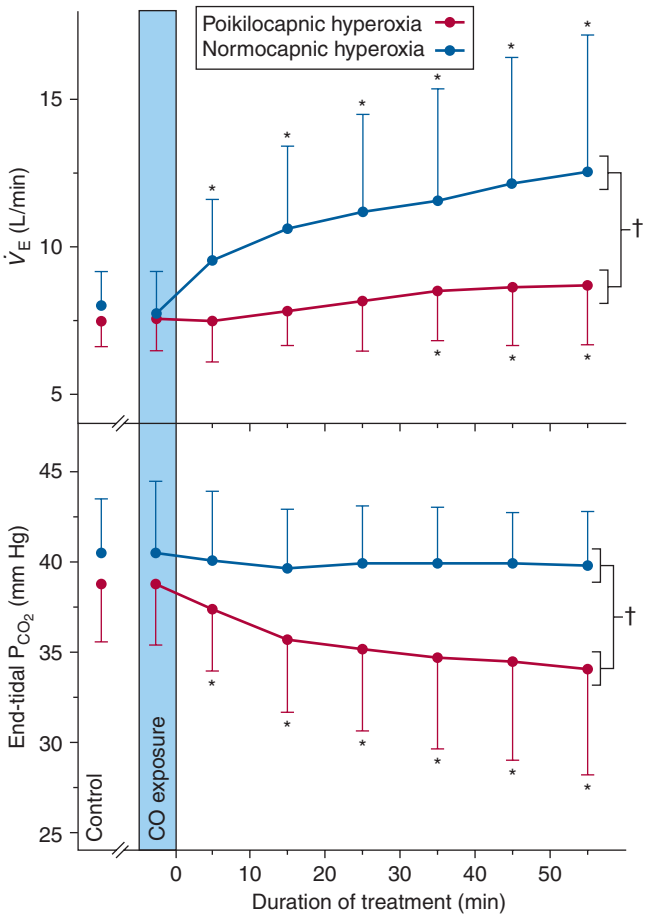

FIGURE 45-3 Steady-state responses of minute ventilation ($\dot{V}_E$) and end-tidal partial pressure of carbon dioxide (P_{CO_2}) to breathing 100% O_2 (hyperoxia) in healthy human subjects (mean ± standard deviation [SD]; n = 14). Poikilocapnic hyperoxia (end-tidal P_{CO_2} was not controlled) produced a mild increase in minute ventilation and a small (4 mm Hg) decrease in end-tidal P_{CO_2}. Normocapnic hyperoxia (CO_2 was added to the inspirate to maintain constant end-tidal P_{CO_2}) produced a marked and progressive increase in minute ventilation. These respiratory stimulant effects of hyperoxia are due largely to the Haldane effect, which results in increased P_{CO_2} in the brain. *Note:* Before time = 0, subjects were exposed to carbon monoxide in this study of CO elimination. (Used, with permission, from Rucker et al.[41])

at FI_{O_2} = 0.30 and by a remarkable 115% at FI_{O_2} = 0.75.[39,40] Becker et al[40] showed that in both poikilocapnic (nonisocapnic) and isocapnic hyperoxia, the Haldane effect is the most important mechanism of the respiratory stimulant effect of hyperoxia in normals. Rucker et al[41] used these observations and showed in normal subjects that, compared with poikilocapnic hyperoxia, isocapnic hyperoxia more rapidly eliminates carbon monoxide and improves cerebral blood flow and O_2 delivery (secondary to the vasodilator effect of the higher level of Pa_{CO_2}) (see Fig. 45-3).

In contrast to the steady-state respiratory stimulant effect of hyperoxia in normals, hyperoxia may instead cause severe respiratory depression in patients with severe chronic obstructive pulmonary disease (COPD). The relative importance of the various mechanisms remains controversial. The conventional view is that hyperoxic hypercapnia is caused by alveolar hypoventilation resulting from reduced hypoxic ventilatory drive secondary to the rise in arterial P_{O_2} (Pa_{O_2}),[42] analogous to "O_2 apnea" in patients recovering from general anesthesia.[17] Other mechanisms include the Haldane effect, deterioration of ventilation–perfusion ($\dot{V}/\dot{Q}$) matching in the lung secondary to hyperoxic release of hypoxic pulmonary vasoconstriction, and development of atelectasis (true shunt). O_2 may also impair $\dot{V}/\dot{Q}$ matching by release of hypoxia-induced bronchoconstriction.[43,44]

The data in both acutely decompensated[45] and stable[46–48] patients with COPD, however, indicate that deterioration of $\dot{V}/\dot{Q}$ matching is the predominant mechanism. Using the multiple inert gas elimination technique in COPD patients, Wagner et al[49] found no systematic changes in the

distribution of $\dot{V}/\dot{Q}$ ratios with 100% O_2. But they did not report attempts to correlate individual changes in Pa_{CO_2} and changes in $\dot{V}/\dot{Q}$ distribution. In mechanically ventilated patients, Dunn et al[50] reported that hyperoxia both worsened $\dot{V}/\dot{Q}$ matching and depressed respiratory drive. For an informative interchange, see Stradling[51] and Aubier et al.[52]

In a more recent study of patients with exacerbations of COPD, Robinson et al[44] used the multiple inert gas elimination technique to compare those patients who retained CO_2 with O_2 with those who did not. In both groups, hyperoxia worsened $\dot{V}/\dot{Q}$ matching by increasing perfusion to relatively poorly ventilated lung units (release of hypoxic vasoconstriction). In only the group who retained CO_2, however, hyperoxia decreased minute ventilation (by 20%) and increased ventilation to overventilated units (increased alveolar dead space). Later, they[53] concluded that in the group that retained CO_2, the largest contribution (46%) was from a decrease in minute ventilation, followed closely (43%) by an increase in alveolar dead space, with a much smaller contribution (11%) from the Haldane effect. The modest Haldane effect was likely secondary to only the modest degree of baseline hypoxemia (mean Pa_{O_2} = 55 mm Hg). They also showed that the risk of hyperoxic hypercapnia is better predicted by a low baseline Pa_{O_2} than by the baseline Pa_{CO_2}.[44]

Neff and Petty[54] showed that severe *chronic* respiratory acidosis (mean P_{CO_2} of 90 torr, mean pH of 7.32) in patients with COPD is well tolerated. Acute hyperoxic respiratory depression can be avoided by using controlled low-flow O_2 administration.[55,56] Hyperoxic hypercapnia may also occur in neuromuscular disease[57] and near-fatal asthma.[58,59]

In a prospective randomized controlled trial[60] of resuscitation of asphyxiated newborn human infants, those resuscitated with room air had better outcomes (Apgar scores, time to first breath, and first cry) than those resuscitated with 100% O_2. These results were attributed, in part, to the respiratory depressant effect of O_2.[60] The current recommendation is that room air is preferred over 100% O_2 for newborn resuscitation.[61]

Absorption Atelectasis

Absorption atelectasis during O_2 breathing occurs in lung units with sufficiently low $\dot{V}/\dot{Q}$ ratios.[62] In such units the rate of capillary absorption of O_2 exceeds the rate of replenishment of alveolar gas during inspiration. This effect depends on the $\dot{V}/\dot{Q}$ ratio, the pattern of ventilation (e.g., the presence of sighs), the FI_{O_2}, the duration of the O_2 exposure, the intrinsic stability of the lung units (e.g., tissue and surfactant factors), and the sensitivity of the local hypoxic pulmonary vasoconstriction to hyperoxic release (which acts synergistically by further lowering the $\dot{V}/\dot{Q}$ ratio). Using the inert-gas elimination technique in healthy nonsmoking subjects, Wagner et al[62] showed that within 30 minutes of breathing 100% O_2, eight of the nine subjects had developed small shunts, averaging 0.5% to 3.2%, with the largest at 10.7% (Fig. 45-4). Theoretically, only approximately 6 minutes is required for the development of such shunts.[63] Clearly, when 100% O_2 breathing is used to quantify a shunt, its magnitude might be overestimated compared to that present during air breathing.

Hyperoxia also enhances absorption from other gas spaces: middle ear and sinuses (causing headache), and

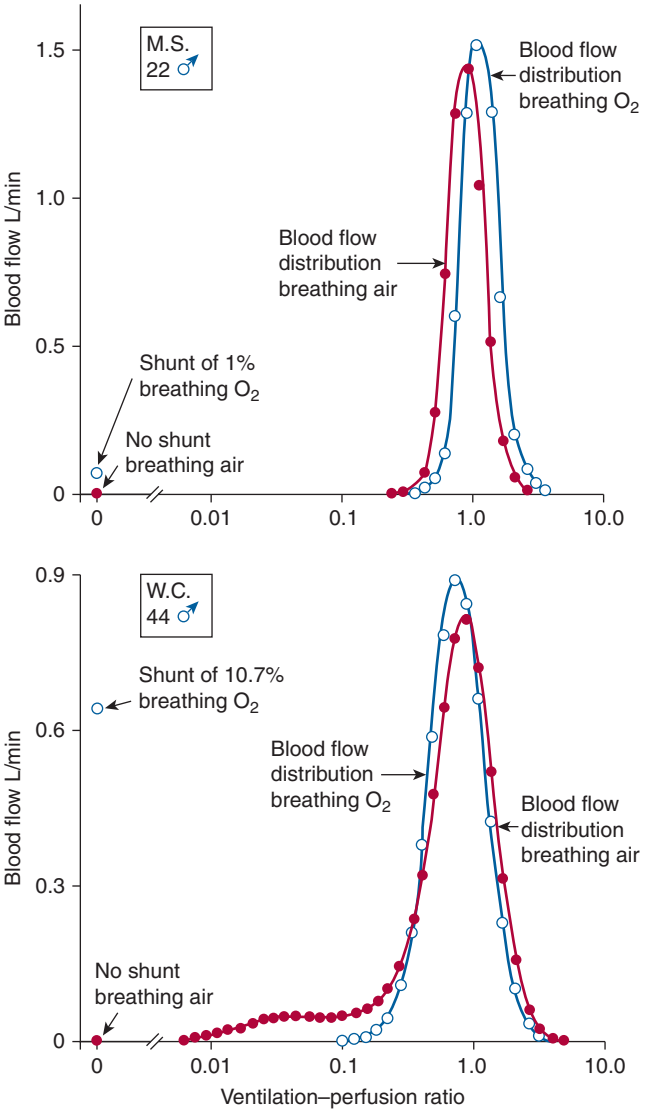

FIGURE 45-4 Distributions of blood flow with respect to ventilation–perfusion ($\dot{V}_A/\dot{Q}$) ratios in two normal subjects while breathing air (normoxia) and after 30 minutes of breathing 100% O_2 (normobaric hyperoxia). *Upper panel.* In the younger subject hyperoxia produced (a) a 1% shunt, indicating a minor degree of hyperoxia-induced atelectasis, and (b) an overall shift of the main body of the distribution to the right to higher $\dot{V}_A/\dot{Q}$ ratios, indicating mild hyperoxia-induced hyperventilation in the steady state. *Lower panel.* In the older subject hyperoxia produced more dramatic changes: The left "shoulder" of the normoxic blood flow distribution (i.e., the blood flow distributed to lung units with low $\dot{V}_A/\dot{Q}$ ratios) was converted by hyperoxia to a 10.7% shunt, indicating substantial amounts of hyperoxia-induced atelectasis, but the main body of the distribution was little altered. (Used, with permission, from Wagner et al.[62])

therapeutically in pneumothorax, bowel obstruction or ileus, and subcutaneous emphysema.[17]

Hyperoxia may also cause atelectasis by interfering with the pulmonary surfactant system,[64] both by injury to the alveolar type II pneumocyte, which synthesizes, secretes, and recycles surfactant, and by injury to the alveolar–capillary interface, resulting in the influx of plasma proteins, which inhibit surfactant function. Hyperoxia-induced atelectasis has also been demonstrated in patients with acute lung injury[65] using the multiple inert-gas elimination technique.

Acute Tracheobronchitis

Comroe et al[66] described acute tracheobronchitis in 1945. Normal subjects breathing 100% O_2 for 24 hours noted substernal distress, cough, sore throat, nasal congestion, eye irritation, ear discomfort, fatigue, and paresthesia, and had a reduction in vital capacity. Symptoms began within 4 and 22 hours after initiating oxygen breathing. Substernal distress was also noted while breathing 75% O_2, but not 50% O_2, for 24 hours. Substernal distress is generally the first symptom noted in normal subjects. It is thought to represent acute tracheobronchitis,[26] but it may also be the result of atelectasis alone.[67] Using fiber-optic bronchoscopy, Sackner et al[68] directly observed evidence of such tracheobronchial inflammation (focal areas of redness, edema, and injection of small vessels of the trachea, depression of mucus velocity) in healthy human subjects after 6 hours of breathing 90% to 95% O_2.

A decrease in vital capacity[66] is considered the best index of O_2 toxicity. In humans, this decrease in vital capacity probably results from the inspiratory pain of the acute tracheobronchitis and from absorption atelectasis. In animals, it is more clearly related to parenchymal lung injury. By impairing an important host defense mechanism, acute tracheobronchitis could predispose to nosocomial pneumonia,[68,69] but this has not been well studied. In rats, hyperoxia also impairs alveolar macrophage function,[70] perhaps adding to the risk of ventilator-associated pneumonia. In healthy subjects with moderate responsiveness to methacholine at baseline, breathing 95% O_2 for 12 hours produced no change in methacholine responsiveness, despite signs and symptoms of acute tracheobronchitis.[71]

Threshold Oxygen Tension for the Development of Oxygen Toxicity

Like other toxic drugs, the effects of O_2 can be viewed in terms of a classical pharmacologic dose–response curve.[13] The dose of O_2 can be expressed as the product of PI_{O_2} and the duration of the exposure (i.e., dose = $PI_{O_2} \times$ time). When plotted, this relationship is a rectangular hyperbola (Fig. 45-5), which expresses the dose–response in terms of vital capacity decrements. The horizontal asymptote of 50% O_2, or 0.5 atm, assumes that at that level of hyperoxia, individuals can be exposed safely for prolonged periods of time.

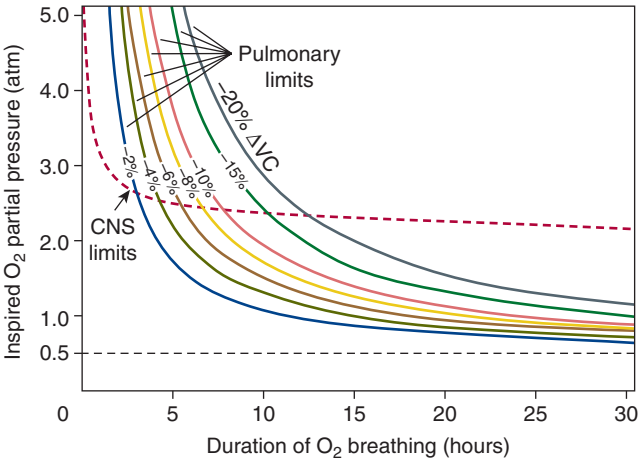

FIGURE 45-5 Oxygen tolerance or dose–response curves for pulmonary and central nervous system (CNS) toxicity in healthy human subjects. Each curve in the family of curves for pulmonary O_2 toxicity is a rectangular hyperbola and represents equivalent O_2 partial pressure-duration "doses" of O_2 exposures. These curves are based on the development of the indicated changes in vital capacity in 50% of the individuals subjected to the indicated O_2 partial pressure-duration exposures. The horizontal asymptote for the lowest pulmonary toxicity curve is at an O_2 partial pressure of about 0.6 atmospheres (atm), indicating that O_2 partial pressures below 0.6 atm appear to be "safe" for exposures of indefinite duration. (Used, with permission, from Lambertsen.[305])

Carpagnano et al[72] reported that breathing 28% O_2 for only 1 hour increased inflammatory markers (8-isoprostane and interleukin-6) in exhaled breath condensate in both healthy subjects and patients with COPD. Vital capacity, however, did not change in either group. These results were likely a manifestation of subclinical tracheobronchitis (see above).

The validity of setting at 0.5 atm the threshold PI_{O_2} for the development of O_2 toxicity, as reflected by a decrease in vital capacity, for exposures of indefinite duration was carefully discussed by Clark and Lambertsen[21] and Clark.[22] Earlier these authors had suggested a less-conservative threshold of 0.6 atm.[73] The rationale for the 0.5-atm PI_{O_2} threshold is based largely on the responses of vital capacity to prolonged hyperoxia in healthy men in the three studies of Comroe et al,[66] Helvey et al,[74] and Michel et al.[75] Figure 45-6 summarizes these exposures and those of two subsequent studies in healthy men.[76,77] Comroe et al[66] exposed nine normal men to a PI_{O_2} of 0.75 atm for 24 hours, with return to air breathing for 15 minutes every 3 hours. They found that five of the nine had chest symptoms and that the group had a modest decrease in vital capacity (mean decrease <300 mL). None of six subjects exposed to PI_{O_2} = 0.5 atm for 24 hours had chest symptoms, and the mean decrease in vital capacity was even less (only approximately 210 mL). They concluded that the safe limit of PI_{O_2} lies between 0.5 and 0.75 atm, probably close to 0.6 atm.[66]

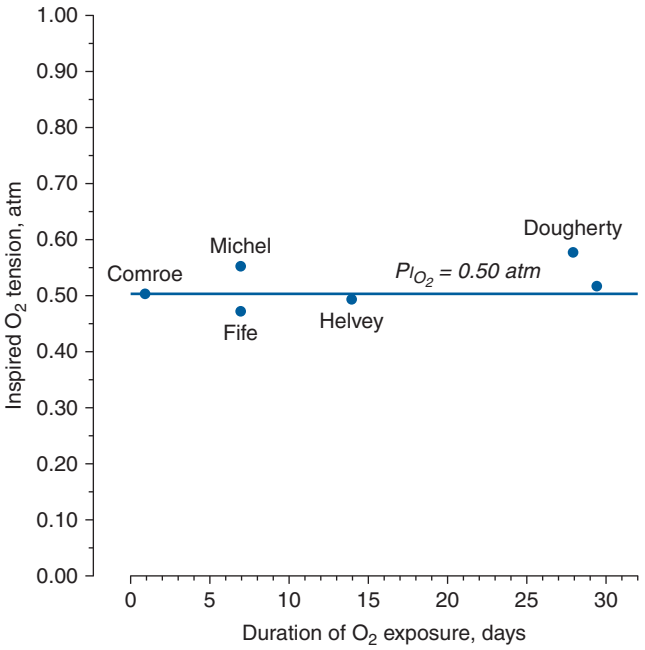

FIGURE 45-6 A summary of studies of prolonged exposure of normal human subjects to an inspired O_2 tension (PI_{O_2}) near 0.5 atm. The points indicate the PI_{O_2} and duration of exposure for the respective studies. The name associated with each point indicates the original reference. Each of these studies reported that the hyperoxic exposure was generally well tolerated, with little or no symptoms of chest tightness, little or no decrease in vital capacity or other pulmonary function tests, and no long-term sequelae. See text for details. (Data from Comroe et al,[66] Helvey et al,[74] Michel et al,[75] Fife et al,[76] and Dougherty et al.[77])

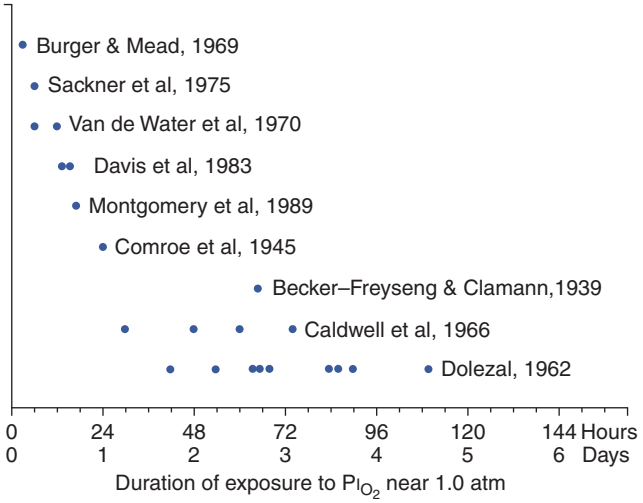

FIGURE 45-7 A summary of studies of prolonged exposure of normal human subjects to an inspired O_2 tension (PI_{O_2}) near 1 atm. The horizontal arrays of points indicate the various durations of exposure within a given study. The names associated with each horizontal array of points indicate the original references. See text for details. (Data from Burger and Mead,[67] Sackner et al,[68] Van de Water et al,[82] Davis et al,[83] Montgomery et al,[80] Comroe et al,[66] Becker-Freyseng and Clamann,[84] Caldwell et al,[85] and Dolezal.[88])

Similar findings were reported by Ohlsson[78] (not plotted in Fig. 45-6) in six men exposed to a PI_{O_2} of 0.78 to 0.88 atm for 53 to 57 hours. Helvey et al[74] found no change in vital capacity, Pa_{O_2}, or chest radiographs after 14 days of exposure to 0.49 atm. Michel et al[75] reported no net change in vital capacity during a 7-day exposure of six normal U.S. Navy men to PI_{O_2} = 0.55 atm. Fife et al[76] studied three subjects at PI_{O_2} of 0.47 atm for 7 days; none developed chest symptoms or a change in vital capacity.

At PI_{O_2} = 0.5 atm for 45 hours, Griffith et al[79] found increased pulmonary clearance of an inhaled tracer and increased albumin in bronchoalveolar-lavage fluid, suggesting the possibility of injury to the alveolar-capillary barrier, or alternatively, only inflamed airways.[80]

Data from the U.S. Navy's Shallow Habitat Air Diving (SHAD) program support 0.6 atm PI_{O_2} as safe for prolonged O_2 exposure.[16] Men tolerated well exposures of 0.51 and 0.57 atm PI_{O_2} for 29.5 and 28 days, without changes in pulmonary function.[16,77,81] With 9-day exposures to mean PI_{O_2} of 0.61 atm (each day, 16 hours at PI_{O_2} = 0.51 atm and 8 hours at PI_{O_2} = 0.81 atm), only one of the three men showed decreased vital capacity (9.7%) and chest discomfort, both coinciding with the daily 8-hour excursions to PI_{O_2} = 0.81 atm.[16,77,81]

Toxicity of Oxygen Near 1 Atmosphere in Normal Subjects

Several studies examining physiologic parameters and other indices of lung injury have also been carried out in humans with exposures at or near a PI_{O_2} = 1 atm (Fig. 45-7). Burger and Mead[67] reported chest pain and tightness and decreases in pulmonary compliance after only 3 hours of breathing pure O_2 at various ambient pressures including 1 atm. The subjects were instructed to refrain from taking deep breaths, yawning, or sighing during the exposure. Postexposure the decrease in compliance and the chest symptoms readily resolved on deep breathing or sighing, suggesting to them that atelectasis rather than direct O_2 toxicity was the etiology. Remarkably, in this study,[67] breathing pure O_2 at only 0.39 atm ambient pressure (PI_{O_2} of only 0.39 atm) produced symptoms that were qualitatively and quantitatively no different from breathing pure O_2 at 1 atm ambient pressure (PI_{O_2} = 1). Yet, breathing with a PI_{O_2} of 1 atm, but in the presence of an equal amount of nitrogen (PI_{N_2} = 1 atm, and total ambient pressure = PI_{O_2} + PI_{N_2} = 2 atm) was virtually no different from control (air breathing at 1 atm ambient pressure). These findings further convinced these investigators that atelectasis, promoted by the lack of nitrogen, was the mechanism of both the chest symptoms and the compliance changes.

As already noted, Sackner et al[68] found bronchoscopic evidence of tracheitis in each of ten normal subjects inspiring a PI_{O_2} of 0.90 to 0.95 atm for 6 hours. None had substernal distress or changes in pulmonary function tests. Tracheal mucus velocity was depressed at 3 hours but was

restored by a β_2-adrenergic agonist. They speculated that the effect on mucus velocity could predispose to bacterial superinfection.[68] In men exposed to 6–12 hours of PI_{O_2} = 1 atm and taking a deep breath every 20 minutes, Van de Water et al[82] found no chest symptoms or changes in pulmonary function or oxygenation.

In fourteen subjects exposed to a PI_{O_2} of 0.95 atm for a mean of 17 hours, Davis et al[83] found that nine had substernal discomfort and six had "mild erythema" on bronchoscopy. Bronchoalveolar lavage fluid showed increased albumin, transferrin, and total protein, consistent with alveolar–capillary leak, but no change in inflammatory cells. In contrast, despite chest pain in subjects breathing PI_{O_2} = 1 atm for 17 hours, Montgomery et al[80] found no changes in pulmonary function tests, solute permeability, or systemic or pulmonary endothelial injury (as reflected by plasma fibronectin and factor VIII). They suggested that the increased albumin and transferrin in bronchoalveolar lavage fluid reported by Davis et al[83] and Griffith et al[79] may not indicate lung parenchymal injury, but may instead have come from the inflamed airways.

Comroe et al[66] studied men exposed to PI_{O_2} = 0.99 atm for 24 hours and found no changes in chest radiographs or oxygenation. Burger and Mead[67] found that breathing pure O_2 at ambient pressure of 0.5 atm, such that PI_{O_2} = 0.5 atm and PI_{N_2} = 0, produced no symptoms but decreased vital capacity.

In 1939 Becker-Freyseng and Clamann[84] reported exposures of two men to a PI_{O_2} of 0.9 atm for 65 hours, or 2.7 days. Both had decreased vital capacity. One developed nausea, vomiting, tachycardia, a febrile tracheobronchitis, dyspnea, and pain in the elbows and knees. The etiology of nausea and vomiting is not clear but could be related to the absorption of bowel gas owing to the absence of nitrogen.[17]

Caldwell et al[85] studied four subjects exposed to PI_{O_2} = 0.98 atm for, respectively, 30, 48, 60, and 74 hours (i.e., 1.25, 2.0, 2.5, and 3.1 days). They were instructed to take five deep breaths and a cough every 2 hours throughout the day but not at night. In addition to chest pain and cough, three of the four had paresthesia, and three had anorexia. They noted decreases in lung volumes, diffusing capacity, but not in the ratio of forced expiratory volume in 1 second to forced vital capacity, and a modest increase in alveolar-arterial (A-a) PO_2 gradient (89 Torr). Chest radiographs were clear. The authors could not exclude atelectasis as the etiology of the decreased vital capacity. The subject with the longest (74 hours) exposure, however, was hospitalized for 2 days postexposure "until his sense of well-being and appetite returned." This subject had dyspnea on exertion for 3 to 4 days postexposure, and his vital capacity did not return to baseline until 24 weeks postexposure.[85] In humans, normobaric hyperoxia does not produce airway obstruction,[71] but may do so in dogs[11,86] and primates.[87] Hyperbaric hyperoxia may produce airway obstruction in humans.[25]

The longest voluntary human exposures to 100% O_2 are by Dolezal.[88] Twelve subjects were exposed to the limit of tolerance. The mean exposure was 74 hours (3.1 days), with a range from 42 hours (1.75 days) to a remarkable 110 hours (4.6 days). P_{CO_2} of the exposure chamber remained high, approximately 7 to 8 torr (1%). In addition to retrosternal pain and cough, the subjects eventually experienced dyspnea, loss of gustatory sensation, anorexia, nausea (after 48 to 60 hours) and vomiting, general weakness, and vertigo (beyond 60 to 72 hours). Three developed fevers of 38.5°C to 39.3°C (101.3°F to 102.7°F). As evidence of additional systemic (nonrespiratory) toxicity, nine of the twelve noted paresthesias and hypesthesias of the finger tips in both hands and feet, which did not resolve until 14 to 21 days postexposure. Vital capacity decreased by 17%, minute ventilation progressively increased by 39% throughout the exposure, and a mild respiratory alkalosis developed. Remarkably, arterial O_2 saturation remained at or near 100% throughout the exposure and was normal postexposure. Dolezal interpreted this intact oxygenation as evidence that pulmonary edema and "hepatization foci," as seen in animal studies, had not developed.[88]

Taken together, these reports seem to imply that evidence for major sustained parenchymal lung injury, or the equivalent of acute respiratory distress syndrome (ARDS), has been much more readily observed in animals than in normal humans.

Toxicity of Oxygen Near 1 Atmosphere in Patients

Most patients who receive prolonged high FI_{O_2} have severe parenchymal lung injury (e.g., ARDS). Intriguing data are available, however, from human patients without major lung disease. In eighteen patients postoperative from cardiac surgery, Singer et al[89] confirmed that short exposures to 100% O_2 for a mean of 24 hours (range 15 to 48 hours) have no demonstrable adverse effects. They found no change in shunt, compliance, dead space, radiologic atelectasis, or clinical course compared to a group who received only the FI_{O_2} (mean: 0.32) required for adequate oxygenation. Singer et al[89] also reported two additional patients who were ventilated with 100% O_2 for 5 and 7 days, respectively. Throughout the 5-day and 7-day periods, these patients showed progressive improvement in Pa_{O_2}, from 368 to 430 torr and from 155 to 404 torr, respectively. The first patient was extubated on the fifth day and subsequently discharged from the hospital. The second patient died on the seventh day of massive pulmonary hemorrhage related to a greatly prolonged bleeding time on anticoagulants.

In a companion paper by the same group, Barber et al[90] reported the effects of ventilating patients with massive cerebral trauma and resultant irreversible, ultimately fatal brain damage, with either 100% O_2 (n = 5) or air (n = 5). Ventilation with the respective gases continued until death, which occurred within 31 to 72 hours, or 1.3 to 3 days (mean: 2.2 days), in the O_2 group and within 50 to 216 hours, or 2.1 to 9 days (mean: 4.3 days), in the air group. None had preexisting lung disease. None had spontaneous respirations. All received tidal volumes greater than 800 mL, periodic tracheal suctioning, frequent changes in body position, and

treatment with corticosteroids. After 2 days, the O_2 group had a lower mean Pa_{O_2} (120 vs. >400 torr, tested on 100% O_2 in both groups), greater shunt and dead space, but no difference in compliance. The O_2 group also had greater worsening of chest radiographs, progressing to multilobar infiltrates, consolidation, or collapse. At autopsy the O_2 group also had greater lung weights. Perhaps the most striking finding was that at autopsy no histologic differences between the groups were apparent. Both had varying degrees of bronchopneumonia, intraalveolar and interstitial edema, atelectasis, congestion, hemorrhage, and intravascular coagulation. Hyaline membranes, however, were "conspicuously absent" in both groups. It seems likely that hyperoxia-induced atelectasis (and perhaps ventilator-induced lung injury, with an 800-mL tidal volume), could explain many if not all of their findings, especially in such patients with no spontaneous respiratory effort.

Hyde and Rawson[91] reported the effects of inadvertent exposure to 83% to 91% O_2 for 12 to 32 days in five intubated patients with neuromuscular disease. The authors made a presumptive diagnosis of hyperoxic pneumonitis based on scattered patchy infiltrates on chest radiographs, fever, and leukocytosis. The postmortem examination of the one patient who died (a depressed patient who was found dead with the respirator disconnected) showed "thickening of the alveolar septa by edema and fibroblastic proliferation … fibrin deposition and increased numbers of lining cells in the alveolar lumina." No hyaline membranes were described. However, interpretation of their findings is confounded by the fact that these patients also had copious secretions, "a major degree of atelectasis" (four of the five patients), and pneumonia (four of five), which are common complications of such patients even in the absence of hyperoxia. Furthermore, unlike ARDS, these patients responded rapidly to minimizing the FI_{O_2}, "vigorous tracheal aspiration (and) meticulous tracheal toilet," and antibiotics. In fact, after these changes in management, all four were weaned from mechanical ventilation within 2 to 5 days.

Perhaps the longest reported exposure of a patient to hyperoxia was that of a 32-year-old man with myasthenia gravis, who was ventilated with 80% O_2 (which could not be lowered for technical reasons) for 150 days, at which time he developed blindness bilaterally with retinal artery constriction and retinal atrophy.[92] Hyperoxia constricts retinal arteries in adults as well as neonates.[93] During the exposure his Pa_{O_2} remained 250 to 300 torr. He remained another 130 days on 60% O_2 (Pa_{O_2} 120 to 160 torr) before weaning from mechanical ventilation on day 280, after which his Pa_{O_2} remained normal (80 to 100 torr). Except for the elevated $P(a\text{-}a)O_2$ gradient, consistent with atelectasis, inadequate control of secretions, or pneumonia, no signs or symptoms of pulmonary O_2 toxicity were reported.

In a brief communication Smith et al[94] reported the absence of any evidence of O_2 toxicity, as determined by radiographs, pulmonary function, bronchoscopy, or histopathology, in forty-one patients treated with high-frequency jet ventilation using a mean FI_{O_2} of 0.92 (range: 0.80 to 0.95) for a mean of 4.1 days (range: 8 hours to 12 days). They suggested that their lack of O_2 toxicity may be secondary to the lack of "stretching and shearing forces" encountered in conventional mechanical ventilation.

More recently, Capellier et al[95] retrospectively studied seventy-four patients with FI_{O_2} ≥0.90 continuously for at least 48 hours. They found that the duration of this exposure in the seventeen survivors was surprisingly long (mean: 5.6 days) and not different form the fifty-seven nonsurvivors (5.9 days). One survivor had exposure to FI_{O_2} ≥0.90 for 15 days and was eventually discharged, breathing spontaneously with a normal Pa_{O_2} on room air. The majority of deaths were related to sepsis and multiorgan failure rather than to progressive hypoxemic respiratory failure. Of the thirty-seven patients exposed to FI_{O_2} ≥0.90 for at least 4 days, only 5 (14%) died with hypoxemia. These authors concluded that the lungs of patients with acute respiratory failure appear relatively resistant to prolonged hyperoxia, that high plateau pressures may be more injurious than high FI_{O_2}, and that a prospective trial may be helpful in clarifying the optimum management of FI_{O_2} for such patients.[95]

Pathology of Pulmonary Oxygen Toxicity: Diffuse Alveolar Damage

In 1958 Pratt[96] was the first to note in patients pathologic changes attributed to hyperoxia. The pathology of pulmonary O_2 toxicity has been reviewed by a number of authors[13,16,20,23–26,28,97,98] and is the subject of a monograph.[11] Because of preexisting lung disease in most human studies, the most persuasive data come from animals. A few studies, however, of hyperoxic pulmonary pathology in humans without preexisting lung disease are available,[99–101] and the findings are consistent those in animals. The histologic pathology of hyperoxia-induced acute lung injury is that of diffuse alveolar damage.[98] *Diffuse alveolar damage* is a descriptive term for the predictable but nonspecific features of acute lung injury from a variety of toxins, including infectious agents, other inhalants, pharmaceutical agents and other ingestants, radiation, and the multiple causes of ARDS, including trauma and sepsis.[98] Hyperoxia has in common with all other causes of diffuse alveolar damage an initial injury to both the alveolar endothelial and epithelial cells.

Diffuse alveolar damage can be divided into two stages, as first defined by Nash et al,[102] and detailed in Table 45-2.[97] The first is an early acute or exudative stage within the first week, characterized by interstitial and intraalveolar edema, intraalveolar hemorrhage and fibrin deposition, sloughing of the alveolar lining cells (type I pneumocytes) with denudation of the alveolar basement membrane, and hyaline membranes, which represent cytoplasmic and nuclear debris from sloughed cells mixed with fibrin.[98] Late in the first week an inflammatory cell infiltrate into the interstitium is evident. The small pulmonary arterioles and alveolar capillaries may show fibrin thrombi. Also by the end of the first week, proliferation of type II pneumocytes appears along the alveolar

TABLE 45-2: DIFFUSE ALVEOLAR DAMAGE IN HUMANS AT 0.8 TO 1 ATMOSPHERES OF OXYGEN

Changes	Time of Occurrence
A. Exudative	
1. Capillary congestion, focal intraalveolar edema, few cases with fibrin thrombi in capillaries and small arteries	Less than 3 days
2. Interstitial edema	After 3 days
3. Hyaline membranes lining alveolar septa	22 hours to 7 days, decreasing or focal thereafter
4. Interstitial mononuclear cell infiltrate (lymphocytes, plasma cells, unclassified cells)	Less than 1 week
B. Proliferative	
1. Alveolar lining cell hyperplasia	Focal at 3 days, diffuse at 1 week
2. Interstitial fibrosis	Focal at 3 days, diffuse at 8 days, severe by 2 weeks

Derived from light microscopic data of Katzenstein et al.[100]

Data from Balentine JD. *Pathology of Oxygen Toxicity*. New York: Academic Press; 1982.

lining, representing a reparative phase; the type II pneumocytes can later differentiate into type I pneumocytes.[98]

The second stage of diffuse alveolar damage[98] is a proliferative or organizing stage and is noted beyond the first week. Fibroblastic proliferation in the interstitium and focal intraalveolar fibrosis appear. Whereas the edema and hyaline membranes have largely resolved, the interstitial inflammatory infiltrate and the alveolar lining cell hyperplasia are still present. A striking interstitial fibrosis develops in association with extensive interstitial deposition of collagen.

The issue of just how sensitive the human lung is to hyperoxic lung injury is still somewhat open to question. Remarkably, as noted above, in patients without prior lung injury who received 100% O_2 for up to 7 days, typical histologic lesions were not found.[89,90] These observations prompted Katzenstein[98] to suggest that humans may be susceptible to significant hyperoxic lung injury only after their lungs are first damaged by other insults. Other authors have concluded simply that no consistent evidence shows that hyperoxia (FI_{O_2} >0.60) is dangerous in acute lung injury or ARDS.[103]

Bronchopulmonary Dysplasia

Bronchopulmonary dysplasia was initially described in 1967[104] and has been reviewed in detail by Balentine[11] and Truog.[105] It is a form of chronic lung disease that follows therapy for idiopathic respiratory distress syndrome of the newborn, or hyaline membrane disease. Bronchopulmonary dysplasia develops in very low-birth-weight infants (≤1500 g at birth). Its incidence and prevalence have risen substantially in recent years because of the markedly increased survival of these infants.[105] It has become the most common cause of chronic lung disease in infants.[106] Its pathologic features include fibrosis and destruction of acinar structures with a resultant combination of scarring and emphysematous changes. It appears to have three contributing mechanisms: (a) ventilator-induced lung injury,[107] (b) hyperoxia, with increased O_2 radicals in the presence of an immature antioxidant defense system,[108] and (c) peribronchial pulmonary edema secondary to the birth-related increased pulmonary blood flow through an immature and injured pulmonary microcirculation.[105] Because high levels of both mechanical ventilation and hyperoxia virtually always occur together in patients with idiopathic respiratory distress syndrome, the relative roles of these two etiologic factors is unclear. Churg et al[109] have described the equivalent of bronchopulmonary dysplasia, including "honeycombing," in three adult patients who also had received the combination of high ventilator pressures and high FI_{O_2} for 3 to 7 weeks. Baboon and other animal models for bronchopulmonary dysplasia exist.[110,111]

In recent years, the risk and severity of bronchopulmonary dysplasia have decreased with the use of antenatal glucocorticoids, less aggressive mechanical ventilation, including limiting the FI_{O_2} and the use of continuous positive airway pressure,[112,113] and postnatal surfactant.[112–114]

NONRESPIRATORY EFFECTS OF OXYGEN BREATHING

The nonrespiratory effects of hyperoxia have been extensively reviewed elsewhere.[11,13,28,115] The best-recognized effects include hemodynamic changes, suppression of erythropoiesis and serum erythropoietin,[116] the Haldane effect (see the section Respiratory Depression and Stimulation, Pulmonary Vasodilation, and Hypercapnia), retinopathy of prematurity (previously called retrolental fibroplasia), and, only at O_2 pressures exceeding 2 atm, seizures.

Retinopathy of Prematurity

Retinopathy of prematurity results from hyperoxic vasoconstriction and injury to the exquisitely susceptible, growing retinal capillaries of premature neonates (<26 weeks gestation).[11,117,118] The resulting paradoxical "hyperoxic hypoxia" and tissue ischemia induces neovascularization within the retina and adjacent vitreous. This retinovitreal neovascularization eventually results in retinal detachment and blindness,[118] a process similar to that in diabetic and sickle-cell retinopathies.[117] Both the incidence and severity of retinopathy of prematurity correlate with the duration of exposure to Pa_{O_2} greater than 80 torr.[119] The pathogenesis of retinopathy of the newborn has two phases.[120] The first phase (20 to 30 weeks postmenstrual age) involves hyperoxia and decreased vascular endothelial growth factor (VEGF) levels, whereas the second phase (31 to 44 weeks) involves hypoxia and increased VEGF levels. Activation of the VEGF receptor

TABLE 45-3: ACUTE HEMODYNAMIC EFFECTS OF OXYGEN BREATHING (NORMOBARIC HYPEROXIA)

Parameter	Effect
Heart rate	Decreased
Cardiac output	Decreased
Right-ventricular stroke work	Decreased
Left-ventricular stroke work	Unchanged
Right- and left-ventricular work rates	Decreased
Systemic arterial pressure	Variably increased, decreased, or unchanged
Pulmonary arterial pressure	Decreased
Pulmonary arterial wedge pressure	Unchanged
Right-atrial pressure	Increased
Systemic vascular resistance	Increased
Pulmonary vascular resistance	Decreased

Data from Lodato.[115]

VEGFR-1 can prevent the hyperoxia-induced retinal vascular degeneration of retinopathy of prematurity.[121] More recently, it has been reported that intravitreal bevacizumab (anti-VEGF) benefitted infants with retinopathy of prematurity.[120] The optimum oxygenation is unclear. The recent SUPPORT trial in premature infants reported that a lower target range of arterial oxyhemoglobin saturation (Sp_{O_2}) (85% to 89% vs. 91% to 95%) increased mortality but decreased severe retinopathy in the survivors.[112,113]

Acute Hemodynamic Effects

The acute hemodynamic effects of normobaric hyperoxia in healthy humans have been studied by a number of investigators[115,122–134] and summarized by Lodato,[28,115,130] who also found virtually identical responses in conscious dogs.[115,130] Table 45-3 summarizes these results. The decrease in heart rate is vagally mediated.[33,123] The decrease in cardiac output is primarily the result of the relative bradycardia, but some studies also have shown an independent contribution from a decrease in stroke volume or diastolic dysfunction.[135] The decrease in cardiac work[115] is primarily the result of the bradycardia, but right-ventricular afterload is reduced by pulmonary vasodilation.[136]

Systemic vasoconstriction is one of the most consistent findings and occurs independently of any changes in P_{CO_2}.[137,138] Virtually all systemic beds constrict during hyperoxia, but in rats the splanchnic circulation vasodilates.[139] The central nervous system vasoconstrictive effect has been used to treat vascular headaches.[17] The mechanisms are not fully understood and appear quite diverse among various vascular beds. Hyperoxic vasoconstriction may be a continuum of the mechanism of hypoxic vasodilation.[140] That is, red blood cells can regulate vasomotor tone depending on their degree of oxyhemoglobin saturation: As saturation rises with hyperoxia (or falls with hypoxia), the red blood cell releases less (or more, respectively) of the vasodilators adenosine 5′ triphosphate [141] and nitric oxide from *S*-nitroso-hemoglobin.[142] In the central nervous system[143,144] and in the human forearm,[145] hyperoxia vasoconstricts by inactivation of endothelium-derived relaxing factor/nitric oxide by superoxide anion.[140,146] In the coronary bed, hyperoxia constricts by closure of adenosine 5′ triphosphate-sensitive potassium channels.[147] In the human retinal artery the reported mechanisms include release of endothelin-1[148] and prostanoids,[149] in addition to the mechanisms above.[138] The human umbilical vein vasoconstricts to hyperoxia via local release of norepinephrine.[150]

Despite the systemic vasoconstriction, systemic arterial pressure is variably affected, owing to the concurrent decrease in cardiac output. Jubran and Lodato[151] showed that the bradycardia is independent of the arterial baroreceptor reflex.

The hemodynamic changes induced by hyperoxia have also been documented in patients with a wide variety of conditions, including general anesthesia,[152] during cardiopulmonary bypass,[153] immediately following coronary bypass surgery,[154] with cardiac risk,[155] congestive heart failure,[135,156,157] sepsis,[158,159] cirrhosis,[160] and children with acyanotic congenital heart disease.[161]

In patients with pulmonary hypertension from a variety of causes (primary, portal, human immunodeficiency virus, atrial septal defect, ventricular septal defect, scleroderma) with mean baseline $Pa_{O_2} = 64$ mm Hg, breathing 100% O_2 has been reported to decrease pulmonary vascular resistance by 24%.[162] A limitation of this study is that cardiac output was calculated from the Fick principle, assuming that hyperoxia did not change O_2 consumption, an invalid assumption.[115]

Oxygen Consumption

Contrary to Priestley's speculation, which he based on his observations of a candle burning more vigorously in O_2 (see above), that hyperoxia may enhance metabolic rate, recent evidence indicates that hyperoxia can actually decrease metabolic rate as measured by O_2 consumption. It has long been established that hyperoxia decreases O_2 consumption in both cells and tissue preparations, but the biochemical mechanisms are unclear.[163] Chapler et al[164] showed that under certain experimental conditions (e.g., acute anemia, autonomic inhibition) in anesthetized dogs, hyperoxia paradoxically decreased O_2 consumption. Lodato[115] showed under more general physiologic conditions in unsedated, intact, healthy, conscious dogs, that hyperoxia (mean Pa_{O_2} = 475 torr) decreased whole-body O_2 consumption by nearly 20% (Fig. 45-8). Unexpectedly, in this study the arteriovenous difference in O_2 content decreased along with the decrease in cardiac output (both by approximately 10%). Paradoxically, O_2 delivery (cardiac output × arterial O_2 content) did not change, and O_2 extraction (O_2 consumption/O_2 delivery) decreased. Subsequently, Lodato[130] reported that when O_2 consumption and O_2 delivery were plotted in the conventional way, as ordinate and abscissa, respectively,

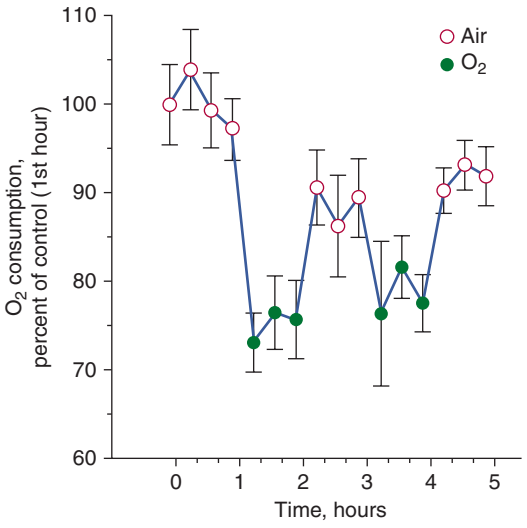

FIGURE 45-8 Time course of resting whole-body O_2 consumption as the inspired gas was alternated hourly between air (*open circles*) and O_2 breathing (hyperoxia; mean Pa_{O_2} = 475 torr) (*closed circles*) in six conscious dogs. Each point is expressed as percent of mean O_2 consumption (6.19 ± 0.65 mL O_2.min.$^{-1}$kg^{-1}) during control period (first hour). Paradoxical decrease in O_2 consumption during hyperoxia was fully developed by 20 minutes, was maintained for at least 1 hour, and was both reversible and reproducible. Mean of each 1-hour period was statistically significantly different from mean of its adjacent 1hour periods. (Used, with permission, from Lodato.[115])

hyperoxia produced a unique parallel shift downward in the O_2 consumption–O_2 delivery relationship (Fig. 45-9). Hyperoxia-induced decreases in O_2 consumption have also been reported in children with acyanotic congenital heart disease,[161] patients with sepsis,[158,159] cardiac-risk patients,[155] and patients during cardiopulmonary bypass.[153]

The mechanisms by which hyperoxia could induce such a decrease in O_2 consumption are obscure. The possibilities include[115] that hyperoxia may produce (a) systemic cellular O_2 toxicity, (b) a paradoxically inadequate O_2 supply ("hyperoxic hypoxia") at the microcirculatory level, owing to the diffuse systemic vasoconstriction,[165–168] or (c) a facultative decrease in O_2 demand, as has been demonstrated in mammals under certain physiologic challenges unrelated to hyperoxia.[169] Reinhart et al[159] investigated the second possibility. In patients with sepsis[159] and in stable patients with cardiac risk,[155] they infused the antioxidant *N*-acetylcysteine. They found that *N*-acetylcysteine attenuated the hyperoxia-induced decreases in both O_2 consumption (from 34% to only 11%) and gastric intramucosal pH (by tonometry, used as a marker of the adequacy of gastric O_2 supply).[159]

Pulmonary versus Systemic Cause of Death from Hyperoxia

Death in experimental animals exposed to prolonged hyperoxia is usually attributable to ARDS-like acute lung injury.[170,171] Hypoxemia, however, is generally absent. Matalon et al[171] found in sheep a terminal severe acute respiratory acidosis but supranormal Pa_{O_2} = 200 torr at death. Harabin et al[172] provided intriguing evidence that *systemic*, rather than pulmonary, O_2 toxicity may be the predominant cause of death. Dogs exposed continuously to 100% O_2 lived for a mean of 88 hours (3.7 days), but surprisingly, they maintained Pa_{O_2} at approximately 500 torr until shortly before death. Their brief preterminal course was characterized by a precipitous decrease in cardiac output and blood pressure accompanied by metabolic acidosis, all of which preceded the terminal deterioration in gas exchange. In fact, the acidosis (presumably lactic as seen terminally in hyperoxemic rabbits[173]) occurred in the face of supranormal Pa_{O_2} of 200 to 400 torr, indicating a systemic, or cardiovascular, rather than a pulmonary (hypoxemic) mechanism of their terminal deterioration.[172] Thus, these animals died clearly *with* lung injury but not so clearly *from* lung injury.

Further evidence of primary cardiovascular O_2 toxicity has been provided by Busing et al[174] (and others[11]), who described disseminated microscopic foci of myocardial necrosis (Fig. 45-10), especially in the subendocardium of the left ventricle, occurring in rabbits subjected to 60 hours (2.5 days) of 100% O_2. Hypoxemia from hyperoxic lung injury was excluded as the mechanism because the cardiac necrosis developed while the Pa_{O_2} was 300 to 400 torr, and, in fact, it preceded any morphologic pulmonary changes. Fracica et al[87,175] reported that baboons exposed to 100% O_2 for more than 80 hours (>3.3 days) had substantial deterioration in cardiac function without significant deterioration in oxygenation (mean Pa_{O_2} = 437 torr). These animals also showed focal areas of myocardial necrosis.[175] Robinson et al[176] studied several species of primates exposed to 100% O_2 for up to 14 days. Pa_{O_2} remained high (400 to 500 torr) until near death when it fell sharply and Pa_{CO_2} rose. The baboons, however, did have other clinical (increase respiratory effort) and pathologic evidence of severe lung injury. In contrast, the squirrel monkeys were surprisingly insensitive to pulmonary O_2 toxicity. They, too, died from the hyperoxic environment but of undetermined cause. Cardiac histopathologic examination was not reported.

Thus, it appears that experimental animals exposed to hyperoxia die primarily from systemic rather than pulmonary O_2 toxicity.

MECHANISMS OF OXYGEN TOXICITY

Formation of Reactive Oxygen Species

It is now generally accepted that the toxic effects of hyperoxia are the direct result of increased concentrations of highly reactive O_2-derived free radicals.[20,177–181] This extensive topic is now the subject of two recent monographs.[182,183] The "O_2-radical hypothesis" was first proposed in 1954 by Gerschman et al,[184] who suggested that hyperoxia-induced tissue injury and X-irradiation-induced tissue injury have as a common mechanism the production of reactive O_2 species

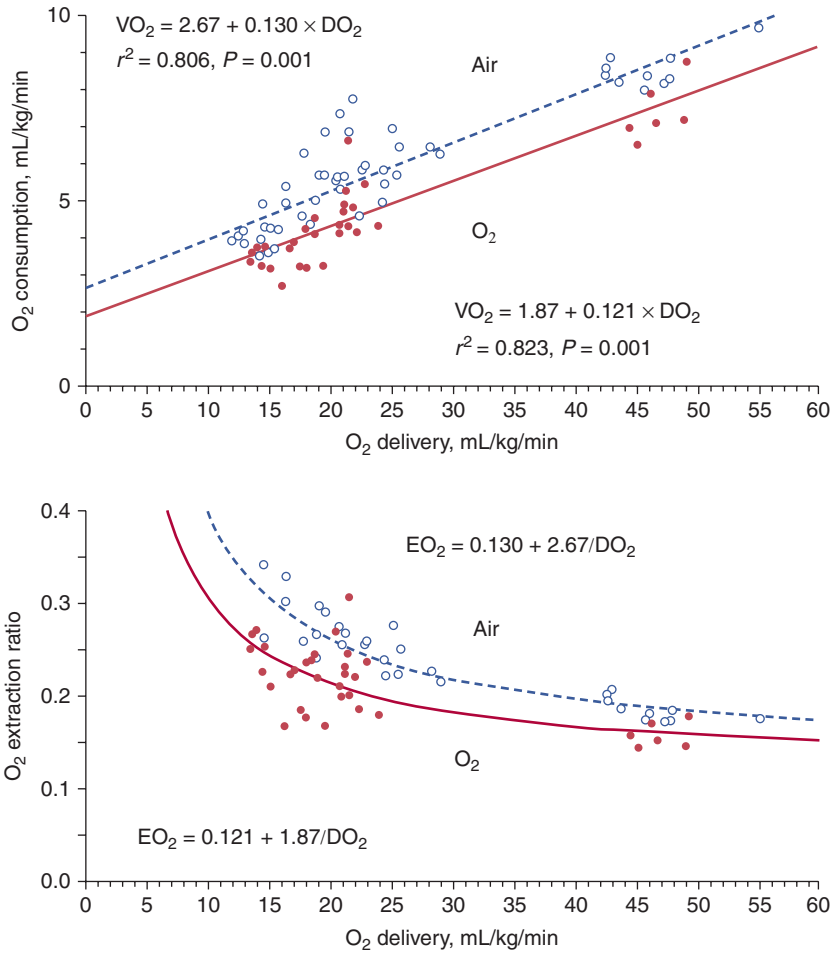

FIGURE 45-9 *Upper panel.* Relationship between O_2 consumption and O_2 delivery in six healthy, resting, conscious dogs for air (*open circles*) versus O_2 breathing (normobaric hyperoxia; *closed circles*). Each dog is represented by $n = 10$ independent determinations during air breathing and by $n = 6$ independent determinations during hyperoxia. Hyperoxia produced a unique parallel shift downward in the O_2 consumption–O_2 delivery relationship (see text). *Lower panel.* Oxygen extraction ratios corresponding to the data points in upper panel. (Used, with permission, from Lodato.[130])

in excess of the antioxidant defenses. Gerschman[185] pointed out that O_2 at 20% is potentially toxic and that its gradual accumulation in the atmosphere induced the evolution of cellular defense mechanisms.

The basic chemistry of reactive O_2 species has been extensively reviewed.[186–190] Molecular O_2 itself is generally nontoxic and only modestly reactive. When it is chemically reduced by the sequential addition of electrons (e^-), however, it forms partially reduced reactive O_2 species (ROS), as follows:

$$O_2 \xrightarrow{e^-} O_2^- \xrightarrow{e^- + 2H} H_2O_2 \xrightarrow{e^- + H} OH\cdot \xrightarrow{e^- + H} H_2O$$

where O_2^- is superoxide anion radical, H_2O_2 is hydrogen peroxide, and OH· is the hydroxyl radical. Superoxide is only modestly reactive. It can, however, yield the very highly reactive hydroxyl radical. Alternatively, superoxide can react with nitric oxide (NO), also a free radical, forming the very highly reactive peroxynitrite anion, $ONOO^-$. Of the ROS, the hydroxyl radical is by far the most reactive, reacting with all known biomolecules so rapidly that it acts only locally where it is produced.[187] In contrast, O_2^- and H_2O_2 can travel some distance and enter cells, H_2O_2 by simple diffusion across the cell membrane and O_2^- via anion channels.[189,191] The high reactivities of ROS and reactive nitrogen species (RNS) such as NO and peroxynitrite are the result of their very high affinity for additional electrons. This extreme electron affinity causes these agents to rapidly pull an electron from the nearest available molecule, resulting in oxidative damage to nearby lipids, proteins, and DNA. This oxidant damage is manifested by lipid peroxidation, enzyme inhibition, and DNA strand breakage, which can lead ultimately to loss of cell integrity and cell death.

The sources of ROS are many (Fig. 45-11). In the normal processes of cellular metabolism, ROS are produced at basal rates. Superoxide radical can be generated by both enzymatic and nonenzymatic (autooxidation) reactions. The major source of ROS in the lung is the mitochondrial electron-transport chain, during the production of adenosine 5′ triphosphate via oxidative phosphorylation.[190] The fate of nearly all O_2 taken up by the body is four-electron catalytic

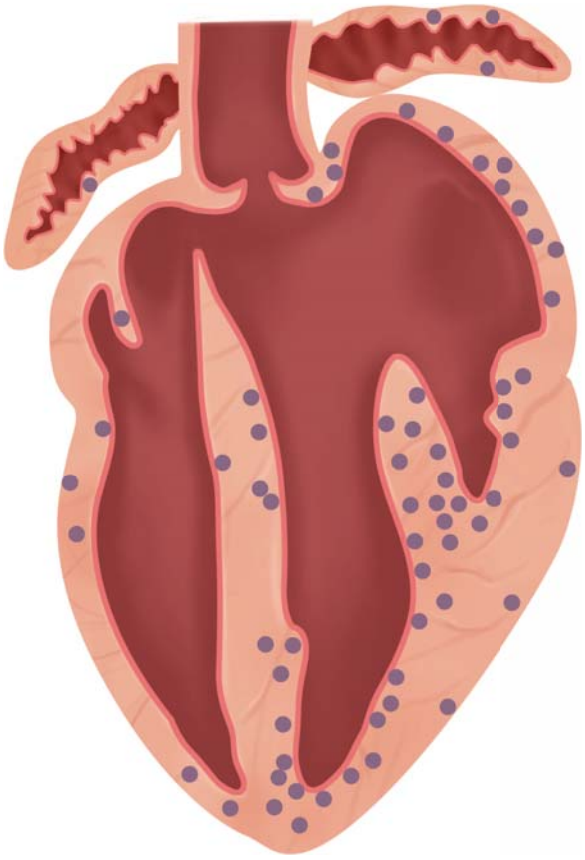

FIGURE 45-10 Distribution of disseminated microscopic foci of myocardial necrosis seen in rabbits exposed to 100% O_2 (normobaric hyperoxia) for more than 60 hours, as illustrated by a schematic longitudinal section through all chambers of the heart. All four chambers were affected, but the subendocardium of the left ventricle, including the papillary muscle and the septum, were the most vulnerable. The arterial O_2 tension was consistently greater than 300 torr, indicating that hypoxemia (from possible hyperoxic lung injury) was not the mechanism of the necrotizing cardiomyopathy. (From Busing CM, Kreinsen U, Buhler F, Bleyl U. Light and electron microscopic examinations of experimentally produced heart muscle necroses following normobaric hyperoxia. *Virchows Arch A Pathol Anat Histol.* 1975;366:137–147. FIGURE 45-11 Sources of reactive oxygen species (ROS) and reactive nitrogen species (RNS) in the lung. Both inflammation (*upper left*) and exogenous toxins (*upper right*), including hyperoxia, produce superoxide ($O_2^{\cdot}$), which can react with nitric oxide (NO) to produce peroxynitrite ($ONOO^-$) and other toxic RNS and ROS. Or, superoxide may be metabolized to hydrogen peroxide (H_2O_2), which may yield water (H_2O) or the toxic hydroxyl radical ($OH^{\cdot}$). See text for details. *CAT*, catalase, *GPx*, glutathione peroxidase, *SOD*, superoxide dismutase. (Reprinted with permission of the American Thoracic Society. Official Journal of the American Thoracic Society.)

reduction by mitochondrial cytochrome *c* oxidase to form water. Normally, a tiny fraction (0.1% to 2%[189,192]) of the electron flow along this chain "leaks" off upstream of cytochrome oxidase, principally at the reduced form of nicotinamide adenine dinucleotide (NADH) dehydrogenase and ubiquinone (Fig. 45-12), and partially reduces O_2 to yield $O_2^{\cdot-}$.[178,193] The other major source of intracellular superoxide generation is the plasma membrane nicotinamide adenine dinucleotide phosphate (NADPH) oxidase.[163,194]

Under pathologic conditions, such as hyperoxia or inflammation, which may itself result from hyperoxic injury or from invading microorganisms, or other exogenous toxins (ozone, cigarette smoke, fibrogenic material, ionizing radiation, paraquat, or cytotoxic drugs), the production of both ROS and RNS is increased (see Fig. 45-11).[179,186–190] One hundred percent O_2 results in a 10-fold to 15-fold increase in mitochondrial H_2O_2 production.[195,196]

Inflammation results in increased production of ROS and RNS by release of proinflammatory chemokines and cytokines, which recruit neutrophils and other inflammatory cells (see Fig. 45-11). These proinflammatory stimuli also activate the membrane-bound NADPH-oxidase complex, which generates large amounts of superoxide,[189] manifested as the "respiratory burst" of neutrophils and macrophages (Fig. 45-13). Inflammation also upregulates inducible nitric oxide synthase, which produces great quantities of NO from L-arginine.[197] Thus, as above, superoxide and NO may react to yield the very highly reactive peroxynitrite anion, $ONOO^-$, which may be the most important species responsible for the incapacitation of microorganisms.[187] Inducible nitric oxide synthase can also generate superoxide.[198] An additional enzymatic pathway to increased ROS and RNS, particularly following ischemia, is via xanthine dehydrogenase.[189]

Superoxide radical, produced by any of the several pathways above, is converted to hydrogen peroxide by both spontaneous and enzymatic dismutation. Hydrogen peroxide, in turn, can be further reduced by transition metals to generate the hydroxyl radical. The metal ion-dependent

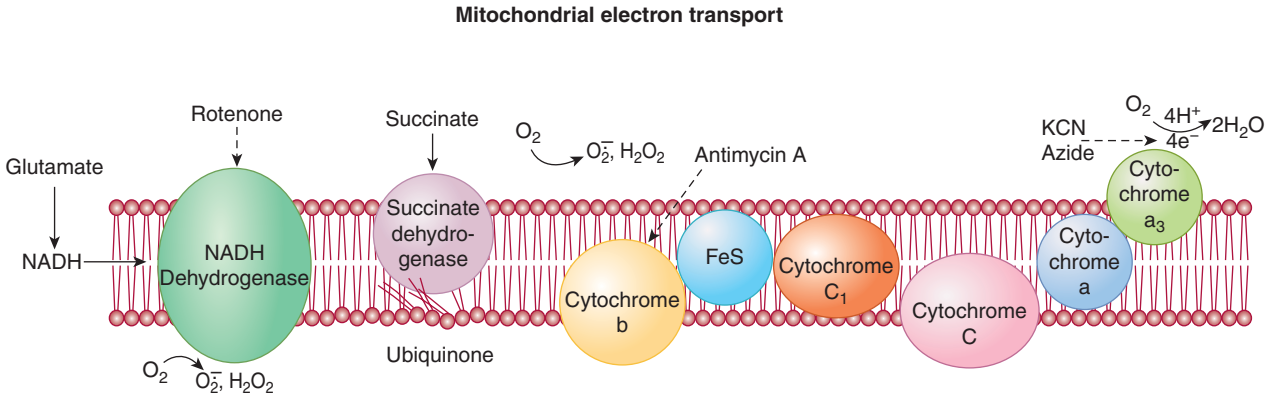

FIGURE 45-12 Generation of reactive oxygen species (ROS) in the mitochondria. The major source of mitochondrial ROS is the electron transport chain located on the inner mitochondrial membrane. Ubiquinone is reduced in a one-electron transfer to form the ubisemiquinone radical, which is reoxidized by molecular oxygen (autooxidation) to form the superoxide radical (O_2^-); this reaction is the major source of mitochondrial superoxide radical, which serves as a precursor to hydrogen peroxide (H_2O_2) and the hydroxyl radical ($OH^\cdot$), as shown. The autooxidation of the reduced form of nicotinamide adenine dinucleotide (NADH) dehydrogenase (a member of the class of flavoproteins) by molecular O_2 is an additional but quantitatively less important source of mitochondrial superoxide radical and thus, hydrogen peroxide and the hydroxyl radical. Also shown are various electron transport inhibitors (*dashed arrows*) used to study mitochondrial sources of superoxide radical. (Reprinted, with permission, from Macmillan Publishers Ltd. formation of OH· from H_2O_2 is accelerated by O_2^- according to the metal-catalyzed Haber-Weiss reaction, which is referred to as the Fenton reaction if the metal is iron:[199]

$$O_2^- + Fe^{3+} \longrightarrow O_2 + Fe^{2+}$$

$$H_2O_2 + Fe^{2+} \longrightarrow OH^- + OH^- + Fe^{3+}$$

Cell Death by Hyperoxia: Apoptosis and Necrosis

Recently, attention has focused on the observation that the morphology of alveolar epithelial and endothelial cell death induced by hyperoxia, in vitro and in vivo, is both apoptotic and necrotic.[200–202] The importance of this observation is that it suggests that the degree hyperoxia-induced lung injury could be modulated by controlling apoptosis,[202,203] as has been shown in a model of ventilator-induced lung injury.[204] Budinger et al[203] showed in mice that oxidants generated in the mitochondria in response to hyperoxia activate the intrinsic cell death pathway by activating BAX and BAK. When activated, these two proteins create channels in the outer mitochondrial membrane, with release of cytochrome *c* and other pro-apoptotic proteins from the mitochondrial intermembrane space into the cytosol, leading to activation of the caspases, cell death, and lung injury[201,203] (see Fig. 45-14). The activity of the pro-apoptotic proteins BAX and BAK are, in turn, counterbalanced by the Bcl-2 family of antiapoptotic proteins, for example, Bcl-2 and A1.[201] The activity of these antiapoptotic proteins (specifically, A1) can be upregulated by cytokines (e.g., interleukin-11 and VEGF) and even hyperoxia itself[200,201] (Fig. 45-14), limiting the damage from hyperoxia. These observations provide a basis for potential therapy for hyperoxic lung injury.

Antioxidant Defense Mechanisms

Four antioxidant defense mechanisms exist in the cell[205]: (a) prevention of the formation of free radicals, (b) conversion of ROS to less-toxic species, (c) compartmentalization of ROS away from vital cellular structures (e.g., the binding of intracellular iron to ferritin to prevent its participation in the Haber-Weiss reaction), and (d) repair of molecular injury induced by ROS.

The primary cellular defense against ROS are enzymes that catalyze the removal of superoxide and hydrogen peroxide, namely, superoxide dismutase (SOD), catalase, and the enzymes of the glutathione redox cycle (see Fig. 45-13).[186,205] No enzyme-scavenging system exists for the hydroxyl radical.[189] Superoxide radical is converted by dismutation to hydrogen peroxide by SOD:

$$2O_2^- + 2H^+ \xrightarrow{\text{Superoxide Dismutase}} H_2O_2 + O_2$$

The lung contains three forms of SOD. These have been reviewed in detail.[186,188] The cytosolic form of SOD contains copper and zinc (CuZnSOD). The mitochondrial form contains manganese (MnSOD). An extracellular form (ECSOD) is concentrated in airway and vessel walls.[206]

Hydrogen peroxide is converted to water by the enzymes catalase (a hemoprotein) and glutathione peroxidase:[187]

$$2H_2O_2 \xrightarrow{\text{Catalase}} 2H_2O + O_2$$

Glutathione peroxidase is a selenium-dependent enzyme that inactivates both hydrogen peroxide and lipid peroxides. It is the key enzyme in the glutathione redox cycle (Fig. 45-15),[205] and requires the sulfhydryl-containing tripeptide glutathione (GSH; L-γ-glutamyl-L-cysteinyl-glycine) as a cosubstrate. The enzyme catalyzes the reaction that forms oxidized glutathione,[207] or glutathione disulfide (GSSG), according to,

$$H_2O_2 + 2GSH \xrightarrow{\text{Glutathione peroxidase}} GSSG + 2H_2O$$

or, in the case of lipid hydroperoxides,[205]

$$L\text{-}OOH + 2GSH \xrightarrow{\text{Glutathione peroxidase}} GSSG + L\text{-}OH + H_2O$$

GSSG is rapidly reduced back to GSH by the NADPH-dependent enzyme, glutathione reductase. NADPH is in turn restored from the oxidized form of nicotinamide adenine dinucleotide phosphate positive ($NADP^+$) by the hexose monophosphate shunt (see Fig. 45-12).[207]

Within the cell are several other antioxidants.[186,188] These include water-soluble cytoplasmic antioxidants (e.g., ascorbate [vitamin C]), and fat-soluble membrane-associated antioxidants (e.g., α-tocopherol [vitamin E]), beta-carotene, and ubiquinol. Vitamin E, one of the most important of the nonenzymatic antioxidants, partitions into and protects lipid membranes.[205] Vitamin E is particularly effective against O_2^-, OH·, and blocks propagation of lipid peroxidation by scavenging peroxy free radicals.[188]

The human lung expresses several other enzymes capable of inactivating H_2O_2,[186] including the thioredoxin–thioredoxin reductase system, thioredoxin peroxidases (peroxiredoxins), and glutaredoxins.[208–210]

Other nonenzymatic antioxidants include glutathione, surfactant protein D, albumin, and proteins that bind iron and copper (powerful promoters of oxidative damage) such as transferrin, ferritin, ceruloplasmin, and lactoferrin.[186] Others include urate and bilirubin.[190]

DIAGNOSIS AND MANAGEMENT OF PULMONARY OXYGEN TOXICITY

Diagnosis

At present, there is no clinically useful means of diagnosing pulmonary O_2 toxicity in patients. Such a diagnostic capability would be most useful is ARDS. Physiologic indexes of pulmonary function (e.g., decrements in vital capacity), require patient cooperation and specialized equipment. But their greatest limitation is that in patients

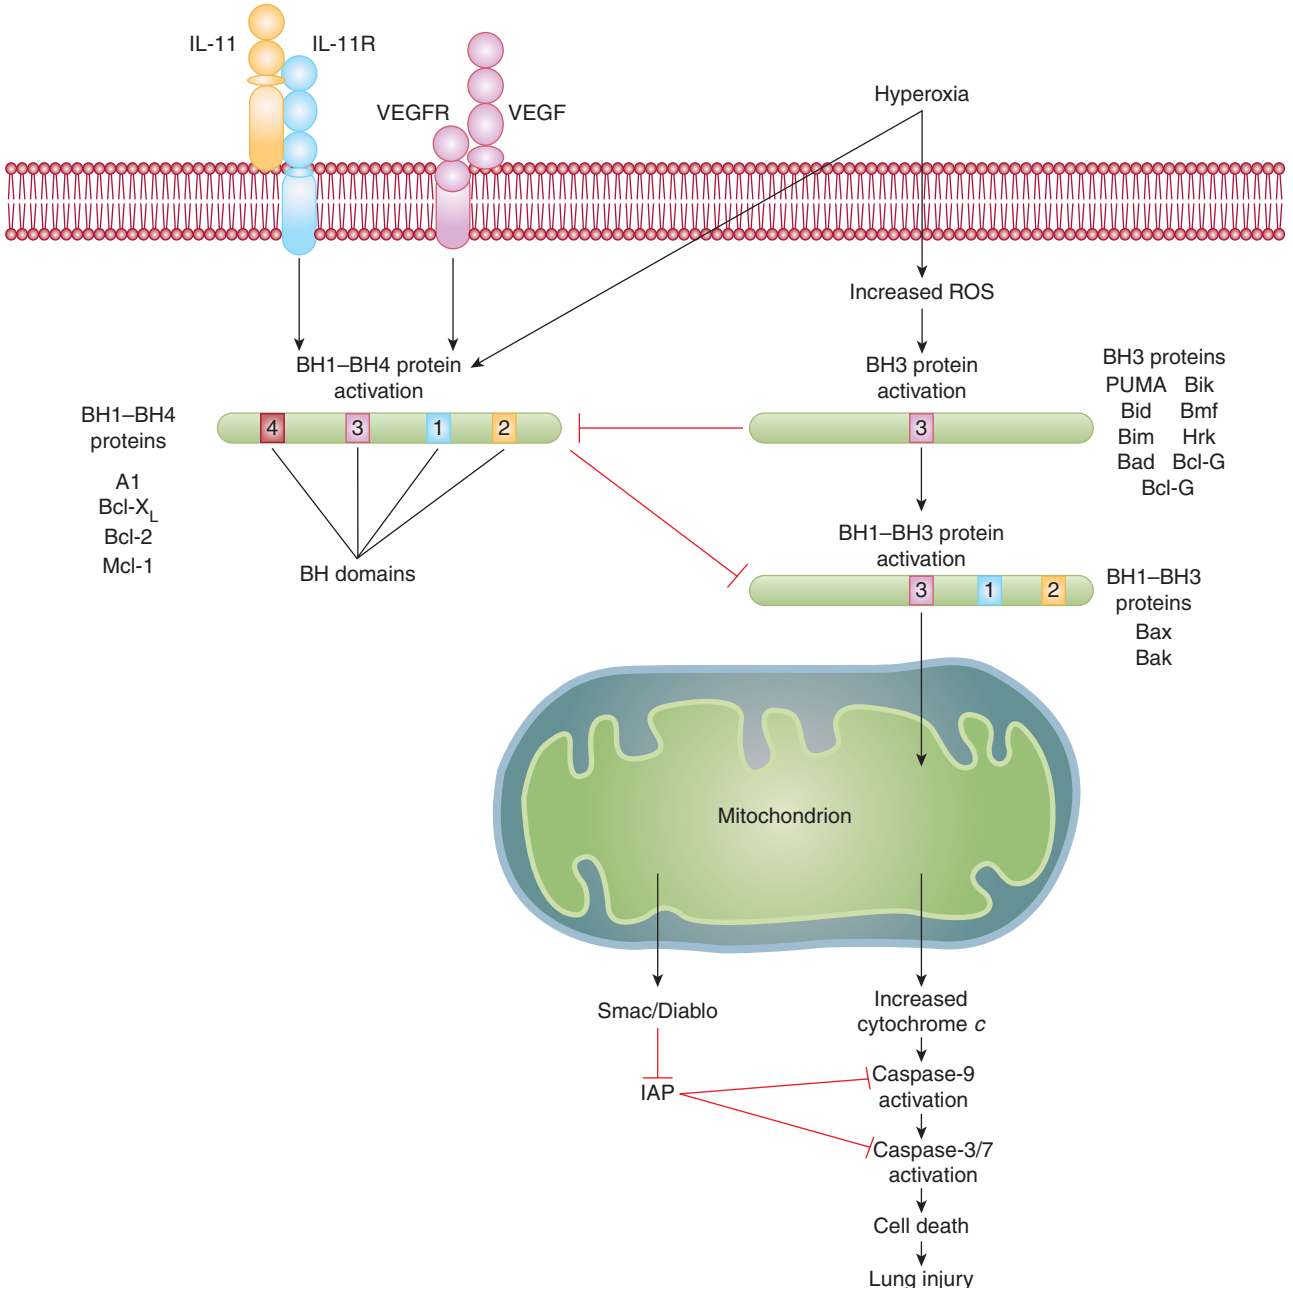

FIGURE 45-14 Schematic of the intrinsic or mitochondrial apoptosis pathway by which hyperoxia is postulated to cause cell death and lung injury. Cytokines, such as interleukin (IL)-11 and vascular endothelial growth factor (VEGF), and hyperoxia itself, upregulate the activity of A1, a member of the antiapoptotic Bcl-2 family of proteins. A1 downregulates the activity of the proapoptotic proteins BAX and BAK and thereby ameliorates the damage from hyperoxia. See text for details. *IAP*, inhibitors of apoptosis; *IL-11R*, interleukin-11 receptor; *PUMA*, p53 upregulated modulator of apoptosis; *ROS*, reactive oxygen species; *VEGFR*, vascular endothelial growth factor receptor. (Used, with permission, from Budinger and Sznajder.[201])

with ARDS such tests cannot distinguish between progressive O_2 toxicity and progression of the underlying cardiopulmonary condition. Chest radiographs also share this diagnostic limitation. Indexes of the lung's ability to metabolize biogenic amines (e.g., serotonin), polypeptides (e.g., by angiotensin-converting enzyme), and prostaglandins are sensitive in experimental animals but their use in critically ill patients is limited by their lack of specificity, dependence on capillary surface area and transit time, and the production by the injured lung of related compounds.[25] The pathology of pulmonary O_2 toxicity, diffuse alveolar damage, is a nonspecific (albeit clearly identifiable) pattern seen in ARDS from any cause. The sophisticated study by Montgomery et al,[80] which examined solute permeability of the lung, indexes of systemic toxicity, and pulmonary function, demonstrated that there is no better index

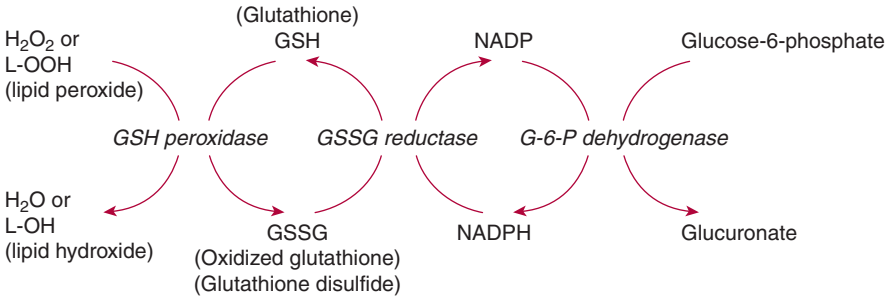

FIGURE 45-15 The glutathione (*GSH*) oxidation-reduction (redox) cycle and its pivotal role in the reduction of toxic intracellular hydroperoxides, including hydrogen peroxide and lipid peroxides. The key enzyme in the GSH redox cycle is *GSH peroxidase*, a predominantly cytosolic enzyme that requires reduced GSH as a substrate. Regeneration of reduced GSH by *GSSG reductase*, which is tightly bound to GSH peroxidase, requires nicotinamide adenine dinucleotide phosphate (NADPH), which is supplied by *G-6-P dehydrogenase* in the hexose monophosphate shunt.

of O_2 toxicity than the individual's subjective symptoms of retrosternal pain suggestive of acute tracheobronchitis. Studies such as theirs suggest that critical care physicians should maintain a heightened awareness and seek out such symptoms in patients on high levels of O_2 and include the possibility of pulmonary O_2 toxicity in the differential diagnosis of chest pain in such patients.

Exogenous Antioxidant Therapy for the Lung

The many approaches that have been taken in efforts to increase pulmonary antioxidant capacity have been reviewed.[188–190,211] The major antioxidant strategies that have been evaluated for the lung include: (a) exogenous administration of normal intracellular enzymatic antioxidants, such as SOD, catalase, and GSH; (b) administration of synthetic antioxidant mimetics; (c) pharmacologic inhibition of free radical generating systems, such as by the iron chelator deferoxamine; (d) supplementation with nonenzyme antioxidants, such as vitamin E, *N*-acetylcysteine, and dietary supplementation with polyunsaturated fatty acid; and (e) agents to prevent the neutrophil-mediated amplification of the hyperoxic injury. All these approaches have been tried in vitro or in animal models, but only a few have been tried in human patients.

Adenovirus-mediated overexpression of MnSOD in mice protects against hyperoxia-induced acute lung injury and lethality[203] and overexpressing ECSOD increases tolerance to hyperoxia.[212,213] In adult baboons exposed to 96 hours of 100% O_2, aerosolized recombinant human (rh) MnSOD improved oxygenation and alveolar epithelial histology, and decreased lung edema.[214,215] Because in these latter reports the MnSOD was found extracellularly, Asikainen and White[190] speculated that the beneficial effect of rhMnSOD may have been scavenging ROS generated by activated inflammatory cells. In premature human infants, intratracheal rhCuZnSOD did not change the 28-day mortality or the incidence bronchopulmonary dysplasia.[216,217] Among the surviving infants, however, those who had been treated with rhCuZnSOD had less frequent acute respiratory events (asthma medication requirements, emergency department visits, and hospitalizations) over the first year of life.[217]

Synthetic SOD-mimetic (catalytic) antioxidants have been studied,[188,190] particularly the metalloporphyrins. They are highly active, stable, potentially nontoxic, and protect against ROS-mediated lung injury in experimental models.[190] They scavenge superoxide, hydrogen peroxide, and peroxynitrite, and inhibit lipid peroxidation.[218] In a fetal baboon model of bronchopulmonary dysplasia, the catalytic antioxidant metalloporphyrin AEOL 10113, given by continuous intravenous infusion, improved histology and proinflammatory mediators, but not oxygenation.[111]

A number of studies have been carried out in effort to enhance the GSH-dependent antioxidant capacity of the lung. *N*-acetylcysteine readily crosses into cells and, by undergoing deacetylation, forms cysteine, the rate-limiting amino acid in GSH biosynthesis. *N*-acetylcysteine acts both by directly reducing O_2^-, H_2O_2, OH·, and HOCl (hypochlorous acid), and by supporting GSH synthesis.[219] Its clinical use is well established in the treatment of acetaminophen-induced hepatotoxicity.[220] In animal studies,[221–226] *N*-acetylcysteine protects against oxidant lung injury. In human studies, however, disappointingly, a half dozen clinical trials of *N*-acetylcysteine in critically ill patients with acute lung injury, ARDS, or multiple organ failure have failed to show benefit in survival or oxygenation.[227–231] In 1998, a clinical trial with procysteine in patients with acute lung injury or ARDS was stopped for lack of efficacy.[232] In very-low-birth-weight infants, supplementation of selenium (required for glutathione peroxidase) also failed to improve outcome.[233]

Lisofylline, an antiinflammatory compound that modulates the metabolism of lipids, including the proinflammatory linoleic acid, showed promise in preclinical studies but failed to show beneficial effects in a randomized controlled trial of 235 patients with acute lung injury or ARDS.[234]

Clinical trials of vitamin E supplementation failed to prevent bronchopulmonary dysplasia in premature newborns[235] or hyperoxic lung injury in neonates.[236] In contrast, vitamin A supplementation slightly decreased the incidence of bronchopulmonary dysplasia in extremely-low-birth-weight

infants.[237] In adult critically ill surgical patients, the combination of vitamins E and C reduced the incidence of organ failure and length of stay in the intensive care unit.[238]

Newborn rats have increased survival during hyperoxic challenge after dietary supplementation with polyunsaturated fatty acid (PUFA), including n-6 PUFA (linoleic and arachidonic acid, from safflower oil),[239] n-3 PUFA (eicosapentaenoic and docosahexaenoic acid; from fish oil),[240] and enteral Intralipid (commercial combination n-6 and n-3 PUFA; from soybean oil).[241] In ARDS, the combination of vitamins E and C plus fish oil (eicosapentaenoic acid) and borage oil (γ-linolenic acid) improved pulmonary neutrophil recruitment, gas exchange, requirement for mechanical ventilation, length of intensive care unit stay, and number of new organ failures.[242] A retrospective analysis of a subset of only forty-three of these patients[243] reported that the twenty-one treated patients had decreased levels of interleukin-8, leukotriene B_4, and neutrophils in bronchoalveolar lavage fluid, and decreased alveolar–capillary membrane permeability. A more recent randomized controlled trial in 100 patients with acute lung injury, reported that, compared to standard diet alone, adding eicosapentaenoic acid plus γ-linolenic acid and antioxidants improved oxygenation, compliance, and time on mechanical ventilation, but not mortality.[244] In a randomized controlled trial of 165 mechanically ventilated patients with severe sepsis, this same dietary intervention improved oxygenation, time on mechanical ventilation, occurrence of new organ dysfunctions, time in the intensive care unit, and mortality.[245] More recently, the ARDS Network OMEGA trial of enteral omega-3 (N-3) fatty acids, γ-linolenic acid, and antioxidants was stopped for futility after enrolling 272 acute lung injury patients, with a 60-day adjusted mortality of 24.6% versus 17.9% in control patients.[246]

In premature baboons the iron chelator deferoxamine to prevent hyperoxic lung injury (by inhibiting iron-catalyzed ROS generation) resulted in rapid cardiovascular collapse and death (<42 hours) in all animals.[247]

Another approach at lung protection from hyperoxic injury is to block neutrophil accumulation in the lung and thereby block further amplification and propagation of ROS-mediated injury.[188] Such blockade can be achieved by antibodies directed against cytokine-induced neutrophil chemoattractant-1 (CINC-1), which is the major rat neutrophil chemoattractant cytokine, or chemokine.[248] This antibody, given intraperitoneally in a newborn-rat model of bronchopulmonary dysplasia, prevented neutrophil influx and preserved lung compliance, alveolar development, and lung cell proliferation.[248] Neutrophil influx can also be prevented by blocking the receptor, CXCR2, through which the chemokines act. In the same rat model, Auten et al[249] showed that a competitive antagonist (SB-265610, a nonpeptide) of this chemokine receptor also prevented hyperoxia-induced neutrophil accumulation. Recent studies also show that other chemokines, including interleukin-8 and monocyte chemoattractant protein-1, play important roles in neutrophil attraction to the lung[188,250] and are potential therapeutic targets. Mercer and Crapo[188] pointed out that the neutrophil-blocking approach and the ECSOD-enhancement approach appear to be complementary. That is, ECSOD enhancement protects against direct oxidant injury and neutrophil blockade prevents injury in areas not well protected by the enhanced ECSOD.

Several other experimental approaches have been investigated and reviewed in detail by Asikainen and White,[190] including catalytic antibodies, lazaroids, and novel approaches involving transcription factors, signaling pathways, DNA repair mechanisms, and growth factors. Despite their promise, none has yet been shown to be effective in humans.

Induction of Tolerance to Hyperoxia

In 1978, Frank et al[251] made the fortuitous discovery that endotoxin fully protected rats from hyperoxic morbidity and mortality. Similar results had been reported earlier following other toxic insults to the lung, including oleic acid,[252] α-naphthylthiourea,[253] and diphosgene,[78] all of which were reported to increase survival on subsequent exposure to hyperoxia. Frank et al[251] also showed that endotoxin induced increases in SOD, catalase, and glutathione peroxidase. They speculated that in patients with acute respiratory failure ("for example… hyaline membrane disease," or infant respiratory distress syndrome), coincident gram-negative infection may modulate the toxic effects of therapeutic hyperoxia.[251]

In animals, other challenges that are protective against the lethality of subsequent exposure to hyperoxia include sublethal hyperoxia,[254,255] hypoxia (in the absence of hypercarbia),[256,257] and the combination of tumor necrosis factor-α and interleukin-1.[258] Tumor necrosis factor-α and interleukin-1 are proinflammatory cytokines that mediate much of the pathophysiology of endotoxin.[197,259,260] In rats the protective effects of each of these pretreatments can be explained by the induction of SOD, catalase, and glutathione peroxidase.[251,254,257,261] The protective effect, however, may also occur in the absence of antioxidant enzyme induction. In the study by White et al,[261] the induction of the antioxidant enzymes induced by pretreatment with tumor necrosis factor-α plus interleukin-1 occurred relatively late (after 72 hours), after all control rats had already died. These authors suggested that the mechanisms of the lung protection may include, in addition to enzyme induction, the recruitment to the lung of more resistant cell lines.[261] Baker et al[255] showed that the protective effect of preexposure to sublethal hyperoxia in adult rabbits, unlike that in neonatal rabbits[262] and rats, is not accompanied by an increase in antioxidant enzymes; it may be explained, instead, by the observed increase in endogenous surfactant induced by the preexposure to hyperoxia.[255] More recently, additional mechanisms to explain the ameliorating effects on lung injury of cytokines or preexposure to hyperoxia have been provided by He et al[200] (see Fig. 45-14 and "Cell Death by Hyperoxia: Apoptosis and Necrosis" above).

The clinical relevance of these observations is obvious. Critically ill patients with acute respiratory failure are commonly exposed to such "pretreatments," namely, hyperoxia, hypoxia, endotoxin, and (endogenous) tumor necrosis factor-α and interleukin-1. Additionally, as part of routine nutritional support, these patients commonly receive nutritional supplementation with polyunsaturated fatty acid, as discussed above.

Exogenous Surfactant Administration

Surfactant is discussed in detail in Chapter 60 and is reviewed elsewhere.[263,264] Endogenous surfactant is a complex mixture of approximately 85% to 90% phospholipids, 7% to 10% apoproteins (surfactant proteins A, B, C, and D), and 4% to 7% neutral lipids.[263] Its primary function is to reduce the otherwise high liquid-gas surface tension within the alveoli and thereby decrease their tendency to collapse. Hyperoxia impairs surfactant function.[265] Both ROS and RNS degrade surfactant, particularly the surfactant proteins, but the damage from RNS, especially peroxynitrite, appears more important.[263] In most species, despite its impairment of surfactant function, hyperoxia also induces surfactant synthesis.[255,266,267] Endogenous surfactant has intrinsic antioxidant activity,[268,269] can enhance intracellular antioxidant enzyme content,[268] and in animal models, protects from hyperoxic lung injury and death.[64,268,270]

Exogenous surfactants vary significantly in their composition.[264] They also have antioxidant activity[271] and in animal models, protect against hyperoxic lung injury and death.[271–274] After administration of exogenous surfactant (Curosurf), human preterm infants with respiratory distress syndrome show enhanced SOD and catalase activity in the tracheobronchial secretions.[275]

Exogenous surfactant therapy is now standard in neonatal intensive care units.[264,276] A number of clinical trials in young patients have reported beneficial outcomes in newborns with respiratory distress syndrome,[276–280] in infants with acute respiratory failure caused by respiratory syncytial virus,[281] and in children with hypoxemic acute respiratory failure.[282] In contrast, in adult patients with ARDS, the results have been disappointing.[264] A trial of 725 adult patients with sepsis-induced ARDS using surfactant (Exosurf) found no benefit.[283,284] The failure of this trial may be related in part to differences in both the surfactant constitutions and the delivery systems, between the neonatal-pediatric trials and the adult trials.[264] Very recently, a trial of recombinant surfactant protein C-based surfactant in 843 adult patients with severe direct lung injury again showed no clinical benefit, perhaps related to insufficient surface activity.[285,286]

Minimization of Oxygen Toxicity in the Intensive Care Unit

Ironically, in several ways the disease process of ARDS itself would seem to provide some degree of protection against hyperoxic injury. First, the alveolar epithelial and endothelial cells in the areas of shunt (presumably the areas of greatest injury) have, by definition, relatively low values of P_{O_2}, similar to the P_{O_2} of the mixed venous blood, and thus are not directly exposed to hyperoxia. Second, in ARDS the systemic circulation is also protected from hyperoxia because, by definition, this syndrome is characterized by systemic arterial hypoxemia. Third, the pathophysiology of ARDS and its management include exposure to hyperoxia, hypoxia, endogenous cytokines such as tumor necrosis factor-α and interleukin-1,[287,288] and, commonly, endotoxin.[287,288] However, as discussed above, prior exposure to each of these agents induces in animals tolerance and protection against future exposure to hyperoxia. Thus, patients who survive the initial insult of ARDS may be better able to withstand ongoing hyperoxic exposure. Fourth, the intraalveolar hemorrhage and exudation of plasma that is characteristic of ARDS (see discussion of pathology above) provides erythrocytes rich in antioxidant enzyme capacity, as noted above, and plasma proteins with substantial antioxidant activities. In fact, bronchoalveolar lavage fluid from ARDS patients possesses greater antioxidant activity than bronchoalveolar lavage fluid from normal subjects, largely as a result of the plasma proteins transferrin and ceruloplasmin.[289]

Once the possibility of pulmonary O_2 toxicity is considered (generally in an ARDS patient requiring $FI_{O_2} \geq 0.60$ for >24 to 48 hours), the only accepted treatment clinically at present is to reduce the FI_{O_2} to lowest level consistent with adequate systemic oxygenation. This goal should be approached by first minimizing excess O_2 demand (e.g., secondary to fever, infection, anxiety, pain, or "fighting the ventilator" with the judicious use of antipyretics,[290] antimicrobials, sedatives, analgesics, or neuromuscular blocking agents,[291] respectively). Second, one should optimize all other determinants of systemic oxygenation, such as hemoglobin concentration, by using a restrictive strategy of red blood cell transfusion,[292,293] and overall respiratory and cardiovascular status.[294]

As discussed in detail in other chapters, the best principles and practice of mechanical ventilation should be applied. These would include optimizing positive end-expiratory pressure, tidal volume, and plateau pressure using an open-lung or lung-protective ventilation strategy,[2] consideration of alternative modes of ventilation (e.g., high-frequency ventilation), prone ventilation,[295] inhaled NO, extracorporeal membrane oxygenation, and so on.

Complicating conditions interfering with oxygenation should be meticulously sought out and treated. These conditions may include superimposed nosocomial pneumonia, excessive secretions, bronchospasm, occult pneumothorax and other parenchymal ventilator-induced lung injury, inadvertent intubation of a mainstem bronchus, occult large posterior pleural effusions, cardiopulmonary shunts unrelated to parenchymal lung injury (e.g., patent foramen ovale[296]), pulmonary emboli, cor pulmonale, low cardiac output, and hydrostatic-pressure pulmonary edema (elevated pulmonary arterial wedge pressure). Hydrostatic-pressure pulmonary edema should be minimized by adopting a conservative

strategy of fluid management[297] and considering, in the hypoproteinemic patient, albumin plus furosemide therapy, which can improve fluid balance, oxygenation, and hemodynamics.[298] Inotropic agents (e.g., dobutamine) should be considered as a possible means of decreasing the pulmonary arterial wedge pressure (and thus the hydrostatic gradient for pulmonary edema formation) while maintaining or increasing cardiac output. Supranormal cardiac indices, however, should be avoided.[299,300]

After the above concerns have been adequately addressed, the FI_{O_2} should be adjusted to the lowest value required to maintain the arterial saturation within an acceptable range (e.g., 88% to 95%[2]). (Mountain climbers tolerate Pa_{O_2} of 28 torr for brief periods[301] and Sa_{O_2} of 73% to 85% for at least 4 days including with exercise.[302,303]) Although the treatment of ARDS is largely supportive, treatment should, of course, be given for the underlying disease that may have produced the ARDS, particularly, if it is infection. In especially difficult patients with ARDS and refractory hypoxemia requiring sustained high levels of inspired O_2, the clinician may be faced with the very difficult task of choosing among (a) accepting a lower level of arterial oxygenation, (b) increasing the already high airway pressures and risking ventilator-induced lung injury, and (c) continuing or even increasing the already high FI_{O_2}. In these very difficult cases it seems prudent to keep in mind that, based on information to date, the known immediate risks of systemic hypoxemia or ventilator-induced lung injury are clearly more established and devastating than the potential future risk of hyperoxia-induced lung injury. That is, the priorities should be, in order of their vital importance: (a) maintenance of arterial oxygenation; (b) avoidance of ventilator-induced lung injury; and (only then) (c) avoidance of high inspired O_2 fractions.

IMPORTANT UNKNOWNS AND THE FUTURE

The most important unknown is the optimum inspired O_2 fraction to use in ARDS. Remarkably, the answer is still unknown more than four decades after ARDS was defined.[304] Other unknowns concern the relationship between O_2 toxicity and ventilator-induced lung injury. These two entities have in common that both are a concern in acute respiratory failure, both share mechanisms of injury, and both initiate their injury in the lung but cause death from systemic multiorgan organ failure more than from their pulmonary injury. Future work should resolve their relative importance in acute lung injury: Are they independent or synergistic forces? Will therapy for one also be therapeutic for the other? In ARDS would there be further benefit in keeping the FI_{O_2} higher than usually done (e.g., near 100%) and thereby allowing use of an even more aggressive lung-protective strategy (that is, even lower tidal volumes and plateau pressures than those targeted in the ARDS Network trial)?[2] Future research should resolve how optimally to trade off the risks of hypoxemia, ventilator-induced lung injury, and O_2 toxicity. This trade-off will be facilitated when more specific markers of O_2 toxicity become available.

The degree to which patients with ARDS have induction of tolerance to hyperoxia (by preexisting hyperoxia, hypoxia, endotoxin, and cytokines; see above) is unknown. This induction could be manipulated to optimize a patient's antioxidant defenses. The potential benefit of combining two or more complementary therapies, for example, neutrophil blocking plus ECSOD enhancement,[188] are yet to be explored. Novel therapies, like activated protein C, which has been successful uniquely in severe sepsis,[305] give hope that similar results can be achieved in ARDS and O_2 toxicity. Other proposed novel approaches involve transcription factors, signaling pathways, DNA repair mechanisms, and growth factors.[190] One of the most promising and recent approaches is to directly inhibit activation of the oxidant-mediated intrinsic apoptotic pathway of cell death (see Fig. 45-14).[200–203]

SUMMARY AND CONCLUSION

More than two centuries after his discovery of O_2, Priestley seems remarkably prescient regarding oxygen's medical and toxic potential. O_2 is now recognized as lifesaving in patient conditions ranging from ambulatory to critically ill. The enormous expansion of knowledge about its biochemistry, physiology, and toxicology has relevance throughout all of biology. Continuing growth in our understanding of this "vital air" of Lavoisier is vital to continuing improvement in the care and safety of patients.

PNEUMONIA IN THE VENTILATOR-DEPENDENT PATIENT

Jean E. Chastre
Charles-Edouard Luyt
Jean-Yves Fagon

Ventilator-associated pneumonia (VAP) is the most frequent intensive care unit (ICU)-acquired infection among patients receiving mechanical ventilation.[1] In contrast to infections of other frequently involved organs (e.g., urinary tract and skin), for which mortality is low, ranging from 1% to 4%, the mortality rate for VAP, defined as pneumonia occurring more than 48 hours after endotracheal intubation and initiation of mechanical ventilation, ranges from 20% to 50% and can even be higher in some specific settings or when lung infection is caused by high-risk pathogens.[1–3] Although the attributable mortality rate for VAP is still debated, it has been shown that these infections prolong both the duration of ventilation and the duration of ICU stay.[1,2] Approximately 50% of all antibiotics prescribed in an ICU are administered for respiratory tract infections.[4] Because several studies have shown that appropriate antimicrobial treatment of patients with VAP significantly improves outcome, more rapid identification of infected patients and accurate selection of antimicrobial agents represent important clinical goals.[2] Consensus, however, on appropriate diagnostic, therapeutic, and preventive strategies for VAP has yet to be reached. In this chapter, we summarize published studies on epidemiology, diagnosis, treatment, and prevention of nosocomial pulmonary infection in critically ill patients mechanically ventilated in the ICU, and present our experience with this infection.

EPIDEMIOLOGY

Accurate data on the epidemiology of VAP are limited by the lack of standardized criteria for its diagnosis. Conceptually, VAP is defined as an inflammation of the lung parenchyma caused by infectious agents not present or incubating at the

time mechanical ventilation was started. Despite the clarity of this conception, the past three decades have witnessed the appearance of numerous operational definitions, none of which is universally accepted. Even definitions based on histopathologic findings at autopsy may fail to find consensus or provide certainty. Pneumonia in focal areas of a lobe may be missed, microbiologic studies may be negative despite of presence of inflammation in the lung, and pathologists may disagree on the findings.[5] The absence of a "reference standard" continues to fuel controversy about the adequacy and relevance of many studies in this field.

Incidence of Ventilator-Associated Pneumonia

The exact incidence varies widely depending on the case definition of pneumonia and the population being evaluated.[6–10] All studies, however, have confirmed that nosocomial pneumonia is considerably more frequent in ventilated patients than in other ICU patients, with an incidence increasing by as much as sixfold to 20-fold in this subset of patients.[11,12] VAP occurs in 9% to 27% of all intubated patients and its incidence increases with duration of ventilation.[10,13] The risk of VAP is highest early in the course of hospital stay and is estimated to be 3% per day during the first 5 days of ventilation, 2% per day during days 5 to 10 of ventilation, and 1% per day beginning from day 11.[13] Because most mechanical ventilation is short term, approximately half of all episodes of VAP occur within the first 4 days of mechanical ventilation. In a large epidemiologic study, independent predictors of VAP retained by multivariable analysis were a primary admitting diagnosis of burns, trauma, central nervous system disease, respiratory disease, cardiac disease, mechanical ventilation during the preceding 24 hours, witnessed aspiration, and use of paralytic agents. Exposure to antibiotics conferred protection, but this effect was attenuated over time.[13] According to four studies, the VAP rate was higher in patients with acute respiratory distress syndrome (ARDS) than other ventilated patients, affecting between 34% and more than 70% of patients with ARDS and often leading to the development of sepsis, multiorgan failure, and death.[14–17]

Mortality, Morbidity, and Cost

Mechanically ventilated patients in the ICU with VAP appear to have a twofold to 10-fold higher risk of death as compared with patients without pneumonia. Although these statistics indicate that VAP can be lethal, previous studies have not demonstrated clearly that pneumonia is responsible for the higher mortality rate of these patients.[18] It is often difficult to determine whether ICU patients with severe underlying illness would have survived if VAP had not occurred. VAP, however, has been recognized in several case-controlled studies or studies using multivariate analysis as an important prognostic factor for different groups of critically ill patients.[18–23]

Other factors beyond the simple development of VAP, such as the severity of the disease, the responsible pathogens, or the appropriateness of initial treatment, may be more important determinants of outcome for patients in whom pneumonia develops.[24] Indeed, it may be that VAP increases mortality only in the subset of patients with intermediate severity of illness,[23] when initial treatment is inappropriate,[25–32] and/or in patients with VAP caused by high-risk pathogens, such as *Pseudomonas aeruginosa*.[24,33] Patients with very low severity and early onset pneumonia caused by organisms such as *Haemophilus influenzae* or *Streptococcus pneumoniae* have excellent prognoses with or without VAP, whereas very ill patients with late-onset VAP, occurring while they are in a quasi-terminal state, would be unlikely to survive. Using a multistate progressive disability model that appropriately handled VAP as a time-dependent event in a high-quality database of 2873 mechanically ventilated patients, Nguile-Makao et al showed that VAP attributable mortality was 8.1% overall, varying widely with case mix, severity at admission, time to VAP onset, and severity of organ dysfunction at VAP onset.[24] These results are consistent with the 10.6% value obtained in five German ICUs using also a multistate model progressive disability model.[34]

It is impossible to evaluate precisely the morbidity and excess costs associated with VAP. All studies, however, have shown clearly that patients with VAP have prolonged duration of mechanical ventilation and lengthened ICU and hospital stay as compared with patients who do not have VAP.[1,2,35,36] Summarizing available data, VAP appears to extend the ICU stay by at least 4 to 6 days, with the attributable ICU length of stay being longer for medical than surgical patients and for patients infected with "high-risk" as opposed to "low-risk" organisms.[37] The prolonged hospitalization of patients with VAP underscores the considerable financial burden imposed on the health care system by the development of VAP.[10,35,36,38–41]

Etiologic Agents

Microorganisms responsible for VAP differ according to the population of ICU patients, the durations of hospital and ICU stays, and the specific diagnostic method(s) used to establish the responsible pathogens. A number of studies have shown that gram-negative bacilli cause many of the respiratory infections in this setting.[1,2,42,43] The data from twenty-four studies conducted on ventilated patients, for whom bacteriologic studies were restricted to uncontaminated specimens obtained using a protected specimen brush (PSB) or bronchoalveolar lavage (BAL), confirmed these results: gram-negative bacilli represented 58% of recovered organisms (Table 46-1).[1] The predominant gram-negative bacilli were *P. aeruginosa* and *Acinetobacter* spp., followed by *Proteus* spp., *Escherichia coli*, *Klebsiella* spp., and *H. influenzae*. A relatively high rate of gram-positive pneumonias was also reported in those studies, with *Staphylococcus aureus*

involved in more than 20% of the cases.[42] Many episodes of VAP are caused by multiple pathogens.[1,44]

Underlying diseases may predispose patients to infection with specific organisms. Patients with chronic obstructive pulmonary disease are at increased risk for *H. influenzae, Moraxella catarrhalis,* or *S. pneumoniae* infections; cystic fibrosis increases the risk of *P. aeruginosa* and/or *S. aureus* infections, while trauma and neurologic disease increases the risk for *S. aureus* infection. Furthermore, the causative agent for pneumonia differs among ICU surgical populations, with 18% of the nosocomial pneumonias caused by *Haemophilus* or pneumococci, particularly in patients with trauma, but not in patients with malignancy or who underwent transplantation, abdominal, or cardiovascular surgery.[1,2]

Despite somewhat different definitions of early onset pneumonia, varying from onset of less than 3 days to less than 7 days, high rates of *H. influenzae, S. pneumoniae*, methicillin-susceptible *Staphylococcus aureus* (MSSA) or susceptible Enterobacteriaceae were constantly found in early onset VAP, whereas *P. aeruginosa*, *Acinetobacter* spp., methicillin-resistant *Staphylococcus aureus* (MRSA), and multiresistant gram-negative bacilli were significantly more frequent in late-onset VAP.[1] The different pattern of distribution of etiologic agents between early- and late-onset VAP is linked to prior antimicrobial therapy in many patients with late-onset VAP. When multivariate analysis was used to identify risk factors for VAP caused by potentially drug-resistant bacteria such as MRSA, *P. aeruginosa, Acinetobacter baumannii*, and/or *Stenotrophomonas maltophilia* in 135 consecutive episodes of VAP, only three variables remained significant: mechanical ventilation duration of longer than 7 days before onset of VAP, prior antibiotic use, and prior use of broad-spectrum drugs (third-generation cephalosporins, fluoroquinolones, and/or imipenem).[45] Not all studies have confirmed this distribution pattern, and in some studies the most common pathogens associated with early onset VAP were *P. aeruginosa*, MRSA, and *Enterobacter* spp., with similar pathogens associated with late-onset VAP.[46,47] These findings might be explained in part by prior hospitalization and the use of antibiotics before transfer to the ICU.

The incidence of multiresistant pathogens is also closely linked to local factors and varies widely from one institution to another. Consequently, each ICU has to continuously collect meticulous epidemiologic data.[48] Clinicians must clearly be aware of the common microorganisms associated with both early-onset and late-onset VAP in their own hospitals so as to avoid the administration of initial inadequate antimicrobial therapy.

Legionella species, anaerobes, and even *Pneumocystis jiroveci* should be mentioned as potential causative agents, but these microbes are not commonly found when pneumonia is acquired during mechanical ventilation. Herpesviridae, namely herpes simplex virus, can be detected in the lower respiratory tracts of 5% to 64% of ICU patients, depending on the population and the diagnostic method used. In most cases, herpes simplex virus recovery from lower respiratory tract samples of nonimmunocompromised ventilated patients corresponds to viral contamination from the mouth and/or throat. For some patients, however, real herpes simplex virus bronchopneumonitis can develop, and it can evolve into ARDS and/or facilitate the occurrence of bacterial superinfection.[49–51] Cytomegalovirus-induced pneumonia is a rare event in ventilated patients. As for herpes simplex virus bronchopneumonitis, it is impossible to know whether cytomegalovirus detection in the lower respiratory tract is merely a marker of disease severity or signals real disease with its own morbidity and mortality.[52–55]

Isolation of fungi, most frequently *Candida* species, at significant concentrations poses interpretative problems. Invasive disease has been reported in VAP but yeasts are isolated more frequently from respiratory tract specimens in the absence of apparent disease, even when retrieved at high concentrations from bronchoscopic specimens.[56–60] Thus, based on current data, the presence of yeasts in respiratory secretions obtained from nonimmunosuppressed ventilated patients usually indicates colonization rather than infection of the respiratory tract and does not justify by itself a specific antifungal therapy. Evidence of lung tissue invasion is needed for making the diagnosis of *Candida* pneumonia in such a setting. Interactions, however, between *Candida* and bacteria, particularly *Pseudomonas*, have been reported, and colonization of the respiratory tract by yeasts may predispose to bacterial VAP.[61–64]

By examining currently available data, the clinical significance of anaerobes in the pathogenesis and outcome of VAP remains unclear except as etiologic agents in patients with necrotizing pneumonitis, lung abscess, or pleuropulmonary infections. Anaerobic infection and coverage with antibiotics, such as clindamycin or metronidazole, should probably also be considered for patients with respiratory secretions documenting numerous extracellular and intracellular microorganisms after Gram staining in the absence of positive cultures for aerobic pathogens.

PATHOGENESIS AND PREDISPOSING FACTORS

Pneumonia results from microbial invasion of the normally sterile lower respiratory tract and lung parenchyma caused by either a defect in host defenses, a challenge by a particularly virulent microorganism, or an overwhelming inoculum. The normal human respiratory tract possesses a variety of defense mechanisms that protect the lung from infection. Examples include anatomic barriers, such as the glottis and larynx; cough reflexes; tracheobronchial secretions; mucociliary lining; cell-mediated and humoral immunity; and a dual phagocytic system that involves both alveolar macrophages and neutrophils.[1] When these coordinated components function properly, invading microbes are eliminated and clinical disease is avoided. When these defenses are impaired, however, or if they are overcome by virtue of a high inoculum of organisms or organisms of unusual virulence, pneumonitis may result.

As suggested by the infrequent association of VAP with bacteremia, most of these infections appear to result from aspiration of potential pathogens that have colonized the mucosal surfaces of the oropharyngeal airways. Intubation of the patient not only compromises the natural barrier between the oropharynx and trachea, but may also facilitate the entry of bacteria into the lung by pooling and leakage of contaminated secretions around the endotracheal tube cuff.[65] This phenomenon occurs in most intubated patients, whose supine position may facilitate its occurrence. In previously healthy, newly hospitalized patients, normal mouth flora or pathogens associated with community-acquired pneumonia may predominate. In sicker patients who have been hospitalized more than 5 days, gram-negative bacilli and *S. aureus* frequently colonize the upper airway.[66]

Uncommonly, VAP may arise in other ways. Observed "macroaspirations" of gastric material initiate the process in some patients. Allowing condensates in ventilator tubing to drain into the patient's airway may have the same effect. Fiber-optic bronchoscopy, tracheal suctioning, or manual ventilation with contaminated equipment may also bring pathogens to the lower respiratory tract. More recently, concerns have focused on the potential role of contaminated inline medication nebulizers, but these devices are infrequently associated with VAP.

Risk factors for tracheobronchial colonization with gram-negative bacilli appear to be the same as those that favor pneumonia and include more severe illness, longer hospitalization, prior or concomitant use of antibiotics, malnutrition, intubation, azotemia, and underlying pulmonary disease.[67] Experimental investigations have linked some of these risk factors to changes in adherence of gram-negative bacilli to respiratory epithelial cells. Although formerly attributed to losses of cell-surface fibronectin, these changes in adherence more likely reflect alterations of cell-surface carbohydrates. Bacterial adhesins and prior antimicrobial therapy appear to facilitate the process. Interestingly, Enterobacteriaceae usually appear in the oropharynx first, whereas *P. aeruginosa* more often appears first in the trachea.[68]

Other sources of pathogens causing VAP include the paranasal sinuses, dental plaque, and the subglottic area between the true vocal cords and the endotracheal tube cuff. Not all authors agree that the gastropulmonary route of infection is truly operative in ICU patients.[69] Progression of colonization from the stomach to the upper respiratory tract with subsequent episodes of VAP could not be demonstrated in several studies and efforts to eliminate the gastric reservoir with antimicrobial therapy without decontaminating the oropharyngeal cavity have generally failed to prevent VAP.[69–71] In fact, there is more than one potential pathway for colonization of the oropharynx and trachea in such a setting, including fecal–oral cross-infection on the hands of health care personnel, and contaminated respiratory therapy equipment. Patient-care activities, such as bathing, oral care, tracheal suctioning, enteral feeding, and the tube manipulations, provide ample opportunities for transmission of pathogens when infection-control practices are substandard.[72]

Risk Factors

Risk factors provide information on the probability of lung infection developing in individuals and populations. Thus, they may contribute to the elaboration of effective preventive strategies by indicating which patients might be most likely to benefit from prophylaxis against pneumonia. Table 46-2 summarizes the independent factors for VAP that were identified by multivariate analyses in selected studies.[13,25,38,73–80]

SURGERY

Postsurgical patients are at increased risk for VAP. In a 1981 report, the pneumonia rate during the postoperative period was 17%.[81] Those authors stated that the development of pneumonia was closely associated with preoperative markers of severity of the underlying disease, such as low serum albumin concentration and a high score on the American Society of Anesthesiologists preanesthesia physical status classification. A history of smoking, longer preoperative stays, longer surgical procedures and thoracic or upper abdominal surgery were also significant risk factors for postsurgical pneumonia. Another study comparing adult

TABLE 46-2: INDEPENDENT FACTORS FOR VENTILATOR-ASSOCIATED PNEUMONIA IDENTIFIED BY MULTIVARIATE ANALYSIS

Host Factors	Intervention Factors
Serum albumin <2.2 g/dL	H_2 blockers ± antacids
Age ≥ 60 years	Paralytic agents, continuous intravenous Sedation
ARDS	
COPD, pulmonary disease	>4 units of blood products
Coma or impaired consciousness	Intracranial pressure monitoring
Burns, trauma	MV >2 days
Organ failure	Positive end-expiratory pressure
Severity of illness	Frequent ventilator-circuit changes
Large-volume gastric aspiration	Reintubation
Gastric colonization and pH	Nasogastric tube
Upper respiratory tract colonization	Supine head position
Sinusitis	Transport out of the ICU
	Prior antibiotic or no antibiotic therapy[a]
	Other factor: Season: fall, winter

Abbreviations: ARDS, acute respiratory distress syndrome; *COPD*, chronic obstructive pulmonary disease; ICU, intensive care unit; *MV*, mechanical ventilation.

[a]See text for explanations.

ICU populations demonstrated that postoperative patients had consistently higher rates of nosocomial pneumonia than did medical ICU patients, with a risk ratio of 2.2.[79] Multiple regression analysis was performed to identify independent predictors of nosocomial pneumonia in the two groups; for surgical ICU patients, mechanical ventilation (>2 days) and Acute Physiology and Chronic Health Evaluation (APACHE) score were retained by the model; for the medical ICU population, only mechanical ventilation (>2 days) remained significant. It has been suggested that different surgical ICU patient populations may have different risks for nosocomial pneumonia: Cardiothoracic surgery and trauma (particularly head trauma) patients were more likely to develop VAP than medical or other types of surgical patients.[13]

ANTIMICROBIAL AGENTS

The use of antibiotics in the hospital setting is associated with an increased risk of nosocomial pneumonia and selection of resistant pathogens.[22,25,45,66,82–85] In a cohort study of 320 patients, prior antibiotic administration was identified by logistic regression analysis to be one of the four variables independently associated with VAP along with organ failure, age greater than 60 years, and the patient's head positioning (i.e., flat on the patient's back or supine vs. head and thorax raised 30 degrees to 40 degrees or semirecumbent).[22] Other investigators, however, found that antibiotic administration during the first 8 days was associated with a lower risk of early onset VAP.[86] For example, Sirvent et al showed that a single dose of a first-generation cephalosporin given prophylactically was associated with a lower rate of early-onset VAP in patients with structural coma.[87] Moreover, multiple logistic regression analysis of risk factors for VAP in 358 medical ICU patients identified the absence of antimicrobial therapy as one of the factors independently associated with VAP onset.[88] Finally, the results of the multicenter Canadian study on the incidence of and risk factors for VAP indicated that antibiotic treatment conferred protection against VAP.[13] This apparent protective effect of antibiotics disappears after 2 to 3 weeks, suggesting that a higher risk of VAP cannot be excluded beyond this point. Thus, risk factors for VAP change over time, thereby explaining why they differ from one series to another.

STRESS-ULCER PROPHYLAXIS

In theory, patients receiving stress-ulcer prophylaxis that does not change gastric acidity, such as sucralfate, should have lower rates of gastric bacterial colonization and, consequently, a lower risk for nosocomial pneumonia, than those receiving antacids or H_2 blockers.[89–90]

According to meta-analyses of the efficacy of stress-ulcer prophylaxis in ICU patients, respiratory tract infections were significantly less frequent in patients treated with sucralfate than those receiving antacids or H_2 blockers.[91,92] This conclusion, however, was not fully confirmed in a very large, multicenter, randomized, blinded, placebo-controlled trial that compared sucralfate suspension (1 g every 6 hours) with the H_2-receptor antagonist ranitidine (50 mg every 8 hours) for the prevention of upper gastrointestinal bleeding in 1200 ventilated patients.[93] Clinically relevant gastrointestinal bleeding developed in ten of the 596 (1.7%) patients receiving ranitidine, as compared with twenty-three of the 604 (3.8%) receiving sucralfate (relative risk [RR], 0.44; 95% confidence interval [CI], 0.21 to 0.92; $p = 0.02$). In the ranitidine group, 114 of 596 (19.1%) patients had VAP, as diagnosed by an adjudication committee using a modified version of the Centers for Disease Control and Prevention criteria, versus ninety-eight of 604 (16.2%) in the sucralfate group (RR, 1.18; 95% CI, 0.92 to 1.51; $p = 0.19$). VAP, however, occurred significantly less frequently in patients receiving sucralfate when the diagnosis of pneumonia was based on Memphis VAP Consensus Conference criteria (if there was radiographic evidence of abscess and a positive needle aspirate, or histologic proof of pneumonia at biopsy or autopsy) ($p = 0.03$).[93]

Sucralfate appears to have a small protective effect against VAP because stress-ulcer prophylactic medications that raise the gastric pH might themselves increase the incidence of pneumonia.[94,95] This contention is supported by direct comparisons of trials of H_2-receptor antagonists versus no prophylaxis, which showed a trend toward higher pneumonia rates among the patients receiving H_2-receptor antagonists (odds ratio [OR], 1.25; 95% CI, 0.78 to 2.00).[91] Furthermore, the comparative effects of sucralfate and no prophylaxis are

unclear. Among 226 patients enrolled in two randomized trials, those receiving sucralfate tended to develop pneumonia more frequently than those given no prophylaxis (OR, 2.11; 95% CI, 0.82 to 5.44).[96,97]

ENDOTRACHEAL TUBE, REINTUBATION, AND TRACHEOTOMY

The presence of an endotracheal tube by itself circumvents host defenses, causes local trauma and inflammation, and increases the probability of aspiration of nosocomial pathogens from the oropharynx around the cuff. Scanning electron microscopy of 25 endotracheal tubes revealed that 96% had partial bacterial colonization and 84% were completely coated with bacteria in a biofilm or glycocalyx.[98] The authors hypothesized that bacterial aggregates in biofilm dislodged during suctioning might not be killed by antibiotics or effectively cleared by host immune defenses. Clearly, the type of endotracheal tube may also influence the likelihood of aspiration. Use of low-volume, high-pressure endotracheal cuffs reduced the rate to 56% and the advent of high-volume, low-pressure cuffs further lowered it to 20%.[99] Leakage around the cuff allows secretions pooled above the cuff to enter the trachea; this mechanism, recently confirmed, underlines the importance of maintaining adequate intracuff pressure for preventing VAP.[100]

In addition to the presence of endotracheal tubes, reintubation is, per se, a risk factor for VAP.[101] This finding probably reflects an increased risk of aspiration of colonized oropharyngeal secretions into the lower airways by patients with subglottic dysfunction or impaired consciousness after several days of intubation. Another explanation is direct aspiration of gastric contents into the lower airways, particularly when a nasogastric tube is kept in place after extubation.

Some investigators postulated that early tracheotomy could lower VAP rate because it can permit easier oral hygiene and bronchopulmonary toilet or less time spent deeply sedated.[102] Such benefit, however, was not confirmed in other studies, including two large recent randomized trials having systematically evaluated this issue.[103–106]

NASOGASTRIC TUBE, ENTERAL FEEDING, AND POSITION OF THE PATIENT

Almost all ventilated patients have a nasogastric tube inserted to evacuate gastric and enteral secretions, prevent gastric distension, and/or provide nutritional support. The nasogastric tube is not generally considered to be a potential risk factor for VAP, but it may increase oropharyngeal colonization, cause stagnation of oropharyngeal secretions, and increase reflux and the risk of aspiration. A multivariate analysis retained the presence of a nasogastric tube as one of the three independent risk factors for nosocomial pneumonia based on a series of 203 patients admitted to the ICU for 72 hours or more.[77]

Early initiation of enteral feeding is generally regarded as beneficial in critically ill patients, but it may increase the risk of gastric colonization, gastroesophageal reflux, aspiration, and pneumonia.[107,108] The aspiration rate generally varies as a function of differences in the patient population, neurologic function, type of feeding tube, location of the feeding port, and method of evaluating aspiration. Clinical impressions and preliminary data suggest that postpyloric or jejunal feeding entails less risk of aspiration and may therefore be associated with fewer infectious complications than gastric feeding, although this point remains controversial.[109,110] Nonetheless, aspiration can easily occur should the feeding tube be inadvertently dislodged. A retrospective study of non–critically ill adult patients showed a 40% rate of accidental feeding tube dislodgment, but all the patients whose tube was dislodged were confused or disoriented or had altered awareness, as is frequently observed in ICU patients.[111]

Maintaining ventilated patients with a nasogastric tube in place in a supine position is also a risk factor for aspiration of gastric contents into the lower airways. When radioactive material was injected through a nasogastric tube directly into the stomach of nineteen ventilated patients, the mean radioactive counts in endobronchial secretions were higher in a time-dependent fashion in samples obtained from patients in a supine position than in those obtained from patients in a semirecumbent position.[112] The same microorganisms were isolated from the stomach, pharynx, and endobronchial samples of 32% of the specimens taken while patients were lying supine. The same investigators conducted a randomized trial comparing semirecumbent and supine positions.[113] The trial, which included eighty-six intubated and ventilated patients, was stopped after the planned interim analysis because the frequency and the risk of VAP were significantly lower for the semirecumbent group. These findings were indirectly confirmed by the demonstration that the head position of the supine patient during the first 24 hours of mechanical ventilation was an independent risk factor for acquiring VAP.[22] To what degree of elevation, however, the head of bed should be targeted remains controversial.[114–117]

RESPIRATORY EQUIPMENT

Ventilators with humidifying cascades often have high levels of tubing colonization and condensate formation that may also be risk factors for pneumonia. The rate of condensate formation in the ventilator circuit is linked to the temperature difference between the inspiratory-phase gas and the ambient temperature, and may be as high as 20 to 40 mL/hour.[118,119] Examination of condensate colonization in twenty circuits detected a median level of 2.0×10^5 organisms/mL, and 73% of the fifty-two gram-negative isolates present in the patients' sputum samples were subsequently isolated from condensates.[119] Because most of the tubing colonization was derived from the patients' secretions, the highest bacterial counts were present near the endotracheal tube. Simple procedures, such as turning the patient or raising the bed rail, may accidentally spill contaminated condensate directly into the patient's tracheobronchial tree.[120] Inoculation of large amounts of fluid with high bacterial concentrations is an excellent way to overwhelm pulmonary defense mechanisms and cause pneumonia. Heating ventilator tubing markedly

lowers the rate of condensate formation, but heated circuits are often nondisposable and are expensive. Inline devices with one-way valves to collect the condensate are probably the easiest way to handle this problem; they must be correctly positioned into disposable circuits and emptied regularly.

To decrease condensation and moisture accumulation in ventilator circuits, several studies have investigated the use of heat–moisture exchangers in place of conventional heated-water humidification systems. Slightly lower VAP rates were observed in four studies and a significant difference in a fifth study, suggesting that heat–moisture exchangers are at least comparable to heated humidifiers and may be associated with lower VAP rates than heated humidifiers.[121–125] Changing the heat–moisture exchangers every 48 hours did not affect ventilator circuit colonization and the authors concluded that the cost of mechanical ventilation might be substantially reduced without any detriment to the patient by prolonging the time between heat–moisture exchangers changes from 24 to 48 hours.[126] Furthermore, using heat–moisture exchangers may decrease the nurses' workload (no need to refill cascades, to void water traps on circuits, and so on), decrease the number of septic procedures (it was clearly shown that respiratory tubing condensates must be handled as an infectious waste), and reduce the cost of mechanical ventilation, especially when used for prolonged periods without change. Because some observational studies, however, have documented an increased resistive load and a larger dead space associated with exchangers,[127,128] their use should be discouraged in patients with ARDS ventilated with a low tidal volume and in patients with chronic obstructive pulmonary disease during the weaning period, if pressure support, and not T-piece trials, are used.

There is no apparent advantage to changing ventilator circuits frequently for VAP prevention. This holds true whether circuits are changed every 2 days or every 7 days compared with no change at all, and whether they are changed weekly as opposed to three times per week.[129–131] A policy of no circuit changes or infrequent circuit changes is simple to implement and the costs are likely lower than those generated by regular, frequent circuit changes; thus, such a policy is strongly recommended by the 1997 Centers for Disease Control and Prevention guidelines and other guidelines.[132–134]

SINUSITIS

While many studies have compared the risk of nosocomial sinusitis as a function of the intubation method used and the associated risk of VAP, only a few were adequately powered to give a clear answer. In one study of 300 patients who required mechanical ventilation for at least 7 days and were randomly assigned to undergo nasotracheal or orotracheal intubation, computed tomographic evidence of sinusitis was observed slightly more frequently in the nasal than oral endotracheal group ($p = 0.08$), but this difference disappeared when only bacteriologically confirmed sinusitis was considered.[135]

The rate of infectious maxillary sinusitis and its clinical relevance were also prospectively studied in 162 consecutive critically ill patients, who had been intubated and ventilated for 1 hour to 12 days before enrollment.[136] All had a paranasal computed tomography scan within 48 hours of admission, which was used to divide them into three groups (no, moderate, or severe sinusitis), according to the radiologic appearance of the maxillary sinuses. Patients who had no sinusitis at admission ($n = 40$) were randomized to receive endotracheal and gastric tubes via the nasal or oral route and, based on radiologic images, respective sinusitis rates were 96% and 23% ($p < 0.03$); yet, no differences in the rates of infectious sinusitis were documented according to the intubation route. VAP, however, was more common in patients with infectious sinusitis, with 67% of them developing lung infection in the days following the diagnosis of sinusitis.[136] Therefore, although it seems clear that infectious sinusitis is a risk factor for VAP, no studies have yet been able to definitively demonstrate that orotracheal intubation decreases the infectious sinusitis rate compared to nasotracheal intubation. Thus, no firm recommendations on the best route of intubation to prevent VAP can be advanced.

INTRAHOSPITAL PATIENT TRANSPORT

A prospective cohort study conducted in 531 ventilated patients evaluated the impact of transporting the patient out of the ICU to other sites within the hospital.[137] Results showed that 52% of the patients had to be moved at least once, for a total of 993 transports, and that 24% of the transported patients developed VAP compared with 4% of the patients confined to the ICU ($p < 0.001$). Multiple logistic regression analysis confirmed that transport out of the ICU was independently associated with VAP (OR = 3.8; $p < 0.001$).

DIAGNOSIS

VAP is typically suspected when a patient has new or progressive radiographic infiltrates and clinical findings suggesting infection, such as the new onset of fever, purulent sputum, leukocytosis, increased minute ventilation, and/or a decline in arterial oxygenation. Because interpretation of chest radiographs is difficult, particularly in patients with prior abnormalities, such as ARDS, it is also mandatory to consider the diagnosis of VAP in ventilated patients who clinically deteriorate, and/or in whom vasopressors should be increased to maintain blood pressure, even in the absence of a clear-cut progression of the radiographic abnormalities.

The systemic signs of infection, however, such as fever, tachycardia, and leukocytosis, are nonspecific findings that can be caused by any condition that releases cytokines. In trauma and other surgical patients, fever and leukocytosis should prompt the physician to suspect infection, but during the early posttraumatic or postoperative period (i.e., during the first 72 hours), these findings usually are not conclusive. Later, fever and leukocytosis are more likely to be caused by pulmonary or nonpulmonary (vascular catheter infection, gastrointestinal infection, urinary tract infection, sinusitis, or wound infection) infections, but even then, other events associated with an inflammatory response (e.g., devascularized tissue, open

wounds, pulmonary edema, and/or infarction) can be responsible for these findings. Although the plain (usually portable) chest roentgenogram remains an important component in the evaluation of ventilated patients with suspected pneumonia, it is most helpful when it is normal and rules out pneumonia. When infiltrates are evident, the particular pattern is of limited value for differentiating among cardiogenic pulmonary edema, noncardiogenic pulmonary edema, pulmonary contusion, atelectasis (or collapse), and pneumonia, even when using computed tomographic scanning.[8,17,138–142] Because the tracheobronchial tree of mechanically ventilated patients is frequently rapidly colonized by potential pathogens, the presence of bacteria at that level is not a sufficient argument to diagnose true lung infection, which constitutes another major obstacle for the diagnosis of VAP.[8,143]

In 1991, a composite clinical score, the clinical pulmonary infection score (CPIS) was proposed, based on seven variables (temperature, blood leukocyte count, volume and purulence of tracheal secretions, oxygenation, pulmonary radiography, and semiquantitative culture of tracheal aspirate) accorded 0, 1, or 2 points.[144] This scoring system, however, is quite tedious to calculate and difficult to use in clinical practice, because several variables, such as progression of pulmonary infiltrates and results of semiquantitative cultures of tracheal secretions, can lead to different calculations depending on the observer.[145] Furthermore, its value was not validated in several subsequent prospective studies, especially in patients with bilateral pulmonary infiltrates.[146–154]

Thus, as soon as a ventilated patient is suspected of developing pneumonia, a more complete diagnostic workup should be undertaken, targeting two objectives. The first objective is the immediate recognition of a true VAP or of an extrapulmonary bacterial infection, so as to start effective antibiotics against the microorganisms responsible for infection as soon as possible.[1,2] Numerous studies indicate that failure to initiate prompt appropriate antimicrobial treatment in this setting is a major risk factor for an increased morbidity and mortality.[155–163] The second objective is to avoid overusing antibiotics in patients with only proximal airways colonization and no ongoing bacterial infection. Epidemiologic investigations have clearly demonstrated that indiscriminate use of antimicrobial agents in ICU patients may have immediate and long-term consequences, which contribute to emergence of multiresistant pathogens and increase the risk of serious superinfections.[164–169] This risk is not limited to one patient. Instead, the risk of colonization or infection by multidrug-resistant strains is increased in patients throughout the ICU and even the entire hospital. Virtually all reports emphasize that better antibiotic control programs to limit bacterial resistance are urgently needed in ICUs, and that patients without true infection should not receive antimicrobial treatment.[164]

To reach these objectives, all diagnostic strategies should follow three consecutive steps: (a) obtaining a respiratory tract sample (from proximal or distal airways) for microscopy and culture (qualitative, semiquantitative, or quantitative) before introduction of new antibiotics; (b) immediately starting empiric antimicrobial treatment, unless there are both a negative microscopy and no signs of severe sepsis; and (c) reevaluating treatment on day 2 or 3, based on microbiologic cultures results and clinical outcome.[1,2]

Qualitative Cultures of Endotracheal Aspirates

The first option is to use a clinical strategy and to treat every patient clinically suspected of having a pulmonary infection with new antibiotics (even when the likelihood of infection is low), arguing that several studies showed that immediate initiation of appropriate antibiotics was associated with reduced mortality.[28,32,157,170–175] Using this strategy, all patients suspected of having VAP are treated with new antibiotics after having obtaining an endotracheal aspirate for microscopy and qualitative culture. The selection of appropriate empirical therapy is based on risk factors and local microbiologic and resistance patterns, and involves qualitative testing to identify possible pathogens. The initial antimicrobial therapy is adjusted according to culture results and clinical response (Fig. 46-1). Antimicrobial treatment is discontinued if and only if the following three criteria are fulfilled on day 3: (a) clinical diagnosis of VAP is unlikely (there are no definite infiltrates found on chest radiography at follow-up and no more than one of the three following findings are present: temperature higher than 38.3°C [100.9°F], leukocytosis or leukopenia, and purulent tracheobronchial secretions) or an alternative noninfectious diagnosis is confirmed;

(b) tracheobronchial aspirate culture results are nonsignificant; and (c) severe sepsis or shock are not present.[176]

This clinical approach has two undisputable advantages: first, no specialized microbiologic techniques are required, and, second, the risk of missing a patient who needs antimicrobial treatment is minimal when all suspected patients are treated with new antibiotics. Because, however, tracheobronchial aspirate culture results are rarely negative secondary to the high rate of proximal airways colonization observed in patients receiving mechanical ventilation, discontinuation of antibiotics on day 3 is difficult to perform, leading to antibiotic overuse in many ICU patients. Qualitative endotracheal aspirate cultures contribute indisputably to the diagnosis of VAP only when they are completely negative for a patient with no modification of prior antimicrobial treatment. In such a case, the negative-predictive value is very high and the probability of the patient having pneumonia is close to zero.[5] This is why some investigators have proposed to replace qualitative cultures of endotracheal aspirates by semiquantitative or quantitative cultures of the same specimens.[177]

Quantitative Cultures of Endotracheal Aspirates

Several studies using quantitative culture techniques suggest that endotracheal aspirate cultures may have an acceptable overall diagnostic accuracy, similar to that of several other more invasive techniques.[177] Not all studies, however, have confirmed this conclusion. To assess the reliability of that method, bronchoscopy with PSB and BAL was used to study fifty-seven episodes of suspected lung infection in thirty-nine ventilator-dependent patients with no recent changes of antimicrobial therapy.[178] The operating characteristics of endotracheal aspirate cultures were calculated over a range of cutoff values (from 10^3 to 10^7 colony-forming units [CFU]/mL); the threshold of 10^6 CFU/mL appeared to be the most accurate, with a sensitivity of 68% and a specificity of 84%. When this threshold was applied to the study population, however, almost one-third of the patients with pneumonia were not identified. Furthermore, only 40% of microorganisms cultured in endotracheal aspirate samples coincided with those obtained from PSB specimens. Other authors have emphasized that, although quantitative endotracheal aspirate cultures can correctly identify patients with pneumonia, microbiologic results cannot be used to infer which microorganisms present in the trachea are really present in the lungs. In a study comparing quantitative endotracheal aspirate culture results to postmortem quantitative lung biopsy cultures, only 53% of the microorganisms isolated from the former samples at concentrations greater than 10^7 CFU/mL were also found in the latter cultures.[179]

The inherent advantage of quantitative cultures of endotracheal aspirates is that they are more specific, permitting the discontinuation of antibiotics in more patients than when using only qualitative cultures. But it must be kept in mind that this technique has several potential pitfalls. First, many patients may not be identified using the cutoff value of 10^6 CFU/mL. Second, as soon as a lower threshold is used, specificity declines sharply and overtreatment becomes a problem. Finally, selecting antimicrobial therapy solely on the basis of endotracheal aspirate culture results can lead to either unnecessary antibiotic therapy or overtreatment with broad-spectrum antimicrobial agents.

The "Singh" Strategy

Another option when using the clinical approach is to follow the strategy described by Singh et al, in which decisions regarding initial antibiotic therapy are based on CPIS, a clinical score constructed from seven variables.[180] Patients with CPIS greater than 6 are treated as having VAP with antibiotics for 10 to 21 days, and antibiotics are discontinued after 3 days if the CPIS is 6 or less (Fig. 46-2). Such an approach avoids prolonged treatment of patients who have a low likelihood of infection, while allowing immediate treatment of patients who are more likely to have VAP.

Two conditions must be fulfilled when using this strategy. First, the selection of initial antimicrobial therapy should be based on the most common microbes responsible for VAP at each institution. For example, ciprofloxacin would not be the right choice in hospitals with a high prevalence of MRSA infections. Second, physicians should reevaluate antimicrobial treatment on day 3, when susceptibility patterns of the microorganism(s) recovered from pulmonary secretions are available, so as to select treatment with a narrower spectrum antibiotic.

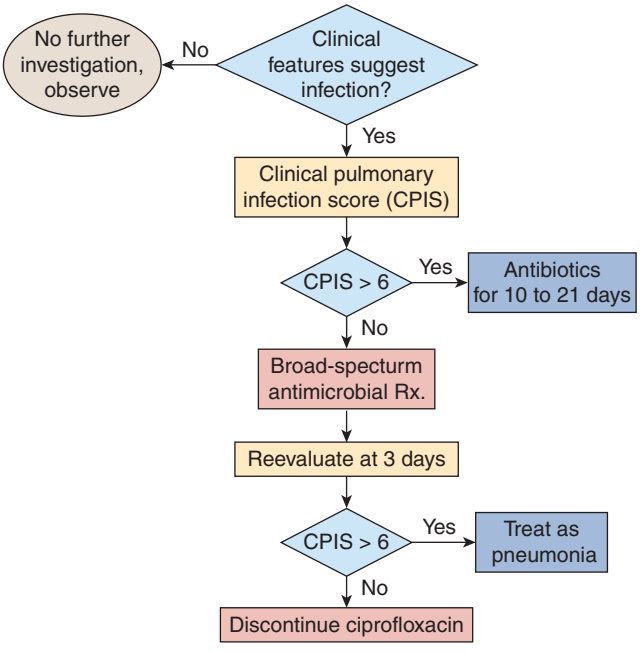

FIGURE 46-2 Diagnostic and therapeutic strategy applied to patients managed with the strategy proposed by Singh et al.[180]

Quantitative Cultures of Distal Specimens Obtained by Bronchoscopy

This strategy uses quantitative cultures of lower respiratory secretions (BAL or PSB collected with a bronchoscope) to define both the presence of pneumonia and the etiologic pathogen(s). Pathogens are present in inflammatory secretions of the lower respiratory tract at concentrations of at least 10^5 to 10^6 CFU/mL, whereas contaminants are generally present at less than 10^4 CFU/mL.[181] The diagnostic thresholds proposed for PSB and BAL are based on this concept. Because PSB collects between 0.001 and 0.01 mL of secretions, the presence of greater than 10^3 bacteria in the originally diluted sample (1 mL) actually represents 10^5 to 10^6 CFU/mL of pulmonary secretions. Similarly, 10^4 CFU/mL for BAL, which collects 1 mL of secretions in 10 to 100 mL of effluent, represents 10^5 to 10^6 CFU/mL.[182–184] Using this strategy, therapeutic decisions are tightly protocolized, using the results of direct examination of distal pulmonary samples and results of quantitative cultures in deciding whether to start antibiotic therapy, which pathogens are responsible for infection, which antimicrobial agents to use, and whether to continue therapy (Fig. 46-3).

One major technical problem with all bronchoscopic techniques is proper selection of the sampling area in the tracheobronchial tree. Almost all intubated patients have purulent-looking secretions and the secretions first seen may represent those aspirated from another site into gravity-dependent airways or from upper-airway secretions aspirated around the endotracheal tube. Usually, the sampling area is selected based on the location of infiltrate on chest radiograph or the segment visualized during bronchoscopy as having purulent secretions.[185] Collection of secretions in the lower trachea or mainstem bronchi, which may represent recently aspirated secretions around the endotracheal tube cuff, should be avoided. In patients with diffuse pulmonary infiltrates or minimal changes in a previously abnormal chest

radiograph, determining the correct airway to sample may be difficult. In these cases, sampling should be directed to the area where endobronchial abnormalities are maximal.[186] In case of doubt, and because autopsy studies indicate that VAP frequently involves the posterior portion of the right lower lobe, this area should probably be sampled as a priority.[187] Although bilateral sampling in the immunosuppressed host with diffuse infiltrates has been advocated, there is no convincing evidence that multiple specimens are more accurate than single specimens for diagnosing nosocomial bacterial pneumonia in ventilated patients.

Because BAL harvests of cells and secretions from a large area of the lung and specimens can be microscopically examined immediately after the procedure to detect the presence or absence of intracellular or extracellular bacteria in the lower respiratory tract, it is particularly well suited to provide rapid identification of patients with pneumonia (Figs. 46-4 and 46-5).[183,188–193] Assessment of the degree of qualitative agreement between Gram stains of BAL fluid and PSB quantitative cultures for a series of fifty-one patients with VAP, however, showed correspondence to be complete for 51%, partial for 39%, and nonexistent for 10% of the cases.[190]

Many groups have investigated the value of quantitative BAL culture for the diagnosis of pneumonia in ICU patients.[183,194,195] When the results of the eleven studies evaluating BAL fluids from a total of 435 ICU patients with nosocomial pneumonia were pooled, overall accuracy was very close to that of PSB: The Q value was 0.84 (Q represents the intersection between the summary receiver operating characteristics curve and a diagonal from the upper-left corner to the lower-right corner of the receiver operating characteristics space).[194] Similar conclusions were drawn in another meta-analysis, which pooled the results of twenty-three studies: Sensitivity and specificity of BAL were 73% ± 18% and 82% ± 19%, respectively.[195] When analysis in these studies was restricted to patients without prior antibiotics or when only lung tissue cultures were used as the reference standard, results of bronchoscopic techniques pneumonia were much better: Sensitivity was always greater than 80%.

Other studies confirm the accuracy of bronchoscopic techniques for diagnosing nosocomial pneumonia. In a study evaluating spontaneous lung infections occurring in ventilated baboons with permeability pulmonary edema, Johanson et al found excellent correlation between the bacterial content of lung tissue and results of quantitative culture of lavage fluid.[196] BAL recovered 74% of all species present in lung tissue, including 100% of species present at a concentration equal to or greater than 10^4 CFU/g of tissue. Similarly, in twenty ventilated patients who had not developed pneumonia before the terminal phase of disease and who had no recent changes in antimicrobial therapy, Chastre et al found that bronchoscopic BAL specimens obtained just after death identified 90% of all species present in the lung, with a strong correlation between the results of quantitative cultures of both specimens.[183] These findings confirm that bronchoscopic BAL samples very reliably identify, both qualitatively and quantitatively, microorganisms present in lung segments, even when the pneumonia develops as a superinfection in a patient already receiving antimicrobial treatment for several days.

Values within 1 $\log_{10}$ of the cutoff must, however, be interpreted cautiously, and bronchoscopy should be repeated in symptomatic patients with a negative ($<10^4$ CFU/mL) result.[197] Many technical factors, including medium and adequacy of incubation, and antibiotic or other toxic components, may influence results. Reproducibility of PSB sampling has been recently evaluated by three groups.[198–200] Although in vitro repeatability was excellent and in vivo qualitative recovery 100%, quantitative results were more variable. In 14% to 17% of patients, results of replicate samples fell on both sides of the 10^3 CFU/mL threshold, and results varied

by more than 1 $\log_{10}$ in 59% to 67% of samples.[198–200] This variability is presumably related to both the irregular distribution of organisms in secretions and the very small volume actually sampled by PSB. As with all diagnostic tests, borderline PSB and/or BAL quantitative culture results should be interpreted cautiously, and the clinical circumstances should be considered before reaching any therapeutic decision.

The most compelling argument for invasive techniques coupled with quantitative cultures of PSB or BAL specimens is that they can reduce excessive antibiotic use. There is little disagreement that the clinical diagnosis of nosocomial pneumonia is overly sensitive and leads to the unnecessary use of broad-spectrum antibiotics. Because bronchoscopic techniques may be more specific, their use would reduce antibiotic pressure in the ICU, thereby limiting the emergence of drug-resistant strains and the attendant increased risks of superinfection.[22,201] When culture results are available, BAL and/or PSB techniques facilitate precise identification of the offending organisms and their susceptibility patterns. Such data are invaluable for optimal antibiotic selection in patients with a true VAP. They also increase the confidence and comfort level of health care workers in managing patients with suspected nosocomial pneumonia.[202] The more targeted use of antibiotics also could reduce overall costs, despite the expense of bronchoscopy and quantitative cultures, and minimize antibiotic-related toxicity. This is particularly true in patients who have late-onset VAP, in whom expensive combination therapy is commonly recommended. A conservative cost analysis in a trauma ICU suggested that the discontinuation of antibiotics upon the return of negative bronchoscopic quantitative culture results could lead to a savings of more than $1700 per patient suspected of VAP.[203]

Finally, a major benefit of a negative bronchoscopy is to direct attention away from the lungs as the source of fever. Many hospitalized patients with negative bronchoscopic cultures have other potential sites of infection that can be identified via a simple diagnostic protocol. In fifty patients with suspected VAP who underwent a systematic diagnostic protocol designed to identify all potential causes of fever and pulmonary densities, Meduri et al confirmed that lung infection was present in only 42% of cases; the frequent occurrence of multiple infectious and noninfectious processes justifies a systematic search for the source of fever in this setting.[141] Delay in diagnosis or definitive treatment of the true site of infection may lead to prolonged antibiotic therapy, more antibiotic-associated complications, and induction of further organ dysfunction.[204]

Quantitative Cultures of Distal Specimens Obtained without Bronchoscopy

At least fifteen studies have described a variety of nonbronchoscopic techniques using various types of endobronchial catheters for sampling distal lower respiratory tract secretions; globally, results have been similar to those obtained with bronchoscopy.[205] Compared to conventional PSB and/or BAL, nonbronchoscopic techniques are less invasive, can be performed by clinicians not qualified to perform bronchoscopy, have lower initial costs than bronchoscopy, avoid potential contamination by the bronchoscopic channel, are associated with less compromise of gas exchange during the procedure, and can be performed even in patients intubated with small endotracheal tubes. Disadvantages include the potential sampling errors inherent in a blind technique and the lack of airway visualization. Although autopsy studies indicate that pneumonia in ventilator-dependent patients has often spread into every pulmonary lobe and predominantly involves the posterior portion of the lower lobes, several clinical studies on ventilated patients with pneumonia contradict those findings, as some patients had sterile cultures of PSB specimens from the noninvolved lung.[17,206] Furthermore, although the authors of most studies concluded that the sensitivities of nonbronchoscopic and bronchoscopic techniques were comparable, the overall concordance was only approximately 80%, emphasizing that, in some patients, the diagnosis could be missed by a blind technique, especially in the case of pneumonia involving the left lung.[17]

Patients Already Receiving Antimicrobial Therapy

Performing microbiologic cultures of pulmonary secretions for diagnostic purposes after initiation of new antibiotic therapy in patients suspected of having developed VAP leads to a high rate of false-negative results, regardless of the method of obtaining the secretions. In fact, all microbiologic techniques are of limited value in patients with a recent infiltrate who have received new antibiotics, even if they have received the new antibiotics for less than 24 hours. A negative finding could indicate that the patient has been successfully treated for pneumonia and the bacteria are eradicated, or that the patient had no lung infection to begin with. Using both PSB and BAL, Souweine et al prospectively investigated sixty-three episodes of suspected VAP.[207] If patients had been treated with antibiotics but did not have a recent change in antibiotic class, sensitivity of PSB and BAL culture (83% and 77%, respectively) were similar to the sensitivities achieved in patients not being treated with antibiotics. In other words, prior therapy did not reduce the yield of diagnostic testing among patients receiving current antibiotics given to treat a prior infection. Conversely, if therapy was recent, sensitivity of invasive diagnostic methods, using traditional thresholds, was only 38% with BAL and 40% with PSB.[207] These two clinical situations should be clearly distinguished before interpreting the results of pulmonary secretion cultures, irrespective of how they were obtained. In the second situation, when the patient receives new antibiotics after the appearance of signs suggesting VAP, no conclusion concerning the presence or absence of pneumonia can be drawn if culture results are negative.[207–209] Pulmonary secretions therefore need to be obtained before starting new antibiotics, as is the case for all types of microbiologic samples.

Use of Procalcitonin and Other Biologic Markers

Procalcitonin (PCT), a 116-amino-acid peptide that is one of the precursors of the hormone calcitonin, has been described as a good diagnostic marker of bacterial infection in patients with community-acquired infections, especially in patients with lower respiratory tract infection.[210–213] Moreover, several interventional trials have shown that PCT could be used to start or to postpone antibiotic treatment in community-acquired lower respiratory tract infections.[214–218] In patients with nosocomial infections, and particularly in patients with VAP, its usefulness as a diagnostic marker is more doubtful.[219–223] There are several reasons to explain why PCT is not a good diagnostic marker in patients with suspected VAP. First, pneumonia may be a localized infection; thus, as for other localized infections, PCT can be synthesized locally without systemic release, explaining its low serum level or apparent decrease in patients with true pulmonary infections. Second, ICU patients may suffer from previous severe sepsis or septic shock, multiorgan failure, or may have developed a systemic inflammatory response syndrome after surgery or trauma, conditions known to increase blood level of biomarkers including PCT in the absence of infection.[222] Thus, a high level of PCT the day VAP is suspected is not useful, because it is not possible to distinguish an elevation caused by a previous noninfectious condition from an elevation caused by an active infection. Third, it is known that a time lag of 24 to 48 hours can exist between bacterial infection onset and peak PCT release, and that may also explain the apparent low level of PCT on the day of VAP onset. Incorporating PCT values in clinical score (such as CPIS) did not improve its diagnostic value.[221,222]

The soluble triggering receptor expressed on myeloid cells-1 (sTREM-1) molecule is known to be specifically released during several infectious processes.[224] Although it was apparently a reliable marker of pneumonia, especially VAP, more recent studies obtained contradictory findings, thereby raising doubt as to its usefulness for VAP diagnosis.[220,225–227] Pending additional studies, and because this marker is not routinely available, sTREM-1 is not recommended as an indicator to guide antibiotic use in such situations.

Gram-negative bacilli cause more than 80% of VAP episodes and are associated with high mortality. Because gram-negative bacilli pneumonia might be diagnosed more rapidly by endotoxin measurement in BAL fluid, several investigators tested this hypothesis.[228–231] Applying a threshold of greater than 5 endotoxin units (EU/mL) in BAL fluid yielded the best operating characteristics for gram-negative bacilli pneumonia diagnosis (100% sensitivity; 75% specificity; area under the receiver operating characteristics curve: 0.88) in a series of sixty-three hospitalized adults suspected of having lung infection.[229] Three other studies confirmed the potential contribution of this tool.[228,230,231] These findings suggest that endotoxin determination in BAL fluid might become an acceptable adjunct for the rapid diagnosis of gram-negative bacilli pneumonia in the near future, when it will be available at bedside.

Summary of the Evidence

Aside from decision-analysis studies[232,233] and a single retrospective study,[202] five trials have used a randomized scheme to assess the effect of a diagnostic strategy on antibiotic use and outcome in patients suspected of having VAP.[26,27,234–236] In three randomized studies conducted in Spain, no differences in mortality and morbidity were found when either invasive (PSB and/or BAL) or noninvasive (quantitative endotracheal aspirate cultures) techniques were used to diagnose VAP.[26,27,234] These studies were relatively small, ranging from fifty-one to eighty-eight patients. Antibiotics were continued in all patients despite negative cultures, thereby offsetting the potential advantage of the specific diagnostic test in patients with suspected VAP. Several prospective studies have concluded that antibiotics can be stopped in patients with negative quantitative cultures, without adversely affecting the recurrence of pneumonia and mortality.[188,237,238]

In a French study in which 413 patients were randomized, those receiving bacteriologic management using BAL and/or PSB had a lower mortality rate on day 14, lower sepsis-related organ failure assessment scores on days 3 and 7, and less antibiotic use.[235] Pertinently, twenty-two nonpulmonary infections were diagnosed in the bacteriologic strategy group and only five in the clinical strategy group, suggesting that overdiagnosis of VAP can lead to errors in identifying nonpulmonary infections. A randomized trial conducted by the Canadian Critical Care Trials Group investigated the effect of different diagnostic approaches on outcomes of 740 patients suspected of having VAP.[236] There was no difference in the 28-day mortality rate in patients in whom BAL was used versus those in whom endotracheal aspiration was used as the diagnostic strategy. The BAL group and the endotracheal aspiration group also had similar rates of targeted antibiotic therapy on day 6, days alive without antibiotics, and maximum organ-dysfunction scores. Unfortunately, information about how the decision algorithms were followed in the two diagnostic arms once cultures were available was not provided, raising uncertainties about how de-escalation of antibiotic therapy was pursued in patients with negative BAL cultures. Obviously, the potential benefit of using a diagnostic tool such as BAL for safely restricting unnecessary antimicrobial therapy in such a setting can only be obtained when decisions regarding antibiotics are closely linked to bacteriologic results, including both direct examination and cultures of respiratory specimens.

Our personal bias is that use of bronchoscopic techniques to obtain PSB and BAL specimens from an affected area of the lung in ventilated patients with signs suggestive of pneumonia enables the formulation of a therapeutic strategy superior to that based exclusively on clinical evaluation. Bronchoscopic techniques, when performed before the introduction of new antibiotics, enable physicians to identify most patients who need immediate treatment, and help select optimal therapy in a safe and well-tolerated manner. These techniques also avoid resorting to broad-spectrum coverage of all patients who develop a clinical suspicion of infection.[239] The full impact

of this decision tree on patient outcome remains controversial.[235,236] Yet, being able to withhold antimicrobial treatment from some patients without infection may constitute a distinct advantage in the long-term: It minimizes the emergence of resistant microorganisms in the ICU and redirects the search for another (the true) infection site.

In patients with clinical evidence of severe sepsis and rapid worsening organ dysfunction, hypoperfusion, or hypotension, or patients with a very high pretest probability of disease, the initiation of antibiotic therapy should not be delayed while awaiting bronchoscopy. Patients should be given immediate antibiotics. In this situation, simple nonbronchoscopic procedures find their best justification, allowing distal pulmonary secretions to be obtained on a 24-hour basis, just before starting new antimicrobial therapy.

Despite broad experience with PSB and BAL, it remains unclear which should be used. Most investigators prefer BAL over PSB to diagnose bacterial pneumonia, because BAL (a) has a slightly higher sensitivity to identify VAP-causative microorganisms, (b) enables better selection of an empiric antimicrobial treatment before culture results are available, based on microscopically examined cytocentrifuged preparations, (c) is less dangerous for many critically ill patients, (d) is less costly, and (e) may provide useful clues for the diagnosis of other types of infections. Nevertheless, a very small return on BAL may contain only diluted material from the bronchial rather than alveolar level, and thus give rise to false-negative results, particularly in patients with very severe chronic obstructive pulmonary disease. In these patients, the value of BAL is greatly diminished and PSB is preferred.[184]

When bronchoscopy is not available, we recommend replacing bronchoscopy in the algorithm in Figure 46-3 by one of the simplified nonbronchoscopic diagnostic techniques, or following the strategy described by Singh et al (see Figure 46-3). Such an approach avoids prolonged treatment of patients with a low likelihood of infection, while allowing immediate treatment of patients with VAP.

TREATMENT

Antimicrobial therapy of patients with VAP is a two-stage process. The first stage involves administering broad-spectrum antibiotics to avoid inappropriate treatment in patients with true bacterial pneumonia.[2] The second stage focuses on trying to achieve this objective without overusing and abusing antibiotics. In general, the first goal can be accomplished by identifying patients with pneumonia in a rapid fashion and starting therapy with an empirical regimen that is likely to be accurate. This requires that the choice be driven by anticipation of the likely etiologic pathogens, modified by knowledge of local patterns of antimicrobial resistance and local microbiology. The second goal involves combining a number of different steps, including stopping therapy in patients with a low probability of the disease, commitment to focus and narrow treatment once the etiologic agent is known, switching to monotherapy after day 3, and shortening duration of therapy to 7 to 8 days in most patients, as dictated by the patient's clinical response and information about the bacteriology.

Initial Therapy

Failure to initiate prompt appropriate and adequate therapy (the etiologic organism is sensitive to the therapeutic agent, the dose is optimal, and the correct route of administration is used) has been a consistent factor associated with increased mortality.[32,155–157] Because pathogens associated with inappropriate initial empiric antimicrobial therapy mostly include antibiotic-resistant microorganisms, such as *P. aeruginosa, Acinetobacter* spp., *Klebsiella pneumoniae*, *Enterobacter* spp., and MRSA, patients at risk for infection with these organisms should initially receive a combination of agents that can provide a very broad spectrum of coverage (Table 46-3).[2,173] Several observational studies have now confirmed that the

TABLE 46-3: INITIAL EMPIRIC THERAPY FOR VENTILATOR-ASSOCIATED PNEUMONIA IN PATIENTS WITH LATE-ONSET DISEASE OR RISK FACTORS FOR MULTIDRUG-RESISTANT PATHOGENS

Potential Pathogens	Combination Antibiotic Therapy
MDR Pathogens • *Pseudomonas aeruginosa* • *Klebsiella pneumoniae* (ESBL) • *Enterobacter* species • *Serratia marcescens* • *Acinetobacter* species	Antipseudomonal cephalosporin (cefepime, ceftazidime) *or* Antipseudomonal carbapenem (imipenem or meropenem or doripenem) *or* β-lactam, β-lactamase inhibitor (piperacillin-tazobactam) *plus* Antipseudomonal fluoroquinolone (ciprofloxacin or high-dose levofloxacin) *or* Aminoglycoside (amikacin, gentamicin, or tobramycin) *plus* Linezolid or vancomycin (if MRSA risk factors are present or there is a high incidence locally)
Methicillin-resistant *Staphylococcus aureus* (MRSA)	

Abbreviations: ESBL, extended-spectrum β-lactamase; *MDR*, multidrug resistant; *MRSA*, methicillin-resistant *Staphylococcus aureus.*

use of a regimen that combines initially a broad-spectrum β-lactam with an aminoglycoside increases the proportion of patients appropriately treated as compared to monotherapy or to a regimen combining a β-lactam with a fluoroquinolone.[162,240–242] Only patients with early onset infection, mild or moderate disease severity, and no specific risk factors for multiresistant strains, such as prolonged duration of hospitalization (≥5 days), admission from a health care–related facility, recent prolonged antibiotic therapy, and specific local epidemiologic data, can be treated with a narrow-spectrum drug, such as a nonpseudomonal third-generation cephalosporin.[1,2,243]

When risk factors for multiresistant pathogens are present, the choice of agents should be based on local patterns of antimicrobial susceptibility and anticipated side effects. Having a current and frequently updated knowledge of local bacteriologic patterns can increase the likelihood that appropriate initial antibiotic treatment will be prescribed.[48] The choice should also take into account which therapies patients recently received (within the prior 2 weeks), striving not to repeat the same antimicrobial class, if possible.[244–246]

Use of endotracheal aspirate surveillance cultures two or three times weekly may also make it possible to increase the proportion of patients receiving initially appropriate antimicrobial therapy.[247–251] This strategy rests upon the observation that VAP caused by potentially multiresistant pathogens is typically preceded by colonization of the oropharynx and the proximal airways by the same strains. To be of clinical use in directing initial antibiotic therapy, surveillance cultures must be able to detect this colonization rapidly and with high sensitivity, as false-negative results would place the patient at risk for inappropriate therapy. Moreover, a focused antibiotic choice, with limitation of unnecessary broad-spectrum drugs, requires a low number of false-positive surveillance results. Patients with a prolonged hospital stay and numerous previous antibiotics will benefit the most. Thus, such a strategy can only be recommended when the local prevalence of multiresistant microorganisms is high, when current empirical therapy is suboptimal and cannot be easily increased through adaptation of a decision tree, and when the resources for the microbiologic workup are available.[248]

Stopping Therapy When the Diagnosis of Infection Becomes Unlikely

Because clinical signs of infection are nonspecific and can be caused by any condition associated with an inflammatory response, many more patients than necessary are initially treated with antibiotics. Thus, it is important to use serial clinical evaluations and microbiologic data to reevaluate therapy after 48 to 72 hours.[2,252]

The decision tree should contain an explicit statement that patients with a low probability of infection will be identified and therapy stopped when infection appears unlikely. The algorithm cannot be exactly the same for a "clinical" or an "invasive" strategy, depending on the general principles and microbiologic techniques on which the diagnostic strategy is constructed (see "Diagnosis" above). Using a "clinical strategy" in which all patients with clinically suspected pulmonary infection are treated with new antibiotics, even when the likelihood of infection is low, the decision whether to continue antibiotics or not on day 3 will be based essentially on a combination of clinical signs.[176] Briefly, antibiotics are discontinued if and only if the clinical diagnosis of VAP is unlikely (there are no definite infiltrates found on chest radiography at follow-up), tracheobronchial aspirate culture results are nonsignificant, and there is no severe sepsis or shock. Other decision trees for stopping antibiotics at 3 days can be constructed, for example, by incorporating results of serial levels of procalcitonin in the blood or sTREM-1 in bronchial secretions, but still require validation.[220,223,253]

The decision algorithm for withholding or withdrawing antibiotics using the "invasive strategy" is based on results of direct examination of distal pulmonary samples obtained by bronchoscopic or nonbronchoscopic BAL and results of quantitative cultures (see Fig. 46-3). Briefly, antibiotics are withheld in patients with no bacteria on gram-stained cytocentrifuged preparations and no signs of severe sepsis or septic shock; and discontinued when quantitative culture results are below the cutoff defining a positive result, except in patients with proven extrapulmonary infection and/or severe sepsis.[235] As demonstrated by several studies, patients managed with such a bacteriologic strategy receive fewer antibiotics, and more patients have all their antibiotics discontinued compared to the clinical strategy group, thereby confirming that the two strategies actually differed.[193,202,235,237,239] Future studies should, however, compare bronchoscopy against and in addition to a clinical strategy incorporating an explicit statement for stopping antibiotics in patients with a low probability of infection, for example using the algorithm described above or the CPIS score, as proposed by Singh et al.[146,176,180,254] Formal economic analysis is also required because prevention of resistance and better antibiotic control may result in cost savings. Whatever the diagnostic strategy used, each ICU team should monitor the adherence of their physicians to it and implement corrective measures, as needed.

Focusing Therapy Once the Agent of Infection is Identified

Once the results of respiratory tract and blood cultures become available, therapy can often be focused or narrowed, based on the identity of specific pathogens and their susceptibility to specific antibiotics, so as to avoid prolonged use of a broader spectrum of antibiotic therapy than is justified by the available information.[2,42,161,249,255–258] For many patients, including those with late-onset infection, therapy can be narrowed because an anticipated organism (such as *P. aeruginosa, Acinetobacter* spp., or MRSA) was not recovered or because

the organism isolated is sensitive to a narrower-spectrum antibiotic than used in the initial regimen. For example, vancomycin and linezolid should be stopped if no MRSA is identified, unless the patient is allergic to β-lactams and has developed an infection caused by a gram-positive microorganism.[249] Very broad-spectrum agents, such as carbapenems, piperacillin-tazobactam, and/or cefepime should also be restricted to patients with infection caused by pathogens only susceptible to these agents. In case of infection caused by a piperacillin-susceptible *P. aeruginosa* strain, antimicrobial treatment should be streamlined to this specific drug. Similarly, in the absence of an infection caused by a nonfermenting gram-negative bacilli or an extended-spectrum β-lactamase-producing Enterobacteriaceae, the β-lactam should be changed to a non-antipseudomonal antibiotic, such as ceftriaxone or cefotaxime. Clinicians must be aware, however, that emergence of stable, derepressed, resistant mutants may lead to treatment failure when third-generation cephalosporins are chosen in the case of infections caused by *Enterobacter, Citrobacter, Morganella morganii*, indole-positive *Proteus*, and *Serratia* spp., even if the isolate appears susceptible on initial testing.

Unfortunately, several studies have shown that although de-escalation was not associated with any adverse outcomes, it was not consistently performed in many ICUs.[259–263]

Optimizing Antimicrobial Therapy

Several published reports have demonstrated a relationship among serum concentrations of β-lactams or other antibiotics, the minimal inhibitory concentration (MIC) of the infecting organism, and the rate of bacterial eradication from respiratory secretions in patients with lung infection.[264–270] Consequently, clinical and bacteriologic outcomes can be improved by optimizing a therapeutic regimen according to pharmacokinetic–pharmacodynamic properties of the agent(s) selected for treatment.[161,265,271–278] Most investigators distinguish between antimicrobial agents that kill by a concentration-dependent mechanism (e.g., aminoglycosides and fluoroquinolones) from those that kill by a time-dependent mechanism (e.g., β-lactams and vancomycin). Multivariate analyses based on seventy-four acutely ill, mostly VAP patients, who were treated with intravenous ciprofloxacin (200 mg BID to 400 mg TID), demonstrated that the most important independent factor for probability of cure was a pharmacodynamic variable, that is, the 24-hour area under the concentration–time curve divided by the MIC (AUIC).[271] For AUIC less than 125, the probabilities of clinical and microbiologic cures were 42% and 26%, respectively; with AUIC greater than 125, the probabilities were 80% and 82%, respectively. Routine dosages of fourth-generation cephalosporins, carbapenems, and fluoroquinolones may not achieve the target AUICs for resistant gram-negative bacteria, such as *P. aeruginosa* and *Acinetobacter* spp. Higher dosing regimens and/or prolonged duration of infusion are frequently needed in that case.[264,265,279]

Pharmacokinetic-pharmacodynamic models have also been used to optimize aminoglycoside therapy for VAP caused by gram-negative bacilli, using the first measured maximum concentration of drug in serum (C_{max}).[272] Seventy-eight patients with VAP were analyzed, and the investigators reported an 89% success rate for temperature normalization by day 7 of therapy for C_{max}/MIC greater than 4.7, and an 86% success rate for leukocyte count normalization by day 7 of therapy for C_{max}/MIC greater than 4.5. Logistic regression analysis predicted a 90% probability of temperature and leukocyte count normalizations by day 7 if a C_{max}/MIC greater than 10 was achieved within the first 48 hours of aminoglycoside administration. Aggressive aminoglycoside doses immediately followed by pharmacokinetic monitoring for each patient would ensure that C_{max}/MIC target ratios are achieved early during therapy.

These findings confirm the need to adjust the target dose of antimicrobial agents (used in treating severe pulmonary infection) to an individual patient's pharmacokinetics and putative bacterial pathogens' susceptibilities. Altered pharmacokinetic secondary to increase in volume of distribution in critically ill patients can result in insufficient serum β-lactam concentrations when standard dosages are administered, emphasizing the need to carefully monitor peak and trough levels of antibiotics when treating resistant pathogens, such as gram-negative bacilli.[280–282] Development of a priori dosing algorithms based on MIC, patient creatinine clearance and weight, and the clinician-specified AUIC target might be a valid way to improve treatment of these patients, leading to a more precise approach than current guidelines for use of antimicrobial agents.[273–277]

Switching to Monotherapy at Days 3 to 5

The two most commonly cited reasons to use combination therapy for the duration of antibiotic treatment are to achieve synergy and to prevent the emergence of resistant strains. Synergy, however, has only been clearly documented to be valuable in vitro in the therapy of *P. aeruginosa* or other difficult-to-treat gram-negative bacilli and in patients with neutropenia[283] or bacteremic infection,[284,285] which is uncommon in hospital-acquired pneumonia or VAP. When combination therapy was evaluated in randomized controlled studies, its benefit was inconsistent or null, even when the results were pooled in a meta-analysis or the analysis was restricted to patients infected by *P. aeruginosa*.[286–293] Combination therapy did not prevent the emergence of resistance during therapy, but did lead to a significantly higher rate of nephrotoxicity. In a retrospective analysis of 115 episodes of *P. aeruginosa* bacteremia, the use of adequate combination antimicrobial therapy as empirical treatment until receipt of the sensitivity was associated with a better rate of survival at 30 days than the use of monotherapy.[294] Adequate combination antimicrobial therapy given as definitive treatment for *P. aeruginosa* bacteremia, however, did not improve the rate of survival compared to adequate definitive monotherapy.

Based on these data, therapy could be switched to monotherapy in most patients after 3 to 5 days, provided that initial therapy was appropriate, clinical course appears favorable, and that microbiologic data do not suggest a very difficult-to-treat microorganism, with a very high in vitro minimal inhibitory concentration, as it can be observed with some nonfermenting gram-negative bacilli.

Shortening Duration of Therapy

Efforts to reduce the duration of therapy for VAP are justified by studies of the natural history of the response to therapy. Dennesen et al demonstrated that when VAP was adequately treated, significant improvements were observed for all clinical parameters, generally within the first 6 days of antibiotics.[295] The consequence of prolonged therapy to 14 days or more was newly acquired colonization, especially with *P. aeruginosa* and Enterobacteriaceae, generally during the second week of therapy. These data support the premise that most patients with VAP, who receive appropriate antimicrobial therapy, have a good clinical response within the first 6 days.[295–297] Prolonged therapy simply leads to colonization with antibiotic-resistant bacteria, which may precede a recurrent episode of VAP.

Reducing duration of therapy in patients with VAP has led to good outcomes with less antibiotic use with a variety of different strategies. Singh et al used a modification of the CPIS scoring system to identify low-risk patients (CPIS ≤6) with suspected VAP who could be treated with 3 days of antibiotics as opposed to the conventional practice of 10 to 21 days of antibiotic therapy.[180] Patients receiving the shorter course of antibiotic therapy had better clinical outcomes than the patients receiving longer therapy, with fewer subsequent superinfections attributed to antibiotic-resistant pathogens, although many of these patients may not have had pneumonia. A multicenter, randomized, controlled trial demonstrated, in a large series of 413 patients with microbiologically proven VAP, that patients who received appropriate initial empiric therapy for 8 days had outcomes similar to patients who received therapy for 15 days.[298] A trend toward greater rates of relapse for short-duration therapy was seen if the etiologic agent was *P. aeruginosa* or *Acinetobacter* spp., but clinical outcomes were exactly the same. These results were recently confirmed by two other studies, including a prospective, randomized trial of 290 patients evaluating an antibiotic discontinuation policy.[254,299]

Based on these data, an 8-day regimen can probably be standard for patients with VAP. Possible exceptions to this recommendation include immunosuppressed patients, those whose initial antimicrobial treatment was not appropriate for the causative microorganism(s), and patients whose infection was caused by very difficult-to-treat microorganisms and had no improvement in clinical signs of infection.

Many clinicians, however, remain hesitant about prescribing fewer fixed days of antibiotics for patients with VAP, and would prefer to customize antibiotic duration based on the clinical course of the disease and/or using serial determinations of a biologic marker of infection, such as PCT. The rationale for using a biomarker to tailor antibiotic-treatment duration relies on the fact that the inflammatory response is most often proportional to infection severity.[212] When that response is absent or low, it might be logical to discontinue antibiotics earlier. Moreover, it is well known that PCT levels reflect the inflammatory response intensity and are related to outcome.[223,300,301] Thus, adapting antimicrobial treatment duration to PCT kinetics seems reasonable, and has been demonstrated as useful in several randomized trials targeting patients with acute respiratory infection, including five trials conducted in the ICU.[211,214–218,222,302–308]

Stolz et al randomized 101 patients with VAP to be managed with an antibiotic discontinuation strategy according to guidelines (control group) or to serum PCT concentrations.[304] In patients randomized in the PCT group, attending physicians were recommended to stop antibiotics when the PCT concentration was below 0.5 ng/m, or had decreased by more than 80% from the baseline value. Using this algorithm, the number of antibiotic-free days alive within 28 days after VAP diagnosis was significantly higher in the PCT group than in the control group (median [interquartile range], 13 days [2 to 21] vs. 9.5 days [1.5 to 17]). This reduction in antibiotic administration was not associated with a worse outcome, because ventilator-free days, ICU-free days, length of hospital stay, 28-day mortality, and hospital mortality rates were similar in the two groups.[304] Similar results were observed by Bouadma et al in the PRORATA (PROcalcitonin to Reduce Antibiotic Treatments in Acutely ill patients) trial, a randomized trial that included 621 ICU patients, of whom 141 had microbiologically proven VAP.[305] Using predefined algorithms to initiate or discontinue antibiotics according to serum PCT levels, the duration of antibiotic treatment for the first episode was significantly decreased in the seventy-five patients randomized in the PCT-guided group compared to the control group managed using international and local guidelines (7.3 ± 5.3 days vs. 9.4 ± 5.7 days, $p = 0.02$, respectively), with no detrimental effects on patients' outcome.[305]

Aerosolized Therapy

Because insufficient dosing of antibiotics at the site of infection in patients with VAP may lead to clinical and microbiologic failures, efforts to optimize pulmonary penetration of antimicrobial agents are warranted. Directly delivering the drug to the site of infection via aerosolization may represent a valid option, providing that this technique actually allows improved lung-tissue concentrations at the infected site. This mode of administration, by achieving high pulmonary antibiotic concentrations, could increase the antibacterial activity of concentration-dependent antibiotics, such as aminoglycosides, or restore the bactericidal activity of antibiotics in the case of infections caused by pathogens of impaired sensitivity. Furthermore, by limiting systemic exposure, it could also allow the administration of antibiotics

characterized by a high systemic toxicity, such as aminoglycosides and polymyxins.

Pooling the results of the five randomized controlled trials that examined the potential benefit of inhaled or endotracheally instilled antibiotics for the treatment of patients with hospital-acquired pneumonia or VAP, a statistically higher success rate was demonstrated in patients receiving antimicrobial agents via the respiratory tract.[309] No difference in mortality, however, could be documented and the meta-analysis was based on a very limited number of patients. It should also be noted that the bronchial deposition of aerosolized antibiotics might have rendered cultures of endotracheal samples falsely "negative," which could have artificially increased the rate of success in patients randomized to aerosolized or endotracheally instilled antibiotics, casting some doubt on the validity of the results.

Several recent studies, based on a new generation of nebulizers with improved technology, have renewed the interest in aerosolized antibiotic therapy for patients with VAP.[310–313] In anesthetized piglets on prolonged mechanical ventilation for a severe experimental *E. coli* bronchopneumonia, amikacin lung-tissue concentrations were markedly higher following aerosolization as compared to intravenous administration.[314] Seventy-one percent of lung segments were found sterile after two nebulizations and 25 hours of treatment, whereas cultures of lung segments were comparable in nontreated and intravenously treated animals. In a recent study using a new device with a vibrating plate and multiple apertures to produce an aerosol of amikacin conducted in sixty-nine patients with gram-negative bacilli VAP, the authors found that the nebulized drug was well distributed in the lung parenchyma, with high tracheal and alveolar levels but low serum concentration, below the renal toxicity threshold.[315] Moreover, aerosolized amikacin was well tolerated, without any severe adverse event, and patients who received amikacin twice daily required significantly less antibiotics than patients given placebo.[316]

Data on the impact of aerosolized antibiotics active against gram-positive bacteria are scarce. In a placebo-controlled trial, Palmer et al randomized forty-three patients with purulent tracheobronchitis and gram-stain-identified microorganisms to receive aerosolized antibiotics ($n = 19$) or placebo ($n = 24$).[311] The antibiotic was chosen according to tracheal aspirate gram-staining results (vancomycin for gram-positive, gentamicin for gram-negative). Antibiotic aerosolization led to faster resolution of clinical signs of pneumonia than placebo, fewer subsequent VAP episodes, less bacterial resistance and use of systemic antibiotics, and perhaps accelerated weaning from mechanical ventilation.[311]

Aerosolized polymyxin is also being used increasingly for treating patients with infections caused by multidrug-resistant gram-negative bacilli, mainly *A. baumannii* and *P. aeruginosa,* with mixed results.[312,313] In a randomized trial that included 100 patients with VAP caused by gram-negative bacilli (predominantly multidrug-resistant *A. baumannii* and/or *P. aeruginosa*), patients who were treated with a combination of systemic antibiotics and nebulized colistin had a higher rate of favorable microbiologic outcome than did patients who were treated with systemic antibiotics alone (microbiologic eradication or presumed eradication 61% vs. 38%), but there was no differences in clinical outcome (51% vs. 53%).[313] In a retrospective case-control study that included eighty-six patients with VAP caused by multidrug-resistant gram-negative bacilli (predominantly *A. baumannii*) treated with a combination of intravenous and aerosolized colistin compared with intravenous colistin alone, there was only a trend toward improved rates of clinical cure, pathogen eradication, and mortality in the patients who received aerosolized and intravenous colistin.[312]

Thus, although the results of recent investigations emphasize the potential contribution of aerosolized antibiotics to treat VAP as an efficient adjunctive therapy to intravenous antibiotics, the clinical impact of such a strategy has not yet been definitively established. At present, aerosolized antibiotics can only be recommended to treat patients with multidrug-resistant VAP, for which no effective intravenous antibiotics are available. Indisputably, large prospective trials are needed to evaluate the potential usefulness of this therapeutic modality.

PREVENTION

Because VAP is associated with increased morbidity, longer hospital stay, increased health care costs, and higher mortality rates, prevention is a major challenge for intensive care medicine.[2,317,318] A number of recommendations for the prevention of VAP are empiric rather than based on controlled observations, which make evaluation of the impact of such interventions difficult in this setting for several reasons: (a) the difficulty in obtaining an accurate diagnosis of VAP, that is, to distinguish patients with true infection from patients with tracheal colonization and/or other pathologic processes as only patients who develop true VAP are likely to benefit from preventive measures; (b) the difficulty of precisely determining the impact of prophylactic measure on the overall mortality of a general ICU population, that is, to identify preventable deaths, directly attributable to VAP, among all deaths occurring in a population of ventilated ICU patients; and (c) the difficulty of evaluating the consequences of a preventive measure on a potentially pathogenic mechanism, for example, to evaluate the exact role played by prevention or reduction of tracheal colonization in modifying the development of VAP.

Conventional Infection-Control Approaches

These measures should be the first step taken in any prevention program.[319] The design of the ICU has a direct effect on the potential for nosocomial infections. Adequate space and lighting, proper functioning of ventilation systems, and facilities for handwashing lead to lower infection rates.[320] It should, however, be kept in mind that physical upgrading of

the environment does not per se reduce the infection rate unless personnel attitude and practices are improved. In any ICU, one of the most important factors is the health care staff, including the number, quality, and motivation of medical, nursing, and ancillary members.[321] The team should include a sufficient number of nurses to minimize them moving from one patient to another and to avoid having them working under constant pressure.[322–325] The importance of personal cleanliness and attention to aseptic procedures must be emphasized at every possible opportunity. At the same time, unnecessarily rigid restrictions should be avoided.[326] The importance of personal cleanliness and attention to aseptic procedures must be emphasized at every opportunity. It is clear that careful monitoring, decontamination, and compliance with guidelines for the use of respiratory equipment all reduce the incidence of nosocomial pneumonia.[324] In particular, handwashing and handrubbing with alcohol-based solutions remain the most important components of effective infection control practices in the ICU.[132,324,327]

A bacterial monitoring policy facilitates the early recognition of colonization and infection and is associated with significant reductions in nosocomial infection rates.[328] The focal point for infection control activities in the ICU is a surveillance system designed to establish and maintain a database that describes endemic rates of nosocomial infection. Awareness of the endemic rates enables the recognition of the onset of an epidemic when infection rates rise above a calculated threshold.

Adoption of an antibiotic policy restricting the prescription of broad-spectrum agents and useless antibiotics is of major importance.[22,164,235,329] Better use of antibiotics in the ICU can be achieved by implementing strict guidelines, avoiding the treatment of patients who do not have bacterial infections, using narrow-spectrum antibiotics whenever possible, and reducing the duration of treatment. Similarly, transfusion of red blood cells and other allogenic blood products should follow a strict policy, because several studies have identified exposure to allogenic blood products as a risk factor for postoperative infection and pneumonia.[330–335] Some very simple, safe, inexpensive, and logical measures may have major effects on the frequency of VAP in ventilated patients. These include avoiding nasal insertion of endotracheal and gastric tubes, maintaining the endotracheal tube cuff pressure above 20 cm H_2O to prevent leakage of bacteria around the cuff into the lower respiratory tract, prompt reintubation of patients who are likely to fail extubation, removing tubing condensate, and providing adequate oral hygiene with tooth brushing.[101,119,136,336,337]

Specific Prophylaxis against Ventilator-Associated Pneumonia

Specific strategies aimed at reducing the duration of mechanical ventilation (a major risk factor for VAP), such as improved methods of sedation, use of protocols to facilitate and accelerate weaning, using low tidal volume and adequate levels of positive end-expiratory pressure, and use of intensive insulin therapy to control blood glucose should be considered as integral parts of any infection-control program.[338–343] All are based on the application of strict protocols. Noninvasive ventilation is an alternative approach to using artificial airways to avoid infectious complications and injury of the trachea in patients with acute respiratory failure. Many observational studies and seven randomized trials suggest that patients who tolerate noninvasive ventilation have a lower incidence of pneumonia than those tracheally intubated.[338,344–352]

Apart from protocols aimed at reducing the duration of mechanical ventilation, eight prophylactic approaches have been studied: semirecumbent positioning, oscillating and rotating beds, continuous or intermittent aspiration of subglottic secretions, ventilator circuits management, methods of enteral feeding, stress-ulcer prophylaxis, oral decontamination with antiseptics, and selective digestive decontamination.

SEMIRECUMBENT POSITIONING

Supine positioning is independently associated with the development of VAP.[22] Placing ventilated patients in a semirecumbent position to minimize reflux and aspiration of gastric contents is a simple measure, although some practical problems can occur in unstable patients. Only a few trials have evaluated the efficacy of semirecumbent positioning.[112–114,117,353–355] In a randomized trial based on a small number of patients, Drakulovic et al observed lower rates of both clinically suspected and bacteriologically confirmed VAP, and identified supine positioning as an independent risk factor for VAP with enteral nutrition, ventilation for 7 days or longer and a Glasgow coma score of less than 9 points. The feasibility and efficacy of this intervention in a larger patient population, however, remain unknown, all the more as its efficacy was not confirmed in a subsequent trial that included 221 ventilated patients or in a recent meta-analysis.[117,353] Raising the head of bed to 30 degrees or higher may also have some detrimental skin effects and may increase the incidence of pressure ulcer formation.[115] Pending additional studies, most experts currently recommend maintaining the head of the bed elevated to at least 20 degrees to 30 degrees in all ventilated patients who are hemodynamically stable, particularly when they are receiving enteral nutrition.[134,317,356–361]

OSCILLATING AND ROTATING BED

Immobility in critically ill patients treated with mechanical ventilation results in atelectasis, impaired secretions drainage, and potentially predisposes to pulmonary complications including VAP. Oscillating and rotating beds may help in preventing pneumonia.[317] Six randomized trials, which included mostly surgical and trauma patients, ventilated or not, and summarized in a meta-analysis by Choi and Nelson,[362] compared continuous lateral

rotational therapy with standard beds. The meta-analysis found a significant reduction in the risk for pneumonia, principally concerning early onset (<5 days) pneumonia and a decreased duration of ICU stay. Notably, the only randomized, controlled trial—not included in the meta-analysis—conducted on a general ICU population did not show any differences in pneumonia rates but showed a significantly shorter length of ICU stay.[363] Some adverse events have been described with these beds including disconnection of catheters or pressure ulceration; in addition, nursing care is potentially complicated with oscillating beds. Finally, despite the cost of such beds, cost-to-benefit analyses suggested favorable results, mainly caused by the reduction of ICU length of stay.

ORAL DECONTAMINATION WITH ANTISEPTICS

Topical application of chlorhexidine or other antiseptics to the oral mucosa may decrease respiratory pathogen colonization and secondary lung infection in ventilated patients. Randomized, controlled trials, however, have reported mixed results: Some showed little effect whereas others found a reduction in the incidence of VAP.[364–376] Combining the results of the seven randomized controlled trials that evaluated the potential efficacy of chlorhexidine, a 30% relative reduction in the risk of VAP was observed, but no effect of chlorhexidine on reduction of mortality or duration of mechanical ventilation could be demonstated.[377] The varying concentration of the chlorhexidine solutions used in these studies may have affected the results. In the study by Koeman et al,[369] a 2% solution of chlorhexidine was used, a much higher concentration than in the other published studies, most of which used a 0.12% or 0.2% solution; this may partially explain the benefit of chlorhexidine for reducing VAP in this study. Reported adverse effects of oral use of chlorhexidine include staining of the teeth, which is reversible with professional cleaning, and a transient abnormality of taste.[377] The optimal concentration, frequency of application, effect on promoting resistance among oropharyngeal flora, and cost-effectiveness of chlorhexidine should be addressed in future studies.

ASPIRATION OF SUBGLOTTIC SECRETIONS AND USE OF SPECIALIZED ENDOTRACHEAL TUBES

Repeated micro inhalations of colonized oropharyngeal (subglottic) secretions are the major mechanism of VAP. Continuous or intermittent suctioning of oropharyngeal secretions has been proposed as a means to avoid chronic aspiration of secretions through the tracheal cuff of intubated patients. Aspiration of subglottic secretions requires the use of specially designed endotracheal tube with a separate lumen that opens into the subglottic region. Thirteen randomized controlled trials have studied aspiration of subglottic secretions for the prevention of VAP for a total of 2442 randomized patients.[378–386] Of the thirteen studies, twelve reported a reduction in VAP rates in the subglottic secretion drainage arm. When the results were combined in a meta-analysis, the overall risk ratio for VAP was 0.55 (95% CI, 0.46 to 0.66; $p < .00001$) with no heterogeneity, and the use of subglottic secretion drainage was associated with reduced ICU length of stay, decreased duration of mechanical ventilation, and increased time to first episode of VAP.[386] No effect, however, on hospital or ICU mortality could be demonstrated.[386] Some experimental data in sheep and ICU patients suggest the possibility of tracheal damage with the use of this type of tube.[382,387,388]

Bacterial aggregates in biofilm dislodged during suctioning might not be eradicated by antibiotics or effectively cleared by host immune defenses, thereby constituting dangerous inoculums for the lung. Preliminary data obtained in animal models and from small randomized human studies support the hypothesis that an endotracheal tube coated externally and internally with a potent antiseptic product such as silver could have a sustained antimicrobial effect within the proximal airways and block biofilm formation at its surface.[389–394] Such a device was evaluated in a large, randomized, multicenter, single-blind trial by Kollef et al.[395] The authors conclude that the new device was able to lower the VAP frequency from 7.5% for the control group to 4.8% for the group receiving the silver-coated endotracheal tube. The silver-coated tube, however, did not reduce mortality rates, the duration of intubation, hospital length of stay, or the frequency or severity of adverse effects.

VENTILATOR CIRCUIT MANAGEMENT

Decreased frequency of ventilator circuit change, replacement of heated humidifiers by heat and moisture exchangers, decreased frequency of heat and moisture exchanger change, and closed suctioning systems have been tested for preventing VAP.[2,317,318,396] Four randomized trials of decreased frequency of ventilator circuit changes have been published. Changes every 2 days, 7 days, and no scheduled change did not find significant difference in the rate of VAP as summarized in a recent meta-analysis.[397] One meta-analysis summarized the results of five randomized, controlled trials which compared the effects of heated humidifiers and heat and moisture exchangers on the risk of VAP.[318] Only one of these five studies found a significant reduction of VAP rate with the use of heat and moisture exchangers.[125] Efficacy of both humidification strategies seems comparable. Two studies, however, reported increased rates of endotracheal tube occlusion with the use of heat and moisture exchangers; the increased resistive load can cause difficulties in ventilation and weaning in patients with severe acute respiratory distress syndrome—related to larger dead space. No other adverse effects were observed. No effect on mortality was reported. Finally, one study has evaluated the impact of less frequent changes (daily vs. every 5 days) in heat and moisture exchangers on the development of VAP.[398] No difference in the VAP rates was observed.

To avoid hypoxia, hypotension, and contamination of suction catheters entering the tracheal tube, investigators

have examined closed suctioning systems.[396,399–400] They either found a nonsignificantly lower prevalence of VAP for patients managed with the closed system compared to the open system, without any adverse effect,[400] or they found that its use was associated with an increased frequency of endotracheal colonization.[399] Closed-suction systems also failed to reduce cross-transmission and acquisition rates of the most relevant gram-negative bacteria in ICU patients in a prospective crossover study in which 1110 patients were enrolled.[396]

METHODS OF ENTERAL FEEDING

Nearly all ventilated patients have a nasogastric tube inserted to manage gastric and enteral secretions, prevent gastric distension, or provide nutritional support. A nasogastric tube may increase the risk for gastroesophageal reflux, aspiration, and VAP.[77] Four randomized, controlled trials have evaluated methods of enteral feeding aimed at preventing VAP: postpyloric or jejunal feeding (vs. gastric feeding), the use of motility agents (metoclopramide vs. placebo), acidification of feeding (with addition of hydrochloric acid), and intermittent (vs. continuous) feeding.[108,401,402] These studies did not find differences in incidence of VAP or mortality rates. Potentially serious adverse effects have been observed in patients receiving acidified feeding (gastrointestinal bleeding) or intermittent enteral feeding (increased gastric volume and lower volumes of feeding). Thus, to date, methods of enteral feeding aimed at reducing the incidence of VAP cannot be recommended for routine use.

STRESS-ULCER PROPHYLAXIS

Gastric colonization by potentially pathogenic organisms increases with decreasing gastric acidity.[403] Thus, medications that decrease gastric acidity (antacids, H_2 blockers, proton pump inhibitors) may increase organism counts and increase the risk of VAP. In contrast, medications that do not affect gastric acidity (sucralfate) may not increase this risk. Several meta-analyses of more than 20 randomized trials have evaluated the risk for VAP associated with the methods used to prevent gastrointestinal bleeding in critically ill patients.[91,92,404] The largest randomized trial comparing ranitidine to sucralfate showed that ranitidine was superior in preventing gastrointestinal bleeding and did not increase the risk of VAP.[93] Therefore, despite the potential advantage of sucralfate (potentially less VAP with more gastrointestinal-bleeding) over H_2 blockers (potentially more VAP with less gastrointestinal bleeding) in preventing VAP, stress-ulcer prophylaxis with H_2 blockers appears to be safe in patients who are at high risk for bleeding as well as VAP.[405] Although proton pump inhibitors are now widely used for gastric bleeding prophylaxis in the ICU, based on their potentially higher efficacy, their use is associated with similar rates of nosocomial pneumonia as H_2 blockers.[404,406–410]

SELECTIVE DIGESTIVE DECONTAMINATION

Selective decontamination of the digestive tract (SDD) includes a short course of systemic antibiotic therapy, such as cefotaxime, trimethoprim, or a fluoroquinolone, and topical administration of nonabsorbable antibiotics (usually an aminoglycoside, polymyxin B, and amphotericin) to the mouth and stomach, in order to eradicate potentially pathogenic bacteria and yeast that may cause infections.[411] Since the original study published by Stoutenbeck et al in 1984,[412] which demonstrated a decrease of the overall infection rate in patients receiving the SDD regimen, more than forty randomized, controlled trials, and eight meta-analyses have been published. All eight meta-analyses reported a significant reduction in the risk of VAP, and four reported a significant reduction in mortality.[86,413–416] Recently, three prospective, randomized, controlled trials, all performed in ICUs with low rates of antibiotic resistance, have been published that were large enough to show a significant survival benefit in SDD-treated patients.[417–419] All three were in favor of treatment with SDD, the largest and most recent one by De Smet et al demonstrating a relative decrease in 28-day mortality rate (OR 0.83,95% CI, 0.72 to 0.97) and an absolute survival benefit of 3.5%.[419]

In spite of these benefits, widespread use of SDD in ICU patients remains controversial. The major concern with use of SDD is that it probably needs to be used in nearly all patients in a given ICU, and this widespread use has been shown in some studies to promote the emergence of resistant bacteria, particularly gram-positives such as MRSA.[420–424] This is likely to be even a greater problem in ICUs with a high baseline rate of resistance.[317,318,425] In contrast to what was expected, however, most studies that have evaluated this issue showed a lower incidence of colonization with (multi)resistant bacteria in SDD-treated patients than in control patients.[418,426] In a single-center observational study from Germany, 5-year use of SDD was not associated with an increase of MRSA or aminoglycoside and β-lactam resistance in gram-negative bacteria.[427] Putative explanations why colonization with resistant microorganisms is lower after treatment with SDD include the almost invariable sensibility of gram-negative aerobic bacteria for the commonly used combination of polymyxin E and tobramycin, the fact that treatment with polymyxin E rarely induces resistance, the very high local concentrations in the bowel of the used antibiotics, and the lower rate of use of systemic antibiotics in SDD-treated patients.[428]

IMPLEMENTING A STRUCTURED PREVENTION POLICY

The application of consistent evidence-based interventions to prevent VAP has been highly variable from one ICU to another and often suboptimal.[429–430] Moreover, no single preventive measure can succeed alone, emphasizing the need to use multifaceted and multidisciplinary programs to prevent VAP. Such programs are frequently referred to

as "care bundles." A care bundle is a set of readily implementable interventions that are required to be undertaken for each patient on a regular basis.[431] The key goal is that every intervention must be implemented for every patient on every day of his or her stay in the ICU. Compliance is assessed for the bundle as a whole, so failure to complete even a single intervention means failure of the whole bundle at a particular assessment. The interventions need to be packaged in such a way that they are easy to assess for compliance, which usually means that no more than five interventions are included in each care bundle. The performance goal is to routinely achieve more than 95% compliance. Care bundles make it possible to introduce evidence-based preventive measures, including appropriate nurse staffing levels, hand hygiene with alcohol-based formulations, standardized weaning protocols and daily interruption of sedation, oral care with chlorhexidine, and keeping patients who receive enteral nutrition in a semirecumbent position.[252] All of these measures can be consistently applied to all patients in a coordinated way. The aim of care bundles is therefore only to facilitate and promote changes in patient care and encourage compliance with guidelines. Several studies using quasi-experimental designs confirmed the usefulness of this strategy for preventing VAP in the ICU.[134,355,432–444]

The lack of methodologic rigor of the reported studies, however, precludes any conclusive statements about "bundle care" effectiveness or cost-effectiveness. The exact set of key interventions that should be part of the "VAP-prevention bundle" is also not currently known as well as the optimal way for implementing it.[134,445–447] Successful VAP prevention requires an interdisciplinary team, educational interventions, system innovations, process indicator evaluation, and feedback to health care workers. As shown by a recent study, simply having a checklist available for reference without consideration of a robust implementation and adherence strategy is unlikely to maximize patient outcomes.[444] Whether this organization and data collection can be generalized to all ICUs remains to be determined, as well as the selection of the "optimal" bundle. In the meantime, clinical practice quality indicators must be developed in parallel with guidelines to check the adequacy between the two and to find solutions to improve guideline compliance.

In the United States, the Centers for Medicare and Medicaid Services has proposed stopping hospital reimbursements for care made necessary by preventable complications, including nosocomial infections, aiming for a zero-VAP rate.[448] Although this plan may have the desirable consequences of improving the quality of care, it also may penalize hospitals that admit high-risk patients and inadvertently encourage institutions to underreport VAP or to overuse antibiotics, thereby favoring dissemination of multidrug-resistant microorganisms. This possibility further underscores the need to carefully evaluate all new strategies potentially aimed at preventing VAP against what represents best clinical practices.

CONCLUSION

VAP is associated with mortality in excess of that caused by the underlying disease alone, particularly in case of infection caused by high-risk pathogens, such as *P. aeruginosa* and MRSA. The high level of bacterial resistance observed in patients who develop VAP limits the treatment options available to clinicians and encourages the use of antibiotic regimens combining several broad-spectrum drugs, even if the pretest probability of the disease is low, because initial inappropriate antimicrobial therapy has been linked to poor prognosis. Besides its economic impact, this practice of "spiralling empiricism" increasingly leads to the unnecessary administration of antibiotics in many ICU patients without true infection, paradoxically resulting in the emergence of infections caused by more antibiotic-resistant microorganisms that are, in turn, associated with increased rates of patient mortality and morbidity. Every possible effort should therefore be made to obtain, before new antibiotics are administered, reliable pulmonary specimens for direct microscope examination and cultures from each patient clinically suspected of having developed VAP. Because respiratory tract colonization of ICU patients is generally very complex, corresponding to a mix of self-colonization and cross-transmission, only a multifaceted and multidisciplinary preventive program can be effective.

SINUS INFECTIONS IN THE VENTILATED PATIENT

Jean-Jacques Rouby
Qin Lu

Infection of paranasal sinus cavities is a well-recognized cause of fever in mechanically ventilated patients.[1–7] Easy to detect in maxillary sinuses, the infectious process also frequently involves ethmoid, frontal, and sphenoid sinuses[8] where the diagnosis is more difficult to establish.[9] Infectious sinusitis represents an important reservoir of bacteria[10] that may disseminate into the respiratory tract[11] and intracranially.[12] In contrast to community-acquired sinusitis, ventilator-associated sinusitis is often clinically silent in sedated critically ill patients and may be underdiagnosed if not systematically screened for in the presence of fever of unknown origin. In the absence of diagnosis and appropriate treatment, bacteremia,[2,5] ventilator-associated pneumonia,[13] and life-threatening complications, such as orbital infection,[14] meningitis, mastoiditis, cerebral abscess, or thrombosis of the sinus cavernosus, may result.[12] Early detection and treatment of infectious maxillary sinusitis significantly reduces the incidence of ventilator-associated pneumonia and may decrease intensive care mortality.[11]

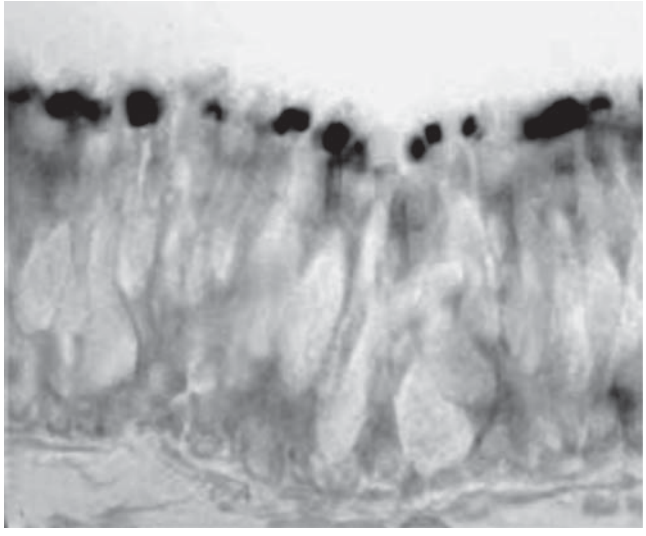
PHYSIOLOGY OF PARANASAL SINUSES

Classical Hypotheses

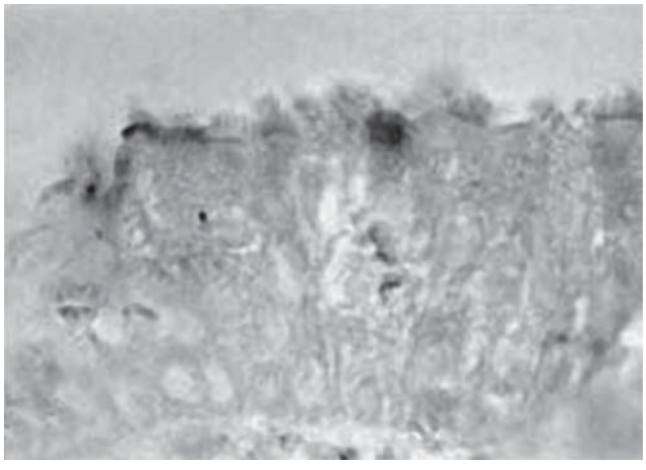
Located at the entry of the respiratory system, paranasal sinuses and the nose serve to humidify, filter, warm, and sense inspiratory gas.[15,16] A number of other presupposed physiologic roles have not yet received firm scientific confirmation.[17] Among them, the most popular are that paranasal sinuses help lighten the bones of the skull, improve the resonance of the voice, serve as a sound box for opera singers, increase the surface area of the olfactory membrane, serve as shock absorbers in mechanical impacts, protect against high pressure in the nasal region when sneezing, act as thermal insulators of the brain, and promote facial growth and architecture. More simply, paranasal sinuses might be considered as evolutionary relics or faults, whose form results from the influence of the forces created during the act of chewing.

Recent Hypothesis: The Role of the Regional Production of Nitric Oxide

Large amounts of nitric oxide are produced in human paranasal sinuses[18,19] and permanently released in the upper airways through the different ostia that link antral cavities to the nostrils.[20] As shown in Figure 47-1, an inducible form of nitric oxide synthetase is present in cilia and microvilli of the maxillary sinus epithelium of healthy volunteers.[18,19] Significant nitric oxide concentrations are also found in the exhaled gas of guinea pigs, pigs, rhesus monkeys, rats, rabbits, horses, and Asian elephants, all species possessing open paranasal sinuses.[20–24] Interestingly, seals and baboons, which do not have open paranasal sinuses, do not exhale nitric oxide,[25,26] thus confirming that pneumatic facial cavities play a critical role in the nasal production of nitric oxide in mammals. Humming, by accelerating gas exchange in sinus cavities, markedly increases exhaled nasal nitric oxide[27] whereas moderate exercise has an opposite effect.[28] Nitric oxide produced in the paranasal sinuses likely has an important role in host defense against inhaled pathogens, in the optimization of ventilation–perfusion ratios during normal breathing,[29] and in the regulation of ciliary motility.[30,31]



A



B

FIGURE 47-1 Immunoreactive sinus inducible nitric oxide synthetase distribution is represented in black on biopsy samples from maxillary sinus epithelium. In a healthy subject (**A**), a strong immunoreactivity is detected in the apical part of the ciliated epithelial cells near the surface. In a patient with radiographic maxillary sinusitis (**B**), the signal is weaker or absent. (Reprinted with permission of the American Thoracic Society. Copyright © 2012 American Thoracic Society. Official Journal of the American Thoracic Society.)

Each paranasal sinus communicates with the corresponding nostril by an ostium, which provides aeration of the antral cavity. Bacteria are present in nasal secretions covering the mucociliary epithelium and on the gingival mucosa and its crevices. Microorganisms may enter the maxillary cavity by the canine fossa and the inferior meatus. Paranasal sinuses, however, are normally sterile[32] as a result of two different protective mechanisms. First, the antral mucosa is covered with a protective mucus layer produced by goblet cells. Bacteria penetrating into the maxillary cavity are immediately enveloped by mucus and moved rapidly to the sinus ostium by respiratory cilia. Second, the antral concentrations of nitric oxide exert a bacteriostatic effect. Many pathogens are sensitive to nitric oxide in concentrations less than 1 part per million.[33–36] The antral concentrations of nitric oxide, produced by the maxillary epithelium, are equal to or greater than 2 parts per million and likely contribute to antral sterility.[32]

PATHOGENESIS AND PREDISPOSING FACTORS

Pathogenesis of radiographic sinusitis diagnosed in intubated and tracheostomized patients is incompletely understood.

Experimental Models

Rabbits have large and accessible nostrils and their sinuses show anatomical similarities to those of humans. In this species, sinuses consist of a number of cavities connected to each other and can be considered as one, called the maxillary sinus.[37] Historically, the first experimental model was created by opening the maxillary sinus through an anterior wall antrostomy, gluing and closing the natural ostium, and injecting bacterial strains directly supress "injected" into the maxillary cavity.[38] Although the model is extremely reliable for producing purulent sinusitis, it causes a traumatic injury that questions its relevance for human sinusitis. As a consequence, a rhinogenic model was proposed in the late 1990s and remains to date the reference:[39,40] a foreign body—an endotracheal tube,[41] a catheter,[42] or a sponge impregnated or not with bacteria[43]—is implanted into nostrils for a period

of time ranging from several days to several weeks. In the rhinogenic rabbit model, computed tomographic evidence of maxillary sinusitis is detected at the sixth day following foreign-body nasal placement.[43]

A number of lessons can be drawn from experimental studies. Direct or indirect obstruction of the ostia rapidly induces an acute sinus inflammation. The intranasal placement of a foreign body over several days results in purulent sinusitis, characterized by the accumulation of a thick and purulent discharge within the sinus cavity.[43] Initial histologic lesions are made of inflammation and exudation of maxillary mucosa; the number of goblet cells increases, augmenting mucus production and causing fluid accumulation within the cavity. Then, inflammatory polyp formation is observed,[41,43,44] associated with permanent loss of cilia, squamous metaplasia, and fibrosis.[43,45] The risk of sinusitis increases with the nasal catheterization period and the size of the intranasal catheter.[41,42] Relief of ostial obstruction promotes resolution of radiographic sinusitis within a few days,[46] whereas sinus inflammation persists for several weeks.[43] Over time, the fluid-filled maxillary cavity is contaminated[41] or infected[43] by species present in the adjacent nostril.[41] Surprisingly, bacteria impregnating the intranasal sponge are rarely found in the nasal cavity and are often replaced by bacteria belonging to the normal flora of the rabbit nostrils.[43,47]

Finally, the following sequence may lead to bacterial sinusitis. First, the presence of a nasal foreign body induces an ipsilateral inflammatory antral disease. Second, mucus accumulates within the antral cavity because of goblet cell proliferation, impairment of mucociliary clearance, and ostial obstruction. Third, the antral contents are contaminated and infected by microorganisms issued from the nostrils whose proliferation into the sinus cavity is facilitated by the lack of regional nitric oxide production.

Macroscopic and Microscopic Aspects of Sinusitis Complicating Mechanical Ventilation

Only a few studies have reported macroscopic and histologic disorders characterizing radiographic maxillary sinusitis in critically ill patients.[19,48–50] In thirty-three neurosurgical patients receiving prolonged mechanical ventilation with radiographic maxillary sinusitis, antroscopies were performed by the canine fossa route.[49] Most of radiographic maxillary sinusitis corresponded to "inflammatory" sinusitis, with the antral cavity filled with thin and transparent secretions and/or gelatinous and transparent mucus with a neutral smell. In a minority of patients, bacterial sinusitis was diagnosed as the presence of viscous and opaque pus with a foul smell. Both types of sinusitis were associated with varying mucosal reactions, ranging from pallid to vermilion edema with different degrees of transparency. Interestingly, in two patients with "inflammatory" sinusitis and one patient with bacterial sinusitis, maxillary mucosa was macroscopically normal. When present, mucosal edema always included the medial side with the ostial region.[49] Biopsy specimens of antral mucosa revealed various grades of inflammation. Acute inflammation involving the maxillary epithelium, the connective tissue, and the vessels with a massive infiltration by polymorphonuclear neutrophils was observed in patients with bacterial maxillary sinusitis. In patients with "inflammatory" sinusitis, mild inflammation was observed, characterized by a moderate cellular infiltration of the connective tissue with a massive infiltration of vessels by eosinophils.[48]

Predisposing Factors

FOREIGN BODIES WITHIN THE NOSTRILS

Several prospective and retrospective studies have shown that the occurrence of radiographic sinusitis has a higher incidence in the antrum adjacent to nasotracheal and nasogastric tubes than in the nonadjacent sinus.[3,4,6,7,51–62] The presence of a nasogastric tube for enteral feeding appears as an independent risk factor.[63] As in experimental sinusitis, the presence of a foreign body within the nostrils creates an ostial obstruction that initiates sinus inflammation and mucus accumulation within the sinus cavity. Confirming experimental data,[42] a large endotracheal tube induces radiographic sinusitis more frequently and faster than a small nasogastric tube.[55,58] In addition, the plastic nasotracheal tube is the site of biofilm formation for bacteria with adhesive capacity and enhanced pathogenicity:[64–66] microorganisms adhere to the internal and external surfaces of the endotracheal tube and some species exude an exopolysaccharide that acts as a slimelike adhesive.[67] Bacteria encased in this biofilm become partially resistant to the action of antimicrobials and host defences.[68,69] The bacterial proliferation around nasal foreign bodies forms a reservoir from which microorganisms penetrate into the antral cavity.[41]

SIZE OF THE MEATUS INFERIOR AND BODY POSITION

Ostial size, upon which drainage and ventilation of the sinus cavities depends, can markedly vary from one patient to another.[70] In humans, supine position is known to reduce ostial patency[71] by inducing swelling of the ostiomeatal complex.[72] A functional ostial area less than 5 mm^2 induces hypoventilation of the maxillary cavity, local hypoxia, decrease in mucosal blood flow, and predispose to maxillary sinusitis by impairing mucociliary clearance.[73]

SEPSIS

Generalized sepsis, well known for stimulating numerous tissue-inducible nitric oxide synthetases, inhibits the nitric oxide metabolic pathway at the maxillary level.[19] Autoinhaled nitric oxide plays an important antiinflammatory and antiviral role in colds.[74] Community-acquired, as well as ventilator-associated, sinusitis decreases exhaled nasal nitric oxide[19,75,76] by reducing its antral production (see Fig. 47-1).

Sepsis originating in other organs also markedly inhibits the antral production of nitric oxide through downregulation of inducible nitric oxide synthetase messenger ribonucleic acid.[19] The sepsis-induced reduction of antral nitric oxide concentrations contributes to impaired mucociliary clearance and decreased perfusion of the maxillary epithelium, both factors that facilitate infection of the maxillary cavity by impairing bacterial cleansing.[77]

EPIDEMIOLOGY AND COMPLICATIONS

Incidence

In critically ill patients, the reported incidence of radiographic sinusitis varies from 25% to 75%.[78] More than 80% of radiographic abnormalities of the maxillary sinuses are associated with radiographic abnormalities of the ethmoid, sphenoid, and frontal sinuses.[8,79] Variability in the estimated incidence stems from the many radiographic techniques used for diagnosis: Conventional radiography is much less accurate than computed tomography or maxillary ultrasound. After 12 hours of nasal endotracheal intubation and/or nasogastric tube placement, 38% of critically ill patients have computed tomographic evidence of radiographic maxillary sinusitis.[8] Among factors other than the presence of a foreign body in the nostrils, the supine position, head[63] and/or facial trauma,[51,53,80] allergy, and sepsis have been incriminated.[81] After 7 days, the incidence of radiographic maxillary sinusitis increases to 80%.[8] Infectious sinusitis is less frequent than radiographic sinusitis, occurring only in 20% to 30% of patients intubated longer than 7 days.[79] Its incidence is higher in nasotracheally than in orotracheally intubated patients.[8]

Nosocomial Sinusitis and Ventilator-Associated Pneumonia

A link between infectious maxillary sinusitis and bronchopneumonia has been established experimentally.[47,82] In critically ill patients, nosocomial sinusitis is considered a major cause of ventilator-associated pneumonia.[8,13,56,62] In a randomized study assessing a systematic search for sinusitis in nasotracheally ventilated patients, the incidence of ventilator-associated pneumonia was significantly higher in the control group than in the study group, where infectious maxillary sinusitis was systematically sought and treated, when confirmed, by sinus drainage and intravenous antibiotics.[11] In addition, the mortality rate significantly decreased from 46% in the control group to 36% in the study group. Although the association between nosocomial sinusitis and ventilator-associated pneumonia appears highly likely, the frequent discordance between microbiologic results from sinus and lower airway cultures[8,11] suggests that these two infections may also arise simultaneously and independently because of shared risk factors and diminished host defense for infection. A heavily contaminated nasopharynx may be the common bacterial reservoir from which sinuses and lungs are infected. Conversely, antral infection, characterized by high concentrations of microorganisms,[8] can also be a reservoir from which the oropharynx, the tracheobronchial tree, and the lung parenchyma are secondarily infected. Interestingly, concentrations of nitric oxide in the maxillary and nasal cavities markedly increase as infectious maxillary sinusitis is treated with antibiotics and sinus lavage.[83] The restoration of normal local concentrations of nitric oxide, by reestablishing maxillary ciliary function and immune defense, may help in preventing maxillary cavity superinfection and eliminating one of the risk factors for ventilator-associated pneumonia.

DIAGNOSIS

Clinical Diagnosis

Unlike clinical symptomatology of community-acquired maxillary sinusitis, clinical signs of ventilator-associated maxillary sinusitis are scarce and of limited specificity.[78] General signs of infection such as fever and leukocytosis have poor specificity. Mucopurulent nasal discharge is evocative but of limited sensitivity.[51] Frontal headache is often blunted by sedative drugs aimed at facilitating mechanical ventilation. As a consequence, ventilator-associated maxillary sinusitis cannot be reliably detected on clinical signs alone and should be systematically sought in the presence of fever of unknown origin.[4,11,84]

Radiographic Diagnosis

Rather than standard sinus radiography using the Blondeau's view performed in the upright position, sinus ultrasound is the first diagnostic tool for demonstrating community-acquired acute maxillary sinusitis in ambulatory and spontaneously breathing patients, and ventilator-associated maxillary sinusitis in ventilated patients lying in the supine position.[85,86]

COMPUTED TOMOGRAPHY SCAN

Paranasal computed tomography is the reference technique for establishing the diagnosis of radiographic sinusitis.[8,87–91] A low-dose computed tomography examination is preferred to avoid excessive radiation exposure.[91] Ten thin, noncontiguous computed tomography sections, using an initial interslice gap of 15 mm aimed at avoiding direct radiation to the eye lens (Fig. 47-2), should be performed. Such a technique decreases radiation exposure by more than 90% without seriously affecting the quality of the images (Fig. 47-3).

In ventilated patients, the computed tomographic image of a given paranasal sinus can be classified into

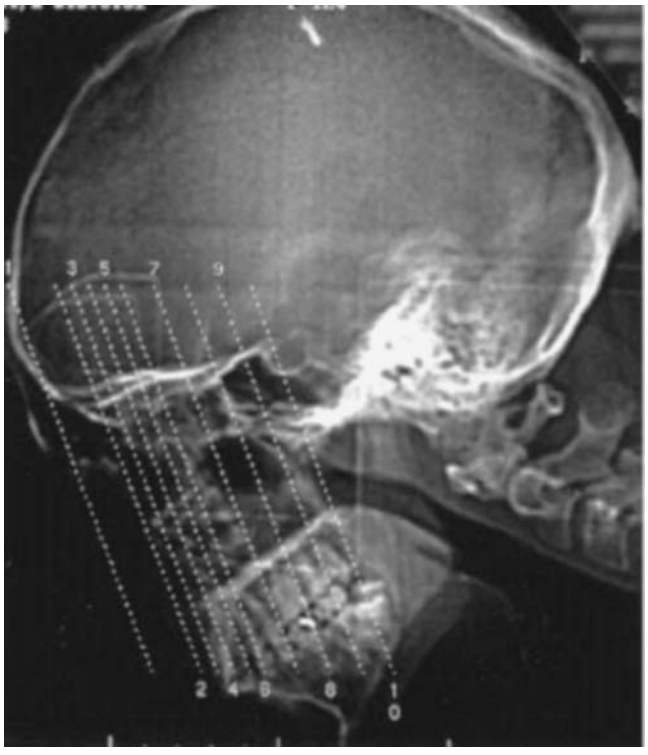


FIGURE 47-2 Scout view with different interslice gap between the 10 slices of the low-dose computed tomography protocol recommended for diagnosis of radiographic sinusitis. (Reproduced, with permission, from Hagtvedt T, Aalokken TM, Notthellen J, Kolbenstvedt A. three categories:[8] normal (Fig. 47-4), mucosal thickening (Fig. 47-5), and radiographic maxillary sinusitis, characterized by a liquid content within the sinus cavity (Fig. 47-6). More than 80% of patients with radiographic abnormalities of maxillary sinuses have also abnormal frontal, ethmoid, and sphenoid sinuses. Conversely, only half of ventilated patients with normally aerated maxillary sinuses have radiographic abnormalities of frontal, ethmoid, and sphenoid sinuses.[8] An air–fluid level in the sinus cavity or the complete sinus opacification are evocative of infectious sinusitis and call for a bacteriologic confirmation. The significance of mucosal thickening in ventilated patients is incompletely understood. Very frequently, it represents an early stage of radiographic sinusitis.[8]

Although considered the gold standard, several limitations preclude the routine use of computed tomography for diagnosing ventilator-associated sinusitis. It requires transportation of ventilated patients outside the intensive care unit, a risky procedure.[92] It is costly and not easily repeatable. As a consequence, ultrasound techniques have been developed over the last 15 years and are currently considered an attractive alternative diagnostic tool.[61,88–90,93]

ULTRASOUND EXAMINATION OF MAXILLARY SINUSES

A-mode sinus ultrasound was proposed in the early 1990s for diagnosing radiographic maxillary sinusitis in ventilated patients.[61] At present, bedside B-mode ultrasound is considered as the reference technique.[88,89,93,94] The patient should be examined at the bedside in a semirecumbent position with a 3.5-MHz probe. The ultrasonic procedure should be performed in a transversal plane using different probe angulations, at the level of the front maxillary sinus wall, delineated by the lower orbital border, the nose, the upper maxilla, and the external cheekbone.[89] Image formation depends on the presence of fluid or mucosal thickening within the sinus cavity that transmits the ultrasonic beam to deep anatomic structures. When the posterior bony wall of the maxillary sinus becomes

visible in part or completely, depending on the amount of gas present in the sinus cavity, a "sinusogram" is observed (Fig. 47-7).

In ventilated patients, the ultrasound image of the maxillary sinus can be classified into three categories:[89,93,94] absence of "sinusogram", partial "sinusogram", and complete "sinusogram" (Fig. 47-8). As shown in Figures 47-7 and 47-8, the absence of a "sinusogram" in a ventilated patient lying in the supine position may correspond either to an air–fluid level or to a normally aerated sinus. Repeating the ultrasound procedure in the half-sitting position, however, may reveal an incomplete "sinusogram", thereby asserting the diagnosis of radiographic maxillary sinusitis.[90,93] A partial "sinusogram" may indicate either mucosal thickening, simple inflammation of the sinus mucosa, or an air-fluid level. Note that in half the patients with complete opacification of the maxillary cavity on computed tomography exhibit a partial "sinusogram", resulting from the presence of small bubbles within the collection.[89] Repeating ultrasound in the supine position may facilitate the differentiation between mucosal thickening and true maxillary sinusitis.[93] The disappearance of the partial "sinusogram" in the supine position is evocative of an air–fluid level, characteristic of radiographic maxillary sinusitis. In contrast, the persistence of a partial "sinusogram" in the supine position is strongly suggestive of mucosal thickening.

If radiographic doubt persists and clinical signs are evocative of infectious maxillary sinusitis, a paranasal computed tomography scan should be performed. A complete "sinusogram" is always related to a true radiographic maxillary sinusitis and requires antral puncture in the presence of fever of unknown origin. Based on these recommendations, bedside maxillary ultrasound has a sensitivity of 100% and a specificity of 97% for diagnosing radiographic maxillary sinusitis in intubated patients undergoing mechanical ventilation.[90] An important limitation of bedside maxillary ultrasound is that it does not provide any reliable information on frontal, ethmoid, and sphenoid sinuses.

Microbiologic Diagnosis

DIAGNOSTIC CRITERIA FOR INFECTIOUS MAXILLARY SINUSITIS

Infectious maxillary sinusitis has to be clearly differentiated from radiographic maxillary sinusitis. The latter corresponds to fluid accumulation within the antral cavity, the liquid

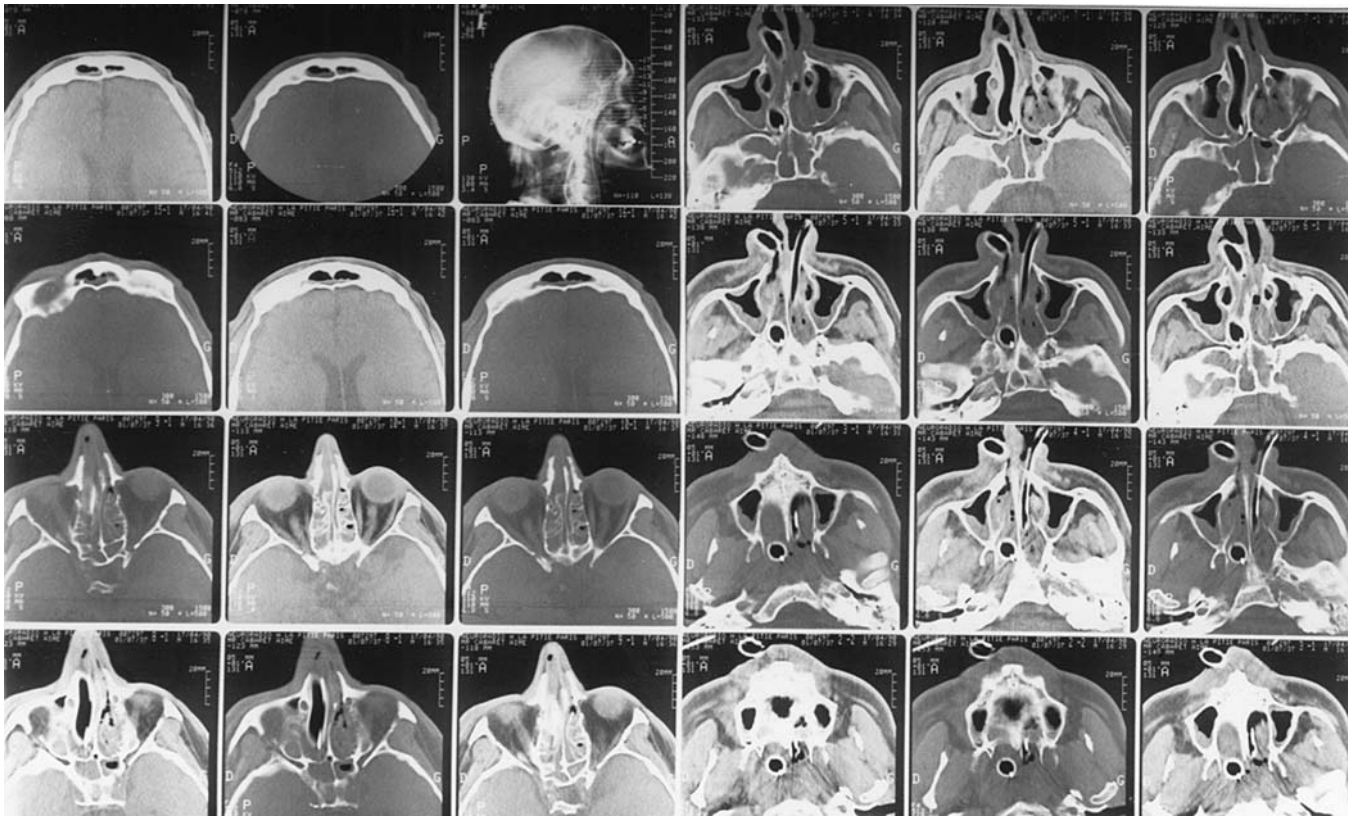

FIGURE 47-5 Computed tomography scan showing mucosal thickening of the right and left maxillary and frontal sinuses, and of the left ethmoid and sphenoid sinuses, associated with complete opacification of the right ethmoid and sphenoid sinuses in a ventilated patient with right nasotracheal intubation and a gastric tube positioned in the left nostril. On a second paranasal computed tomography scan, performed 1 week later without changing the initial position of the endotracheal and gastric tubes, complete opacification of the maxillary, ethmoid, and sphenoid sinuses was observed with a persistent mucosal thickening of both frontal sinuses. (Reprinted with permission of the American Thoracic Society. Copyright © 2012 American Thoracic Society. From Rouby JJ, Laurent P, Gosnach M, et al. Risk factors and clinical relevance of nosocomial maxillary sinusitis in the critically ill. 1994;150:776–783. Official Journal of the American Thoracic Society.)

being either mucus or pus. Infectious sinusitis is defined by the presence of pus in the maxillary cavity and requires cellular and bacterial analysis of the sinus contents. Therefore, antral puncture is indispensable for an accurate diagnosis. Examination of the sinus contents is impossible for frontal and ethmoid sinuses. It requires an easy-to-perform antral puncture for the maxillary sinus and a highly specialized endoscopic puncture for the sphenoid sinus. Maxillary puncture can be performed either by the transnasal or the canine fossa routes.

The transnasal and canine fossa approaches are exposed to massive bacterial contamination issued from the nostrils and gingiva, which are heavily contaminated by nosocomial microorganisms in critically ill patients. The presence of a foreign body in the nose further increases the bacterial burden and seriously complicates the process of nasal decontamination.[8] After a meticulous and time-consuming disinfection of the nasal cavities, only 50% of the nostrils are sterile and 11% remain heavily contaminated.[8] As a result, transnasal puncture of the maxillary sinus carries a significant risk of introducing bacteria into the antral cavity and overestimating the likelihood of infectious sinusitis.[81] As a consequence, a rigid protocol should be followed when performing a transnasal puncture and strict diagnostic criteria required for establishing the diagnosis. After a careful and prolonged disinfection of the nasal cavity using a povidone-iodine or a chlorhexidine alcohol solution,[8,95] a nasal swab is performed to assess the efficacy of nasal disinfection. Then transnasal puncture is performed using an Albertini trocar placed below the inferior turbinate, and sinus contents are directly aspirated before any lavage. The recovered fluid is then examined, using cell and quantitative bacterial analysis preceded by a Gram stain. In addition, the nasal swab is analyzed using a semiquantitative bacteriologic analysis. The diagnosis of infectious sinusitis requires fulfillment of the following criteria: more than five altered polymorphonuclear leukocytes per oil immersion field and a positive culture with a bacterial concentration equal to or greater than 10^3 colony-forming units (CFU)/mL in the case of negative nasal swab, or equal to or greater than 10^4 CFU/mL in the case of positive nasal swab.[8]

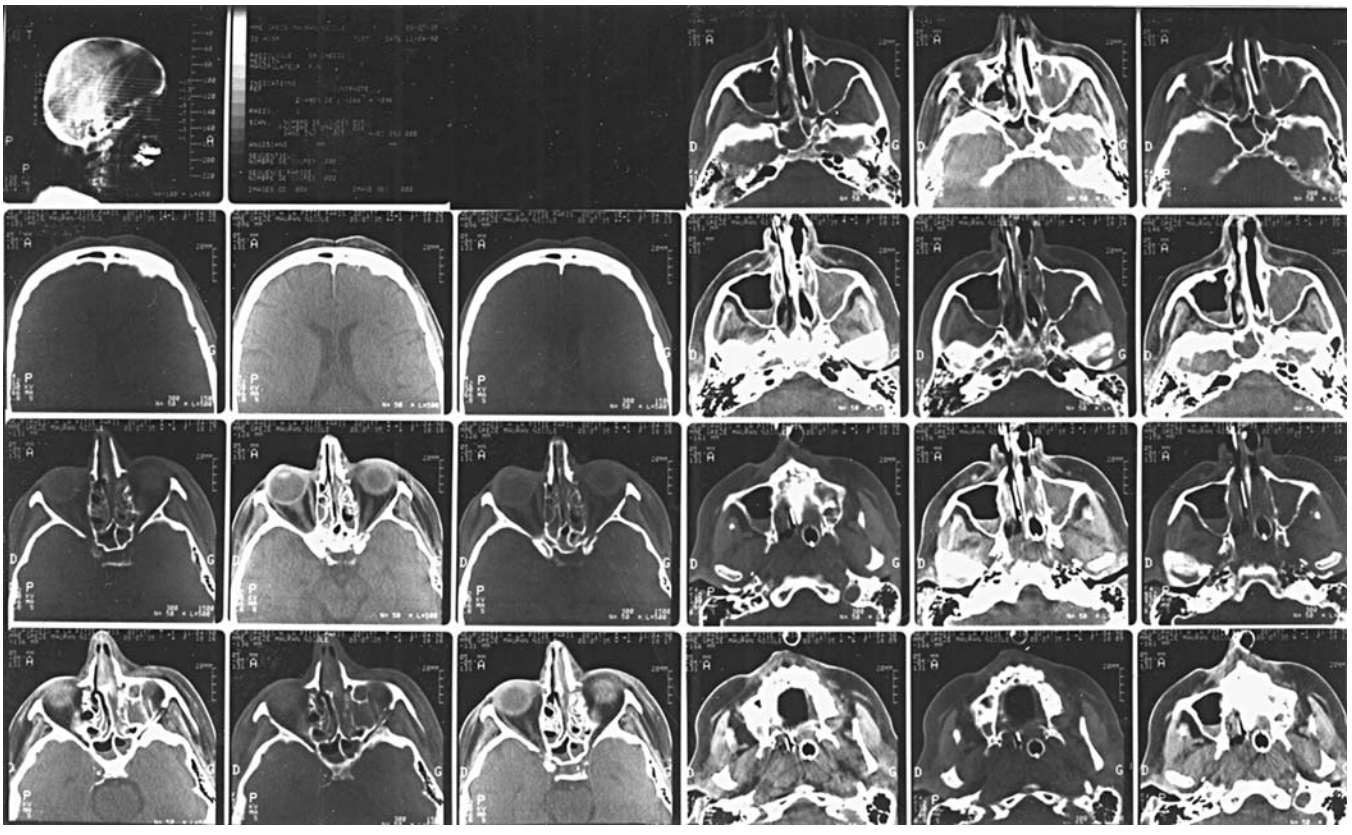

FIGURE 47-6 Typical aspect of radiographic maxillary sinusitis in a ventilated patient with left nasotracheal intubation and a right nasogastric tube. The left maxillary sinus exhibits complete opacification, whereas the right maxillary sinus exhibits a characteristic air–fluid level. Mucosal thickening can be seen in both ethmoid sinuses and the left frontal sinus. Both sphenoid sinuses exhibit air–fluid levels, whereas the right frontal sinus is normally aerated. Risk factors and clinical relevance of nosocomial maxillary sinusitis in the critically ill. *Am J Respir Crit Care Med.* 1994;150:776–783. Official Journal of the American Thoracic Society.)

MICROBIOLOGY OF VENTILATOR-ASSOCIATED MAXILLARY SINUSITIS

Community-acquired maxillary sinusitis is predominantly caused by *Streptococcus pneumoniae, Moraxella catarrhalis,* and *Haemophilus influenzae*. In contrast, the most frequent microorganisms recovered in ventilated adult patients with infectious maxillary sinusitis, are gram-negative bacteria such as Enterobacteriaceae species, gram-positive cocci such as staphylococci or streptococci, anaerobes, and yeasts.[8,11,81,95–97] Very frequently, infection of the antral cavity is polymicrobial.[8,62,79,84] Anaerobes are the causative pathogens in more than 60% of cases of infectious maxillary sinusitis, either in association with aerobic species or alone.[98]

In adult patients, the most common anaerobes infecting the antral cavity are *Prevotella* species and *Fusobacterium nucleatum*, all bacteria that belong to the commensal nasal flora and are known to produce β-lactamases, which reduces their sensitivity to antibiotics.[98] Similar findings have been reported in ventilated children with nosocomial sinusitis: Aerobes were present in only 40% of the patients, anaerobes in only 25% of the patients, and mixed aerobic and anaerobic flora in 35% of the patients.[97] The predominant aerobes were *Pseudomonas aeruginosa*, *Staphylococcus aureus*, *Escherichia coli*, and *Klebsiella pneumoniae*. The predominant anaerobes were *Peptostreptococcus* species, *Prevotella* species, and *Fusobacterium* species.

Anaerobes are more commonly isolated from sinus aspirate samples obtained after prolonged mechanical ventilation.[97] The high incidence of anaerobes and their underestimation by classic means of bacterial examination probably explain the high number of purulent antral secretions remaining sterile on culture.[84] The presence of a nasal foreign body (endotracheal or gastric tube) markedly increases bacterial colonization of the ipsilateral middle meatus.[84] In Figure 47-9, a logical approach, including diagnostic criteria, is proposed for establishing the diagnosis of infectious maxillary sinusitis.

TREATMENT

Prevention of Ventilator-Associated Sinusitis

Although some of the published data on the prevention of sinus infection in ventilated patients are conflicting,[8,56,61,62] the following measures can be recommended for reducing

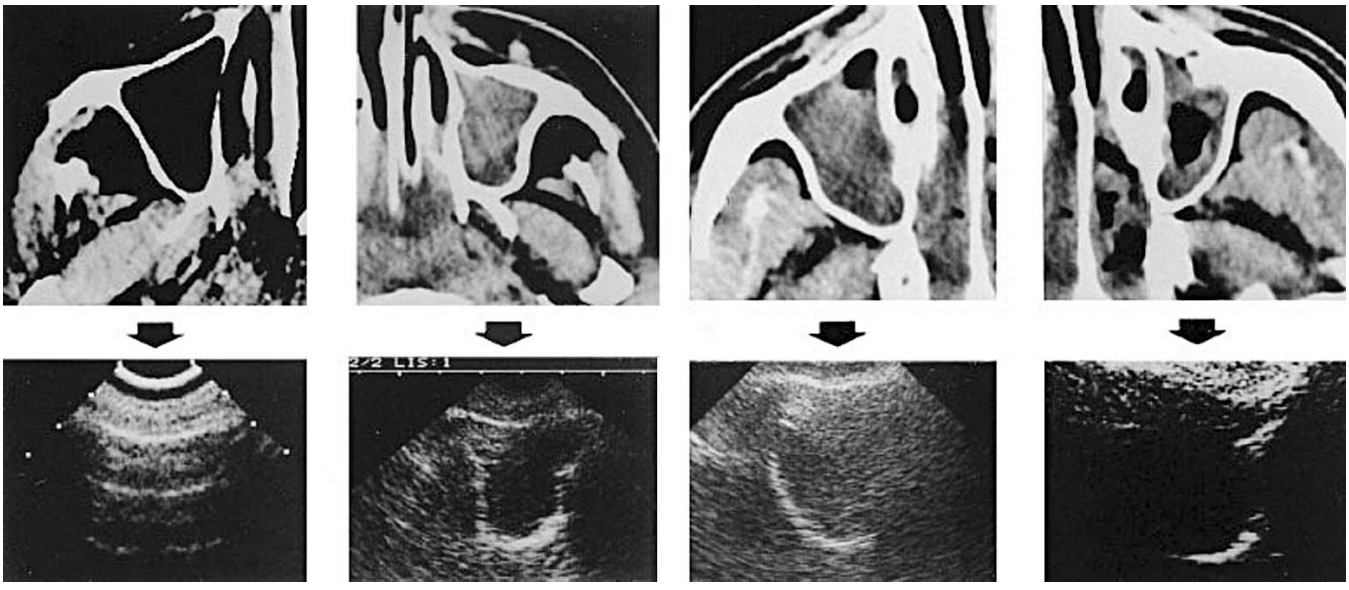

FIGURE 47-7 Normal versus pathologic ultrasound pattern. Computed tomography sections of maxillary sinuses are in the upper row with their corresponding ultrasound pattern in the lower row. *From left to right:* normal pattern—total opacity of the left maxillary sinus (the internal, posterior, and external walls of the sinus are visible, giving a complete "sinusogram"); 90% air–fluid level of the right maxillary sinus (the internal wall is not visualized, giving an incomplete "sinusogram"); and mucosal thickening of the left maxillary sinus (the internal wall is not visible and the external wall is ill-defined, giving a partial "sinusogram"). (Reproduced, with permission, from Lichtenstein D, Biderman P, Meziere G, et al. The "sinuso-gram", a real-time ultrasound sign of maxillary sinusitis. *Intensive Care Med.* 1998;24:1057–1061. With kind permission from Springer Science and Business Media.)

the incidence of ventilator-associated sinusitis. First, nasotracheal intubation and nasogastric tubes should be avoided. Most prospective studies that have examined the influence of nasotracheal intubation on ventilator-associated sinusitis have shown an increased incidence of maxillary sinusitis in nasotracheally intubated patients.[8,56,61] On the other hand, in a randomized single-center study that included 300 ventilated patients, there was no statistically significant difference in the occurrence of ventilator-associated sinusitis between patients intubated via the nasal versus the oral route. A trend ($p = 0.08$), however, suggested less sinusitis in the orotracheal group.[62] Second, the nostrils should remain free of foreign bodies and be regularly cleaned of nasal secretions that tend to accumulate. In a randomized open-label study performed in 79 patients with multiple trauma, the combination of locally applied nasal α-adrenergic and

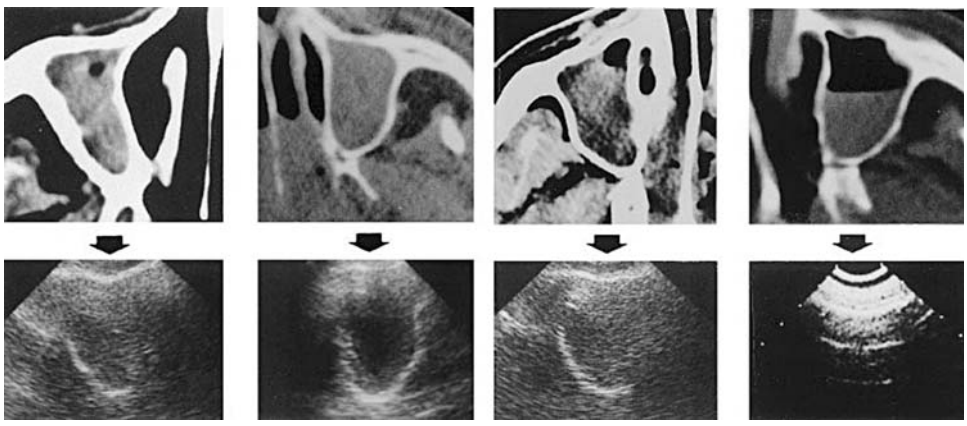

FIGURE 47-8 Different abnormal ultrasound patterns. Computed tomography sections of maxillary sinuses are in the upper row with their corresponding ultrasound pattern in the lower row. *From the left to the right:* total opacity of the right maxillary sinus with a small anterior air bubble (the external wall is visible and the internal wall is not visible, giving an incomplete "sinusogram"); total opacity of the left maxillary sinus (the internal, posterior, and external walls of the sinus are visible, giving a complete "sinusogram"); 90% air–fluid level of the right maxillary sinus (the internal wall is not visualized, giving an incomplete "sinusogram"); and 50% air–fluid level of the left maxillary sinus (the walls are not visible, giving an acoustic barrier, and thus no "sinusogram"). (Reproduced, with permission, from Lichtenstein D, Biderman P, Meziere G, et al. The "sinuso-gram", a real-time ultrasound sign of maxillary sinusitis. *Intensive Care Med.* 1998;24:1057–1061. corticosteroids reduced the incidence of radiologic maxillary sinusitis by 29%.[99] The topical application of a nasal decongestant, together with locally applied corticosteroids to avoid rhinitis medicamentosa, may reduce ostial obstruction and edema of the ostiomeatal complex that initiates sinus inflammation and mucus accumulation. Further studies are required to confirm the efficacy of this mode of prevention. Third, the patient should be kept preferentially in the semirecumbent position to ensure patency of the different ostia. The observance of these preventive measures does not, however, fully protect against ventilator-associated sinusitis. General sepsis, restrictions in regional blood flow resulting from circulatory shock, as well as allergy and systemic inflammation, all factors encountered in the critical care environment, certainly contribute to antral disease and secondary infection of sinus cavities.

Treatment of Infectious Maxillary Sinusitis

Classically, sinus infection diagnosed in ventilated patients requires the administration of intravenous antibiotics.[11,62,78] Removal of nasal foreign bodies, semirecumbent positioning, sinus drainage, topical decongestants, and serum lavage of the antral cavity through the drains are useful adjunctive therapies.

PENETRATION OF ANTIBIOTICS INTO ANTRAL MUCOSA

Two studies have shown adequate sinus deposition of intravenous antibiotics in patients with ventilator-associated maxillary sinusitis.[100,101] In a series of six ventilated patients, a single intravenous dose of piperacillin 4 g achieved bactericidal concentrations for up to 8 hours in the sinus fluid obtained by maxillary drainage.[100] In a series of twenty ventilated patients with ventilator-associated sinusitis, a single intravenous dose of amikacin 15 mg/kg achieved high peak concentrations in the sinus fluid obtained by maxillary drainage.[101] These encouraging results, however, were challenged by a subsequent study performed in seven critically ill patients with inflammatory and bacterial maxillary sinusitis.[102] In all patients, extracellular tissue concentrations of cefuroxime, ampicillin, and vancomycin measured on biopsy samples obtained by sinuscopy were lower than the corresponding plasma concentrations. In patients with noninfectious maxillary sinusitis, the ratio between tissue and plasma concentrations varied from 10% to 73%. In one patient treated with intravenous cefuroxime for a nasogastric tube-induced purulent maxillary sinusitis, very low plasma concentrations with no measurable mucosal concentrations were found. In one patient treated with intravenous ampicillin for a nasotracheal tube-induced purulent maxillary sinusitis, high tissue concentrations were found, reaching 95% of the plasma concentration in the left antral mucosa and 53% in the right antral mucosa. In one tracheostomized patient treated with vancomycin for a left purulent maxillary sinusitis, high mucosal concentrations of vancomycin were found. Surprisingly, in the three patients with purulent maxillary sinusitis, bacterial cultures of the sinus biopsies were positive, irrespective of the antibiotic tissue concentrations.

SINUS DRAINAGE AND ANTIBIOTIC THERAPY

In critically ill patients, infectious maxillary sinusitis frequently emerges despite prior antibiotic administration to which the causative microorganisms are sensitive,[95,102] suggesting that antibiotics may not be a sufficient therapy for ventilator-associated maxillary sinusitis. Several hypotheses have been proposed for explaining the persistence of bacteria within the antral cavity despite the intravenous administration of appropriate antibiotics. As demonstrated in a small number of patients, antral penetration of systemic antibiotics is very variable and mucosal concentrations may remain below minimal inhibitory concentrations.[102] In patients on

long-term mechanical ventilation, the presence of a chronic anaerobic infection might be associated with biofilm formation protecting the bacteria against the bactericidal effects of antibiotics.[102] Measurements of antral antibiotic concentrations require sinuscopy and/or the insertion of drains into the sinus cavity.[100–102] Such invasive procedures may create a regional inflammatory reaction responsible for increased antral antibiotic concentrations that may no longer be representative of true tissue concentrations obtained in the intact sinus cavity.

The logical implication of these clinical findings and hypotheses is that sinus drainage should be adopted as a first-line therapy for ventilator-associated maxillary sinusitis, together with daily sinus lavage and topical antibiotic administration.[8,95] To avoid recurrence of infectious maxillary sinusitis, sinus drains should be left in place until endotracheal extubation and definitive weaning from mechanical ventilation.[8] Removing foreign bodies from the nostrils and positioning the patient in the semirecumbent position may help recovery from antral disease.

IMPORTANT UNKNOWNS

Clinical Relevance of Frontal, Ethmoid, and Sphenoid Sinusitis

Radiographic abnormalities of the ethmoid and sphenoid sinuses are found in more than 80% of ventilated patients.[8] In ventilated patients with computed tomography-delineated abnormalities of maxillary sinuses, more than 95% have radiographic ethmoid and sphenoid sinusitis. Half of ventilated patients with normal maxillary sinuses have computed tomography-delineated abnormalities (mucosal thickening or complete opacification of the sinus cavities) of the ethmoid and sphenoid sinuses.[8] The meaning and clinical impact of these abnormalities remain unknown. Despite sinus drainage associated with topical administration of appropriate antibiotics and the absence of other sites of infection, more than 10% of ventilated patients with documented infectious maxillary sinusitis remain febrile with persistent signs of sepsis, raising the possibility of a residual infection within the ethmoid and sphenoid cavities.[8] Although community-acquired infectious sphenoid sinusitis remains a rare entity,[103,104] further studies are required for assessing the exact incidence of infectious ethmoid and sphenoid sinusitis as a cause of occult fever in ventilated patients.

Role of Antibiotics in the Therapy of Ventilator-Associated Maxillary Sinusitis

There is an ongoing controversy as to whether intravenous or topical antibiotics should be administered to ventilated patients with documented infectious maxillary sinusitis. Available data on the penetration of systemic antibiotics into the diseased antral mucosa of ventilated patients are scarce and are based on very few critically ill patients.[100–102] In addition, the role of viruses in the infection of sinus cavities remains unknown. As with community-acquired acute maxillary sinusitis, the clinical course of which is not influenced by antibiotic treatment,[105] ventilator-associated infectious maxillary sinusitis might be caused by viruses and require specific antiviral therapy rather than intravenous antibiotics. Clinical data support the concept that radiographic maxillary sinusitis is the first step along the path to an established sinus infection[8] and raise the issue of whether removal of nasal foreign bodies and placement of sinus drainage catheters should not be undertaken before frank infection and sepsis occur.[10] Further studies are required to assess factors influencing the penetration of antibacterial agents into the sinus cavities and to clarify many uncertainties concerning treatment optimization of ventilator-associated sinusitis.

CONCLUSIONS AND FUTURE PROSPECTS

Infection of paranasal sinuses is an important cause of occult sepsis in critically ill patients receiving mechanical ventilation. It is a typical nosocomial infection resulting mainly from the presence of nasal foreign bodies. Mechanical and edematous obstruction of the sinus ostia, suppression of the normal sinus ventilation, inhibition of the maxillary production of nitric oxide, and cessation of the normal sinus mucociliary clearance are different factors causing an inflammatory antral disease that becomes rapidly superinfected by pathogens proliferating around nasotracheal and nasogastric tubes. Like any nosocomial infection that may weigh heavily against patients' chances of survival, an active policy of detection and prevention should be undertaken and not lead to antibiotic overuse. Faced with an unknown cause of sepsis, the clinician should systematically perform maxillary sinus ultrasonography at the bedside, searching for radiographic maxillary sinusitis. When present, maxillary sinus puncture should be performed with careful attention to avoid nasal contamination of sinus contents. Once confirmed by quantitative bacteriology and cell analysis, infectious maxillary sinusitis should be treated by prolonged sinus drainage, removal of nasal foreign bodies, positioning in the semirecumbent position, and administration of intravenous or topical antibiotics. If applied early after initiation of mechanical ventilation, orotracheal intubation, oral placement of gastric tubes, and semirecumbent positioning may decrease the incidence of ventilator-associated maxillary sinusitis. A large multicenter randomized study should be undertaken to assess whether these preventive measures are associated with a decrease in the incidence of ventilator-associated pneumonia and mortality.

EVALUATION AND MONITORING OF VENTILATOR-SUPPORTED PATIENTS

MONITORING DURING MECHANICAL VENTILATION

Amal Jubran
Martin J. Tobin

Patients are admitted to an intensive care unit (ICU) for two main reasons. One is for delivery of mechanical ventilation, the varied aspects of which are the subject of this book. The second is to observe a patient more closely than is possible on a hospital ward; that is, to avail of specialized devices used for the monitoring of vital functions (and of staff who have expertise in their operation).

The literature published on these two subjects constitutes the unique corpus of knowledge required for the expert practice of intensive care medicine. Management of some critically ill patients is based on knowledge outside these two areas, such as patients with acute gastrointestinal bleeding or acute renal failure. The principles for managing such conditions have been developed by physician-investigators within the relevant subspecialties rather than by intensive care physicians. Beyond the areas of mechanical ventilation and monitoring, an intensivist seeking the most authoritative writing on a subject must turn to articles and texts published by nonintensivists.

Patients receiving mechanical ventilation are exposed to the full range of monitoring devices. An in-depth discussion of each device would require as much space as the rest of this book. For such discussions the reader is referred to the companion text, *Principles and Practice of Intensive Care Monitoring*.[1] Rather than attempting a synopsis of each individual monitoring technique, this chapter provides a bird's-eye view of the subject. We map out the territory of monitoring through discussion of its goals, the principles of measurement, usefulness of monitoring in various settings, the forms of clinical reasoning used in interpreting generated data, evaluation of the benefit of monitors, and the problems in designing studies that attempt such evaluations. To give a sense of the detailed contours of the terrain being traversed, we offer specific examples of how the general topics relate to the everyday use of monitors.

WHAT IS MONITORING?

An unsatisfactory—and embarrassing—aspect of writing about monitoring is the absence of a generally accepted definition. A definition tries to set criteria that demarcate the boundaries between concepts (or things) so as to prevent overlapping or confusion, and has the goal of providing order or a clear understanding.

The word *monitor* comes from the Latin *monere,* which means "to warn." This meaning connotes one goal of monitoring, to provide an alert, an alarm. But monitors serve

other functions. Monitors replicate many of the characteristics of diagnostic testing, and interpretation of the generated data must comply with the scientific principles developed for use of diagnostic tests. Thus, it might seem reasonable to define monitoring as the serial performance of diagnostic tests at frequent intervals. But how should we demarcate the frequency at which measurements are repeated? Certain signals have such a high-frequency content that obtaining fifty measurements in a second is insufficient to capture a critical data point.

Having struggled long and hard in trying to formulate a meaningful but precise definition of monitoring, we admit defeat. We can do no better than offer a naturalist's definition: Monitoring refers to what physicians and allied health personnel do with monitors.

GOALS OF MONITORING

The major goals of monitoring are to continuously measure key variables that enhance understanding of a patient's underlying disease state, to aid with diagnosis, and to guide management.[1] To accomplish these goals, the monitor should measure a variable that is pertinent to the disease process, be technically accurate, provide interpretable data, be practical for use, and not cause harm.[1,2] The ability of today's monitors to meet these goals depends largely on two factors: whether a monitor is capable of accurately measuring the function or disease manifestation in question, and whether the recorded information will help improve patient outcome. Inextricably linked to these two factors is the caregiver's ability to interpret data, integrate data from multiple sources, discard data that are not important, and then make a wise judgment about diagnosis and therapy.

ACCURACY OF MEASUREMENTS

Advances in electronic and computer technology over the last 30 years have generated several monitoring systems that are accurate and easy to use. To know how to operate a machine and interpret the provided data, a physician needs much more than a manufacturer's manual. The physician needs to know the principles of the monitoring device, how to operate it, the reliability of the measurements, indications and contraindications, complications with use of the device, and how to troubleshoot problems as they arise.

To determine whether the data generated by a monitor are valid, a physician needs to have a basic understanding of measurement theory and its applications. For an extensive review of the science of measurement, the reader is referred to the chapter by Chatburn[3] in the companion book, *Principles and Practice of Intensive Care Monitoring*.[4]

Fundamentals of Measurement Theory

Every measurement has errors. Accordingly, the observed measurement is a mixture of the true value and the error. Errors can be systematic or random. *Systematic error* (also termed *bias*) is the difference between the mean value of repeated measurements and the true value. Systematic errors occur in a predictable manner; they cause measurements to *either* consistently underestimate or consistently overestimate the true value (Fig. 48-1A). These type of errors are not affected by repeated measurements but can be reduced by proper calibration.

Random error (a measure of the imprecision of a measurement) is the difference between the mean of the sample and the measurement of individual values. Random errors occur in an unpredictable manner because of uncontrollable factors; they cause measurements to *both* underestimate and overestimate the true value (see Fig. 48-1B). Increasing the number of measurements can reduce random errors.[3] Figure 48-2 illustrates the effects of bias and imprecision (systematic and random errors) on measurements.

ACCURACY

Accuracy is the ability of a measuring device (or monitoring technique) to capture the true value of a quantity. When assessing accuracy, researchers commonly compare a new method with an established method to determine whether the new method can replicate the established method (Fig. 48-3).

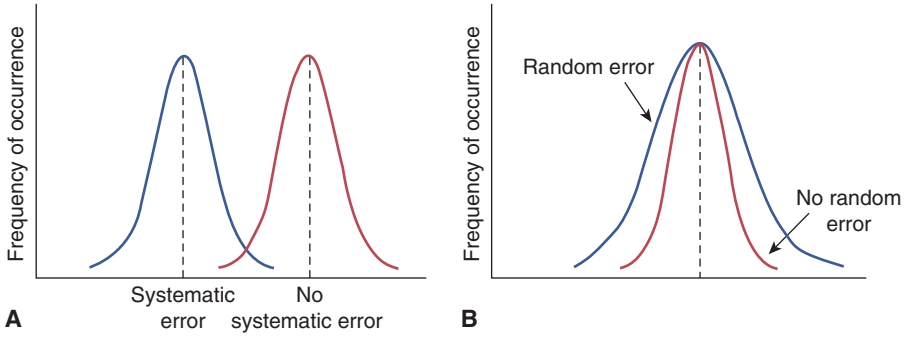

FIGURE 48-1 Distribution of measured values in the presence and absence of systematic (**A**) and random (**B**) errors. A systemic error increases or decreases the average value. A random error increases the variability around the average value.

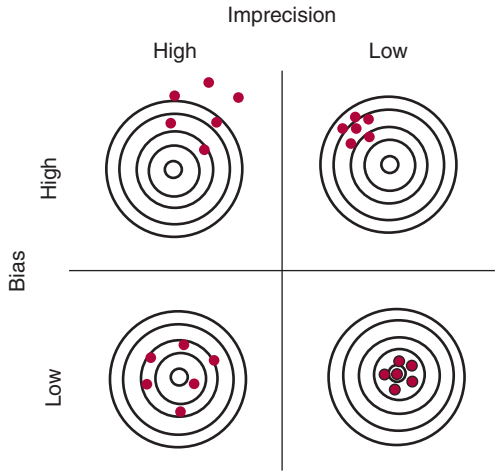

FIGURE 48-2 The effects of bias and imprecision (systematic and random errors) on measurements using the analogy of target practice at a rifle range. When bias is low, measurements (*red circles*) group around the true value (bull's-eye). When imprecision is low, the cluster of measurements is tight and the random error of repeated measurements (rifle shots) is small. Ideally both bias and imprecision are low, resulting in a small total error for repeated measurements. (Used, with permission, from Chatburn.[3])

Accuracy is usually expressed as a percentage of the full scale. In today's ventilators, pressure-measuring systems have an accuracy of ±2 cm H_2O plus 4% of the signal. In other words, if the true pressure is 25 cm H_2O, the displayed pressure could be anything between 22 and 28 cm H_2O.[5] In contrast, the accuracy of flow sensors within ventilators varies much more—from ±1% to ±20% of the setting, depending on the ventilator.[6] Despite their common use, remarkably little information on the accuracy of flow-measuring and pressure-measuring devices has been published in peer-reviewed journals; in general, users must resort to data on accuracy provided by the manufacturers.

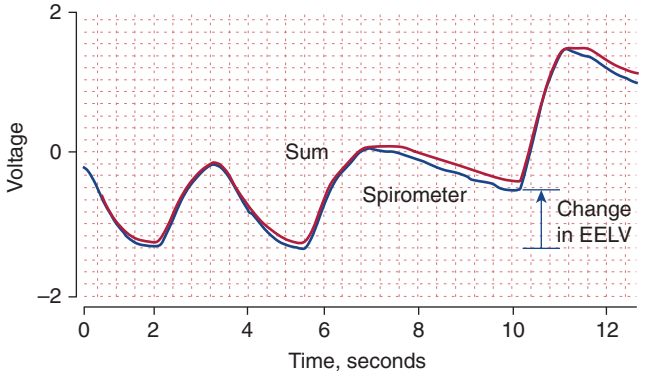

FIGURE 48-3 Changes in end-expiratory lung volume measured simultaneously with a calibrated respiratory inductive plethysmograph (*red*) and a spirometer (*blue*), the reference instrument. The two signals are almost superimposed upon one another indicating good agreement between the two techniques. *EELV*, end-expiratory lung volume.

The monitoring device that has been studied the most in critically ill patients is the pulse oximeter. Compared with the measurement standard (a multiwavelength Co-oximeter), pulse oximeters have a mean difference (bias) of less than 1% and a standard deviation (precision) of less than 2% when arterial oxygen saturation (Sa_{O_2}) is 90% or above (Fig. 48-4).[6–8]

PRECISION

Precision is the ability of a monitor to display the same value repeatedly assuming that the actual quantity has not changed; that is, the degree of consistency between repeated results. Precision is usually expressed in terms of variance, standard deviation, or confidence intervals. In ventilated patients, the precision (quantified as standard deviation) of pulse oximetry in measuring oxygen saturation, Sp_{O_2}) is less than 1.2% when Sa_{O_2} is greater than 90%, and it increases to 2.7% when Sa_{O_2} drops to 90% or less.[6–8]

Reproducibility is the ability of the monitoring technique (or device) to maintain its precision during long-term use. Knowing the reproducibility of a measurement is important for judging whether a change is truly of clinical significance. The reproducibility of the thermodilution technique in measuring cardiac output, quantified as the ratio of standard error to average cardiac output, varied between 2% and 5% when measurements were repeated (an average of three times), and varied between 2.5% and 8.7% for single measurements.[9] Thus, before concluding that a change in cardiac output is clinically significant, a clinician would need to observe a 12% to 15% difference between repeated determinations (three measurements per determination).

A technique may yield reproducible measurements at one sitting, but be unreliable when employed by a different investigator or on a different day. In ventilated patients, a single investigator obtained highly reproducible measurement of maximal inspiratory pressure at a single sitting: The coefficient of variation for triplicate efforts was 11%.[10] When different investigators undertook the measurements, however, the coefficient of variation was 32% ± 4%, despite the measurements being obtained in the same patient and on the same day.

LINEARITY

A device is considered linear when a plot of output data from the device (the measured values) versus the input data (the known values) can be fitted with a straight line. Occasionally, a system measures pressure accurately only over part rather than the entire range of pressures; that is, the system is alinear (Fig. 48-5). Alinearity may occur because the given transducer is not designed for use over the entire range or because it is not functioning properly.

CALIBRATION

Calibration is the process of adjusting the output of a device to match a known input value. Thus, systematic error is minimized. Calibration is considered static when pressure is

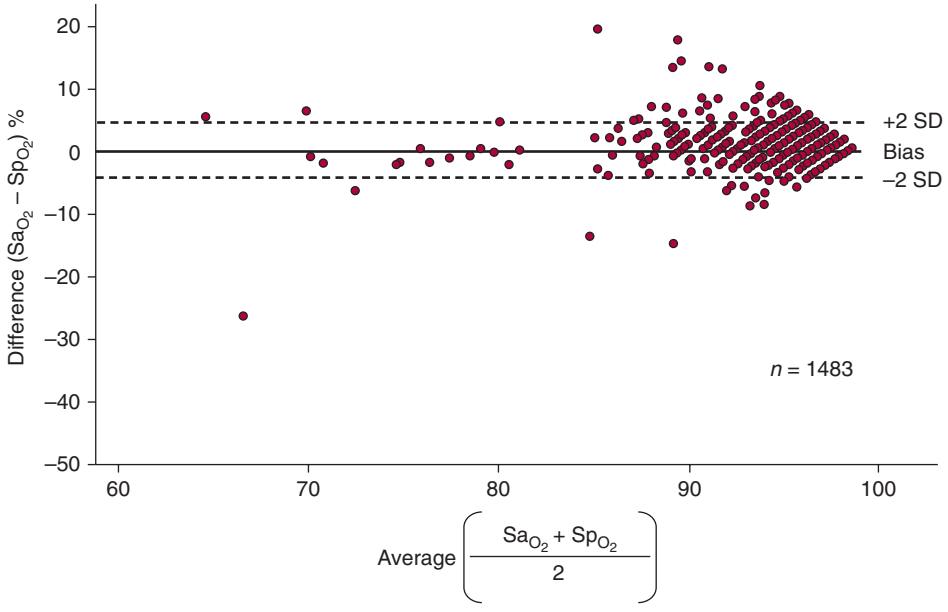

FIGURE 48-4 Differences between arterial oxygen saturation (Sa_{O_2}) measured by a blood-gas analyzer and oxygen saturation measured by pulse oximetry (Sp_{O_2}) plotted against the average O_2 saturation in 102 critically ill patients. The *solid line* is the bias and the *dashed lines* are 95% confidence intervals. Mean difference (bias) between two measurements is small. *SD*, standard deviation. (Reproduced, with permission, from Van de Louw A, Cracco C, Cerf C, Harf A, Duvaldestin P, Lemaire F, et al. Accuracy of pulse oximetry in the intensive care unit. *Intens Care Med.* 2001;27:1606–1613. With kind permission from Springer Science and Business Media.)

changed in steps and each step is maintained long enough to achieve a stable signal output. For a linear measurement system, calibration is a simple two-step procedure (Fig. 48-6). First, the readout is set at zero while no input signal is applied to the instrument. If an offset error occurs, it is adjusted. For a flow-sensing device, the flow sensor is occluded and a reading of no flow should result. If some flow is registered, the readout is adjusted to zero to correct for the offset error. Next, sensitivity (gain or slope) is set by applying an input signal of known value (say 12 L/s from a rotameter), preferably at the upper end of the output range; the readout on the flow sensor is then adjusted to read 12. If the system is linear, the readouts for all input values between these two calibration points will be accurate.

The dynamic response of a measurement system, such as a pressure transducer, is typically tested using a square wave (or sinusoidal) pressure generator. A step change in pressure is followed by a brief delay before the measured pressure begins to change.[11–14] The amplitude of the test should be within ±5% of the amplitude of the reference system at the highest frequency tested. The phase lag is the temporal difference between the two systems.

Sources of Measurement Error during Monitoring

A major challenge in interpreting data from monitors is to determine which data constitute truth and which constitute artifact. Although both systematic and random errors can cause artifact, the major source of error in biologic research is systematic errors.[15]

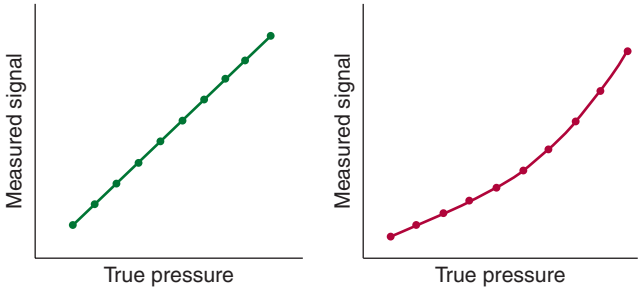

FIGURE 48-5 A measured pressure signal plotted against a reference measurement of pressure ("true pressure") in a linear (*left panel)* and nonlinear (*right panel*) pressure-measuring system. (Used, with permission, from Gallagher.[5])

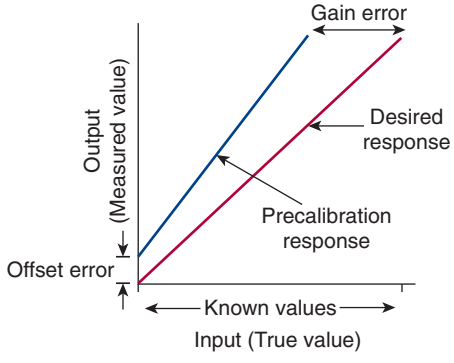

FIGURE 48-6 The two-point calibration procedure. First, the readout on the instrument is adjusted to read zero to overcome offset error. Then, the gain is adjusted to read the desired response. See text for details. (Used, with permission, from Chatburn.[3])

SYSTEMATIC ERROR

Zero offset error occurs when the zero point is not correctly set during calibration but the gain is correct. Consequently, the instrument will read consistently either an inaccurately low or an inaccurately high value over the entire scale. Drift error is a form of time-dependent offset error in which the changes occur over time. The zero point can also change secondary to patient movement without staff being aware.

Range errors occur when the true value of the input system is beyond the operating range of the device. Signals that are either below or above the calibrated scale value may be clipped (the displayed value is different from the true value) (Fig. 48-7).

Response time is the time that a monitoring device takes to respond to a step change in a recorded physiologic variable. The 90% response time is the time from the step change in pressure until the measured signal settles within 10% of its final value. The response time for a pulse oximeter probe varies with its location. Probes placed on the ear respond more rapidly than probes on the finger.[16–18] During calibration of a monitoring device, a slow response time causes error if the user does not allow sufficient time for the instrument to stabilize at the known value.

Frequency response is an instrument's ability to accurately measure an oscillating signal. When the frequency of a signal increases, a measurement system will generate either an underestimate (attenuation) or overestimate (amplification) of the true amplitude of the signal. An optimally damped system will measure all signal frequencies within the working range with equal amplitude (Fig. 48-8).

A system is considered damped when some of the signal-component frequencies are attenuated. Overdamping causes systolic pressure to decrease and diastolic pressure to increase. In a system for measuring vascular pressure, sources of overdamping include air bubbles in the transducer or pressure tubing, clot or fibrin at the catheter tip, and a kinked or partially occluded catheter. Underdamping amplifies the higher harmonics, producing oscillations, which obscure systolic and diastolic values. As such, underdamping causes systolic pressure to increase and diastolic pressure to decrease. Common sources of underdamping include an increase in heart rate interfering with the natural frequency of the pressure-transducer system; a "catheter whip," commonly observed with a pulmonary artery (PA) catheter, can produce an underdamped signal (see Fig. 48-8).

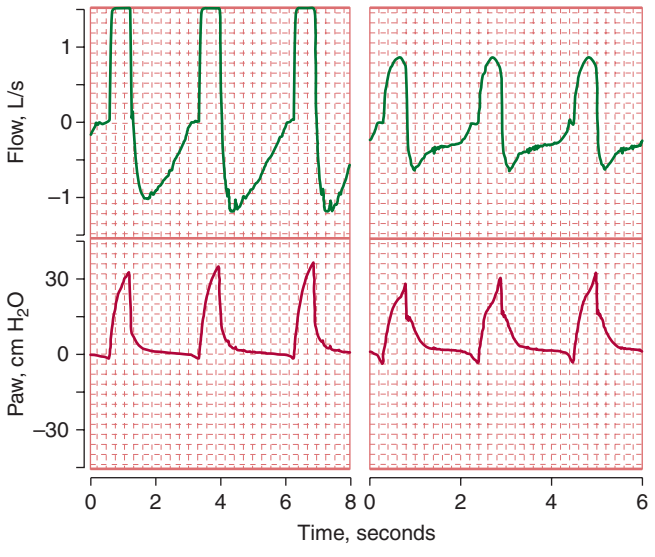

FIGURE 48-7 Flow and airway pressure in two patients receiving assist-control ventilation at a flow rate of 60 L/min. For the patient in the *left panel*, the flow signal is "pinned" or "clipped." The clipping of the flow signal in the left panel was caused by clogging of the pneumotachograph with secretions.

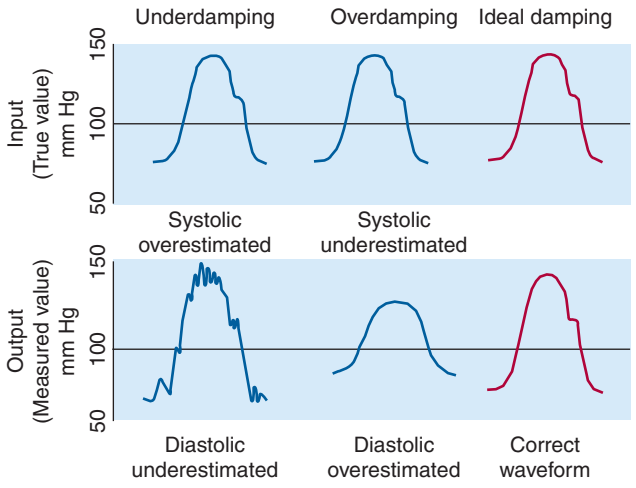

FIGURE 48-8 Effect of three different blood pressure transducers, which exhibited different damping characteristics, on the measurement of blood pressure. (Used, with permission, from Chatburn.[3])

PA waveforms generally contain more high-frequency information than do systemic arterial waveforms, and small errors in pressure assume more clinical significance. Poor dynamic frequency response and overdamped pressure tracings accounted for over half the technical problems encountered in measuring PA wedge pressure.[19] A simple test for assessing the dynamic response of a vascular pressure catheter system is the rapid-flush test.[20]

Alignment of Signals. When employing two different signals to quantify lung mechanics (flow and pressure), it is important to ensure the absence of a phase lag between the two signals. A lag can induce large errors in measurement of resistance and compliance.[5] Phase lags also cause major errors when dynamic intrinsic positive end-expiratory pressure (PEEPi) is measured using an esophageal balloon-catheter system. If a phase lag causes the esophageal signal to occur before flow, PEEPi will be overestimated or considered present when it is truly absent. If a phase lag causes the esophageal signal to occur after flow, PEEPi may be underestimated (Fig. 48-9).

Variable Conditions between Calibration and Data Collection. If a measurement system is used under conditions that differ from the conditions of calibration, and no correction is

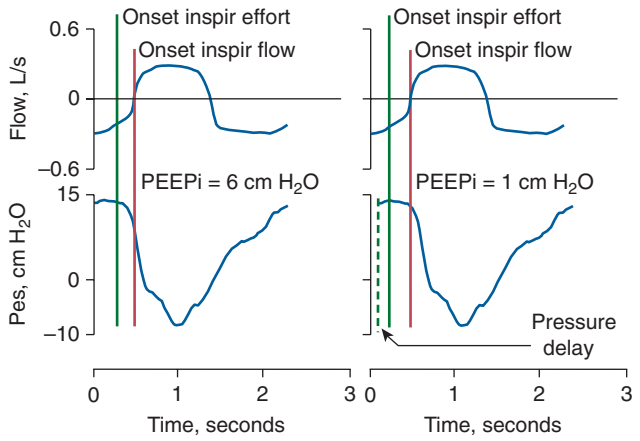

FIGURE 48-9 *Left panel.* Flow and esophageal pressure (*Pes*) signals are properly aligned. Intrinsic PEEP (*PEEPi*), measured as the difference between the onset of inspiratory (*Inspir*) effort and onset of inspiratory flow, is 6 cm H_2O. *Right panel.* Flow and Pes signals are not properly aligned in terms of phase: flow precedes Pes, causing underestimation of PEEPi.

made, systematic errors may result. Flow or volume readings on a ventilator are inaccurate if the temperature or humidity during the recording differs from those present during calibration.[21,22] During calibration, volume may be measured under conditions of ambient temperature, with gas fully saturated with water vapor. If appropriate corrections are not made, subsequent readings of volume, under conditions of normal body temperature and with pressure saturated with water vapor, will underestimate the true volume of gas moving through the lungs. A mass of gas that is 1000 mL at 21°C (69.8°F) can become 1095 mL at 37°C (98.6°F).

Pneumotachographic measurements during mechanical ventilation will become inaccurate if the dimensions of the ventilator tubing during data recording differ from the dimensions used during calibration. The differences in air turbulence and the distribution of flow through the resistive element under the two conditions can lead to measurement errors. When a pneumotachograph was initially calibrated under ideal conditions (with tubing that provided optimized flow characteristics) and then subsequently attached to commonly used ventilator tubing, flow was underestimated by as much as 10% and volume by as much as 15%.[23]

RANDOM ERROR

Noise. All measurements are subject to some degree of rapidly changing interference, termed *noise* or *artifact* (Fig. 48-10).[24] The source of noise can be difficult to trace. Noise distortions occur randomly, so their effects are lessened if measurements are repeated sufficiently. The distortions are not reduced by calibration. The efficiency with which the signal can be distinguished from background noise is defined as the signal-to-noise ratio. Unless the ratio exceeds 1, the signal will be undetectable.

Noise is particularly troublesome when weak signals are highly amplified. Noise is then amplified along with the signal, which eventually limits the sensitivity of the measurement. Cardiac contractions can distort an esophageal pressure signal such that pressure swings appear greater than they truly are. Likewise, the electromyogram signal can be contaminated by the electrical activity from other muscles (Fig. 48-11). As a signal is being transmitted to an amplifier, it is subjected to electrostatic and electromagnetic noise from nearby power lines (Fig. 48-12).[25] Radiofrequency noise may also be added from cellular phones. Finally, physical movement of the catheter cable changes its capacitance and may add low-frequency noise.

Physiologic factors, such as a patient coughing, can lead to error or noise (Fig. 48-13). Physical factors such as slippage of transducers or improper placement of electrodes are also sources of noise. A pulse oximeter probe slipping off the patient's skin accounted for 35% of false alarms recorded in

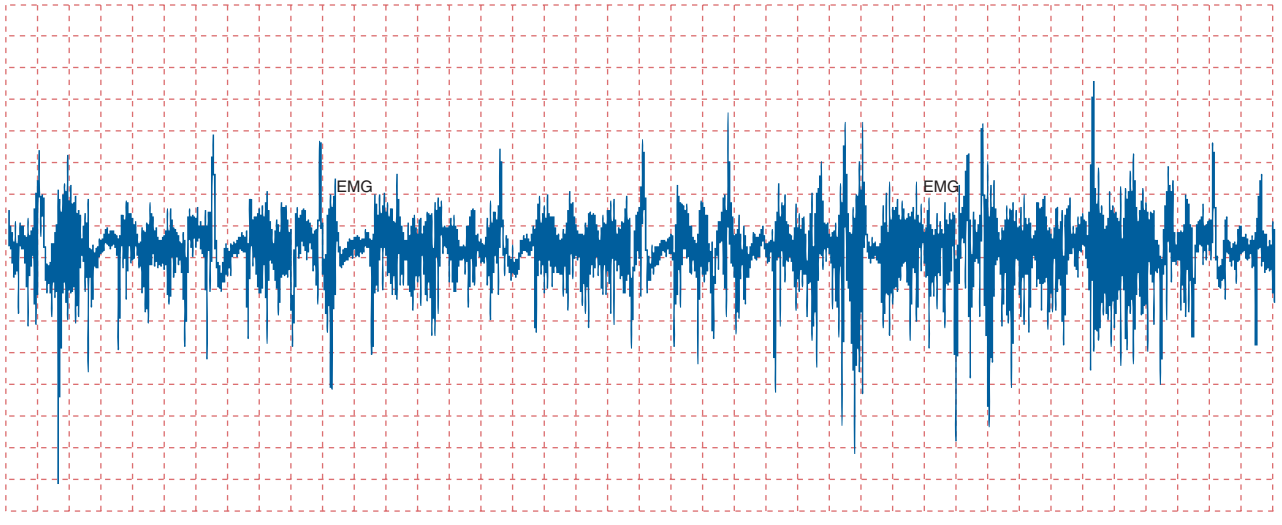

FIGURE 48-10 Electromyelogram tracing of the frontalis muscle reveals considerable noise.

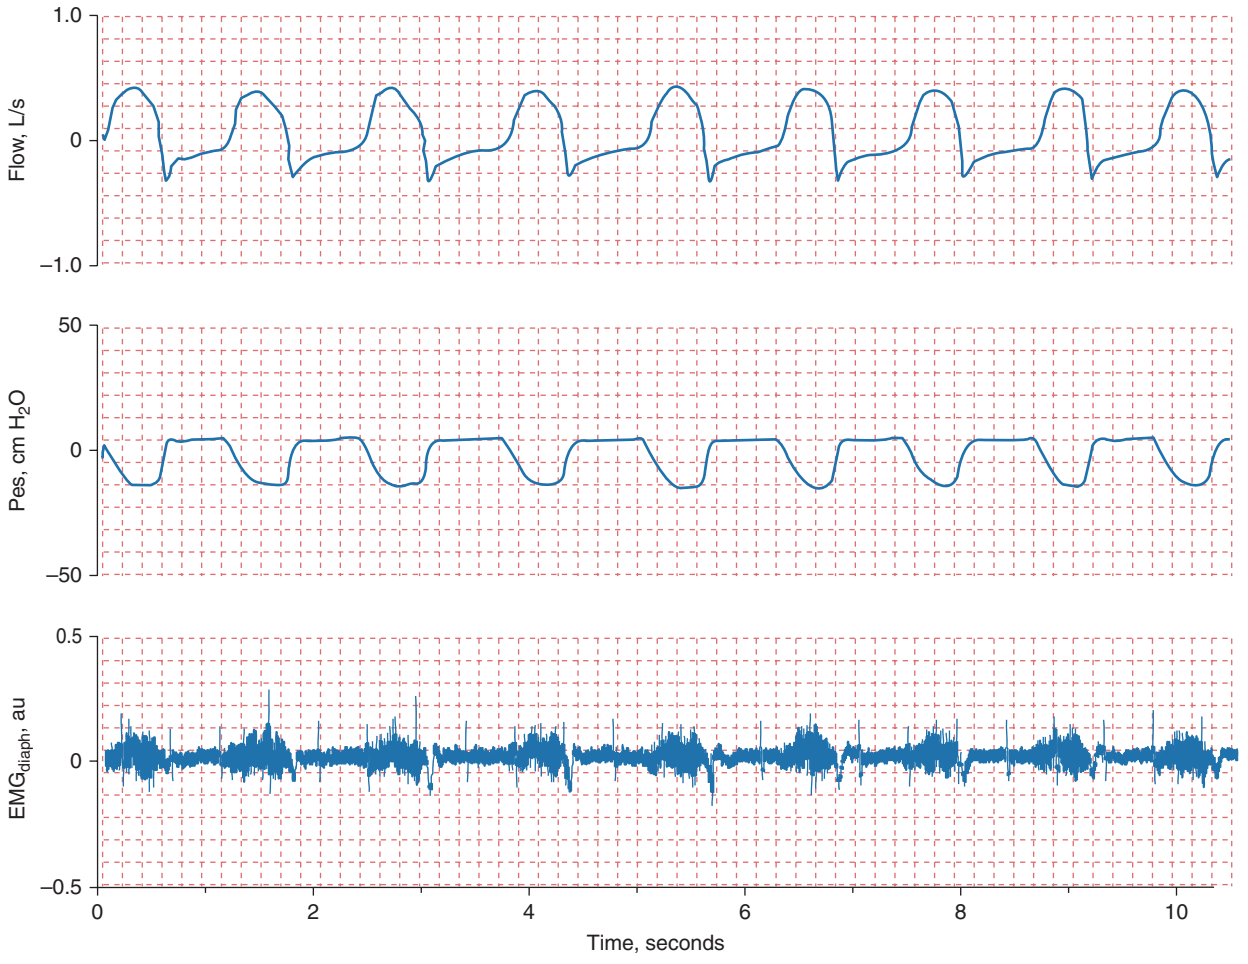

FIGURE 48-11 Flow, esophageal pressure (*Pes*) and electromyogram of the diaphragm (EMG_{diaph}). The diaphragmatic EMG signal is contaminated by spikes from the electrocardiogram signal.

an ICU.[26] Patient movement disturbs the electrode-skin interface and causes electrocardiogram (ECG) noise.[27] "Ringing" after flushing an arterial catheter can interfere with the blood pressure signal and cause faulty readings.[28]

A particularly annoying consequence of signal noise is false alarms.[29–31] Investigators prospectively waited at the bedside for 298 hours in an adult ICU. Of 2942 alarms, 2525 (86%) were false.[26] In a pediatric ICU, 68% of alarms were false.[30] A high rate of false alarms causes noise pollution, wastes nursing time, and contributes to staff burnout.[32]

Nonlinearity. Nonlinearity introduces unpredictable error that varies over the operating range. With measurements of O_2 consumption, nonlinearity of the O_2-sensing system causes a progressive increase in error as fractional inspired oxygen concentration (FI_{O_2}) is increased from 0.21 to 1.0.[33,34]

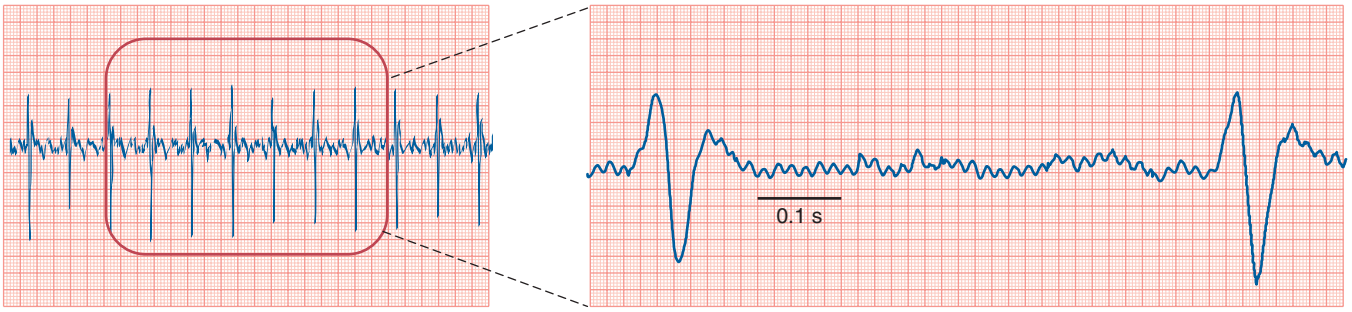

FIGURE 48-12 Electrocardiogram tracing (*left panel*) exhibits background noise. On magnification, the noise in the signal is occurring at a rate of 60 cycles per second (a frequency of 60 Hertz), which is the frequency of electrostatic and electromagnetic signals of power lines.

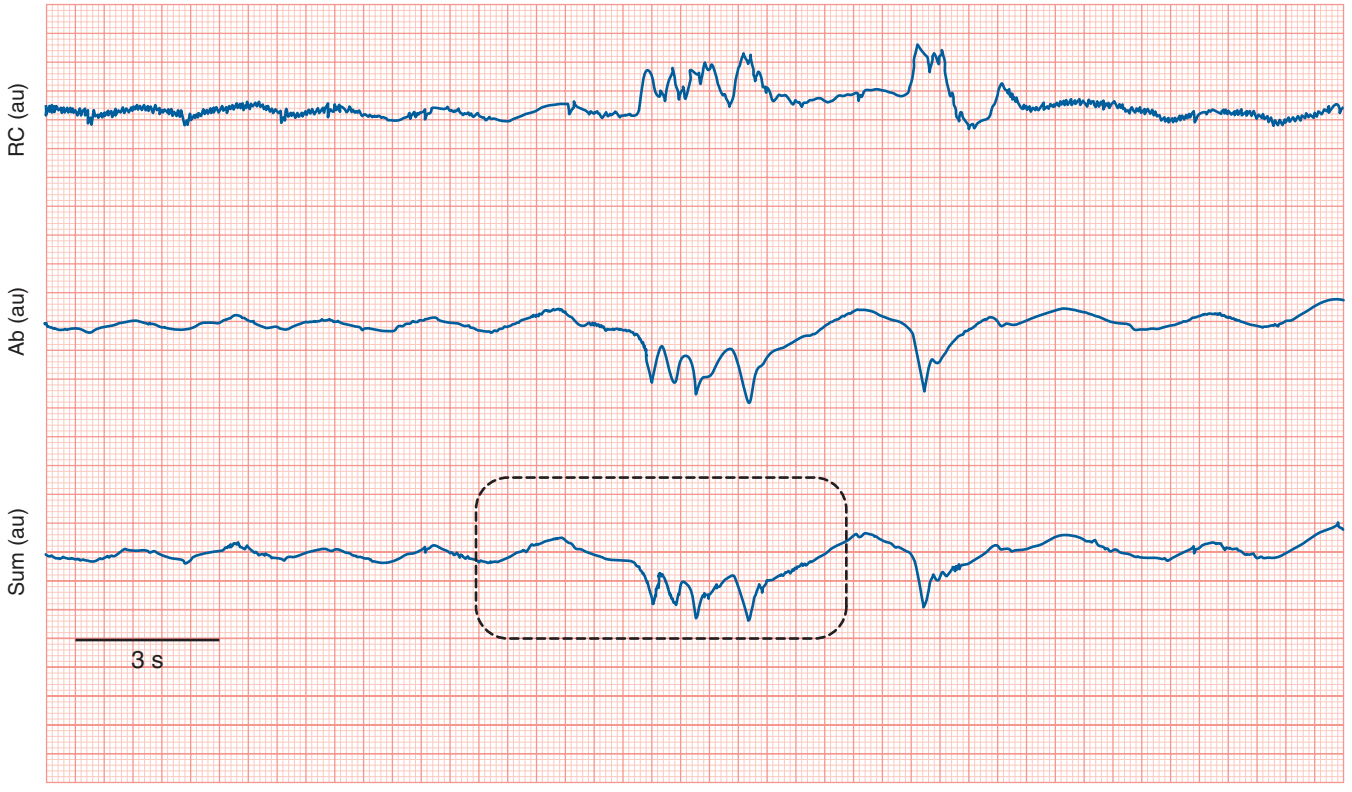

FIGURE 48-13 Recordings of motion of the rib cage (*RC*) and abdomen (*Ab*) obtained with a respiratory inductive plethysmograph in a patient being weaned from mechanical ventilation. The noise in the signal (*dotted rectangular area*) was caused by the patient starting to cough.

Thus, error in measurements of O_2 consumption increases from 2.6% at room air to 17% at an $F_{I_{O_2}}$ of 0.80.[33]

Human Error. Human mistakes in acquiring data are another source of error. Depending on the angle at which the needle on an analog scale is read, different people can perceive different values for the same actual plateau pressure. Measurements that require patient cooperation introduce another source of error. Use of the end-expiratory airway occlusion method to measure PEEPi requires a cooperative patient who does not resist the occlusion.[35] Of 283 attempts in ventilated patients, PEEPi could be quantified in only eighty-six (30%); most of time PEEPi could not be quantified because the patient made an expiratory effort during the occlusion maneuvers (Fig. 48-14).[36]

Patient cooperation is also needed for reliable measurement of maximal inspiratory pressure, a measure of respiratory muscle strength.[37] In patients with low respiratory drive, coaching patients to make vigorous inspiratory efforts led to a 28% increase in pressure.[38]

FIDELITY OF RECORDINGS

Figure 48-15 shows the typical configuration of a data collection system used for bedside monitors in the ICU.[39] The physiologic quantities being measured are referred to as *signals*. A signal (blood pressure, respiratory rate) is converted from a mechanical format to an electrical format using a transducer. The signal is then amplified and conditioned. Next, it is converted from an analog signal to a digital signal with an analog-to-digital converter. Once digitized, the signal is transmitted through a microprocessor. The signal then appears on the monitor screen as a waveform or digital display.[39]

Numbers appearing on the screen of a monitor do not provide all of the information needed to care for a critically ill patient. Studies have revealed that data from bedside monitors account for only 13% to 22% of the data needed to make medical decisions in the care of a critically ill patient.[40]

Of the other data used in clinical decision making, 21% to 22% is derived from observations of a patient by physicians, nurses, and other staff, 38% to 41% from laboratory data, and 13% to 23% from information on medication usage. Caring for a critically ill patient requires the incorporation of all of these data into clinical judgments. Ignoring data that are not important or simply noise is one of the major tasks for a caregiver in the ICU.

Acquiring high-fidelity (minimal amount of noise) data involves the following three factors. First, the transducer and data collection equipment needs to be well designed. For example, to detect the development of dynamic hyperinflation by means of monitoring of changes in end-expiratory

FIGURE 48-14 Airway pressure (*Paw*), esophageal pressure (*Pes*), and gastric pressure (*Pga*) in a patient with chronic obstructive pulmonary disease being ventilated with assist-control ventilation. The airway was occluded during expiration in order to quantify intrinsic PEEP (PEEPi). The patient made an expiratory effort during the occlusion (*arrow*), and thus the recorded pressure overestimated the true PEEPi.

lung volume, one cannot employ a pneumotachograph that exhibits baseline drift (Fig. 48-16). To help in the design of reliable equipment, several standards have been established by organizations such as the Association for the Advancement of Medical Instrumentation (AAMI) and the American National Standards Institute (ANSI).

Second, the clinical staff must properly carry out certain procedures. A perfect catheter, transducer, and flush system can be set up to measure PA wedge pressure. If the catheter, however, is not positioned in the proper location in the PA, overwedging or incomplete wedging can occur, leading to erroneous readings (Fig. 48-17).

Third, rigorous and appropriate processing of the signals generated by a well-designed transducer can eliminate noise in physiologic signals. When signal extraction technology was employed in a pulse oximeter, a 22-fold reduction in noise secondary to gross motion and tremors was observed.[41]

OTHER BARRIERS TO ACCURATE DATA GATHERING

Factors other than accuracy of the measurement can lead to faulty interpretation by the clinician.

Physiologic Variation

Even when a patient is in a steady state, variables monitored in the ICU may not be consistent. To know if a new recorded value of a variable is truly different from an earlier recorded value, it is necessary to know the normal physiologic variation of the variable (Fig. 48-18).[19] Breathing pattern varies considerably. Breath-to-breath variability in tidal volume, as reflected by coefficient of variation, was 33.0 ± 14.9% (SD) in forty-seven young healthy subjects

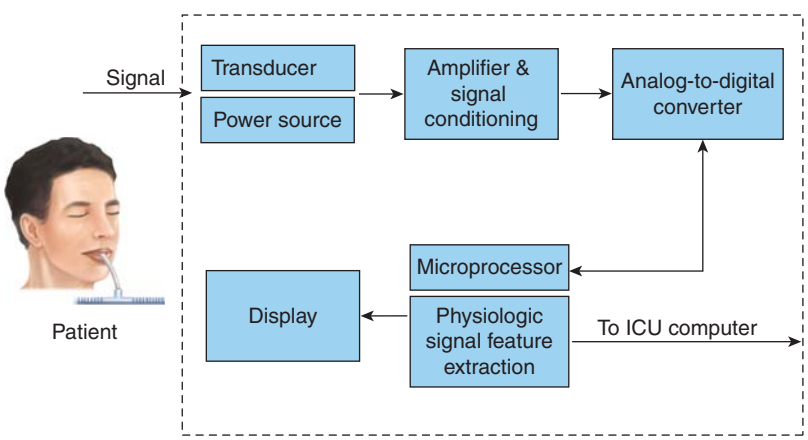

FIGURE 48-15 Schematic of a bedside monitor data-acquisition system. (Modified, with permission, from Gardner.[39])

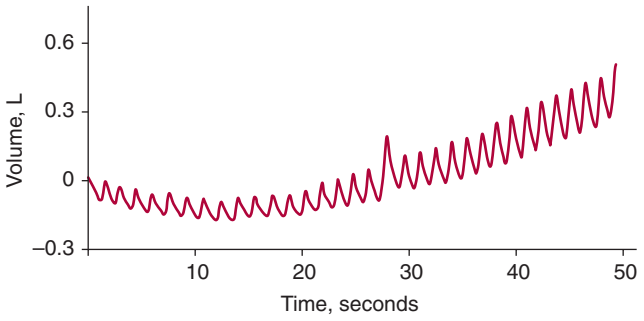

FIGURE 48-16 Breath-by-breath measurements of volume obtained with a pneumotachograph in a spontaneously breathing patient. The drift in the baseline of the signal means that the pneumotachograph does not provide a reliable measure of breath-by-breath change in end-expiratory lung volume, which is desired for detecting the development of dynamic hyperinflation.

(ages 21 to 50 years) and significantly higher in eighteen healthy older subjects (ages 60 to 81 years), 44.0 ± 14.7%.[42] The substantial variability in breathing pattern between subjects, which is further magnified by the considerable breath-to-breath variability within subjects, poses a problem in selecting settings during mechanical ventilation. In a patient being ventilated with the volume-cycled form of assist-control ventilation, if tidal volume is set at the average value during unassisted breathing (approximately 5 to 7 mL/kg), the wide breath-to-breath variation in ventilatory demand means that around half of the delivered tidal volumes will be lower than the patient's demand and may lead to dyspnea.[43]

Arterial pressure varies throughout the respiratory cycle. Minute-to-minute variation in systolic pressure (quantified as standard deviation) is approximately 4 mm Hg, and diastolic pressure varies 2 to 3 mm Hg. In healthy subjects, arterial pressure differs by as much as 20 mm Hg between the two arms.[44] Consequently, a difference of 20 mm Hg between the two arms does not necessarily indicate an underlying disorder such as aortic dissection.

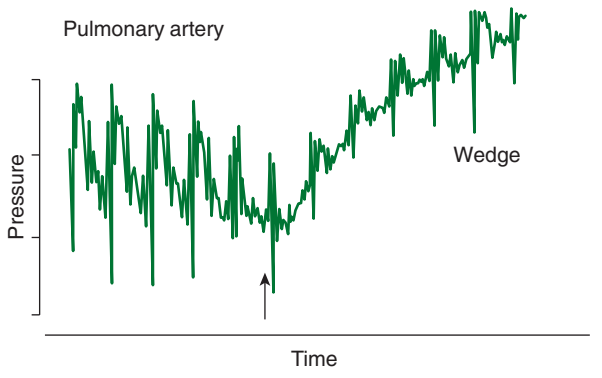

FIGURE 48-17 Pulmonary artery pressure tracing demonstrating overwedging. The *arrow* indicates the point of balloon inflation.

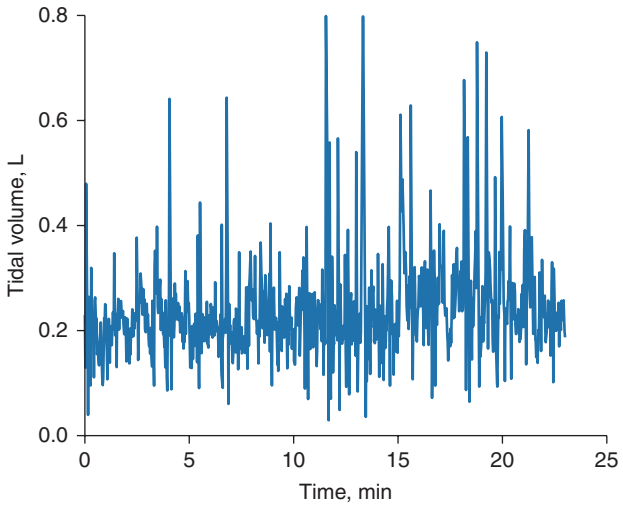

FIGURE 48-18 Breath-by-breath measurements of tidal volume in a patient during a weaning trial. Average tidal volume was 0.23 L. Note the considerable breath-by-breath variability (coefficient of variation was 43%).

Inherent Limitations of Monitors

No machine, including a monitor, is 100% reliable. Despite its undisputed popularity, pulse oximetry fails to provide valid measurements of Sa_{O_2} in a variety of settings.[45] The incidence of overall failure (defined as at least one continuous gap in data that exceeded 10 minutes) in anesthetized patients in an operating room was 9%.[46]

Complexity of Measurements

Many users of monitors have a limited understanding of how a machine functions and the implications of its measurements. Iberti et al[47] found that 47% of physicians (77% of whom were in training) were unable to interpret a straightforward recording of a PA wedge pressure. On average, physicians incorrectly answered ten of thirty-one questions dealing with insertion and complications, cardiac physiology, and interpretation and application of data. More respondents had difficulty with questions regarding data interpretation and patient treatment than with questions related to catheter insertion or cardiac physiology.

Modern ventilators provide a continuous online display of physiologic signals (such as flow, volume, and airway pressure) and numeric computations (resistance, compliance, and work of breathing). The complexity of the physiologic principles that underpin respiratory mechanics, however, has impeded the use of the measurements in clinical practice. The poor understanding of lung mechanics by medicine residents was highlighted in the recent survey.[48] Some 35% of residents were unable to select a ventilator setting that would decrease PEEPi in a patient with chronic obstructive pulmonary disease (COPD) who had become hypotensive immediately after intubation (Table 48-1).

TABLE 48-1: MEDICAL RESIDENT'S KNOWLEDGE OF MECHANICAL VENTILATION

Test items	% Incorrect
Appropriate use of PEEP in hypoxemia	44

Managing auto-PEEP correctly	35
Identifying candidate for noninvasive mechanical ventilation	27
Diagnosing tension pneumothorax	14

Abbreviation: PEEP, positive end-expiratory pressure.

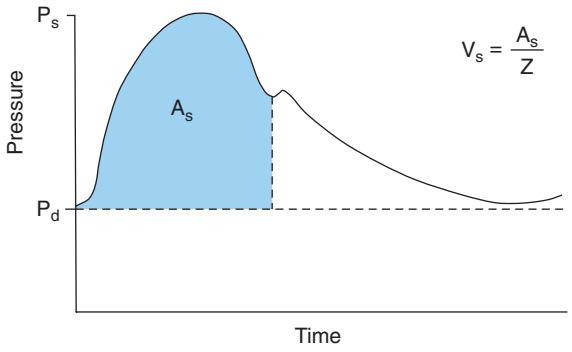

FIGURE 48-19 Schematic of the arterial pressure waveform versus time. P_s represents the systolic pressure, P_d the diastolic pressure, and A_s area under the systolic portion of the pressure-time curve. The heart's stroke volume V_s is related to A_s and the vascular impedance (Z). (Used, with permission, from Mahutte.[57])

The mountains of data generated by monitors make it extremely difficult to differentiate relevant from irrelevant information. More than 230 new data points may be available for review in a single patient on morning ICU rounds.[49] Psychologists have shown that the human mind is capable of assimilating no more than seven variables simultaneously.[50] When the same variable is measured by more than one machine (heart rate recorded by an ECG monitor and a pulse oximeter), the problem is compounded.

Monitoring the Right Physiologic Phenomenon

A major purpose of monitoring is to measure key variables that enhance understanding of underlying pathophysiology. Because of technical limitations, however, we tend to monitor that which we can rather than seeking the information we need.[2,51]

The primary goal of mechanical ventilation is to rest the respiratory muscles. Thus, activity of the respiratory muscles is the single variable most needed when monitoring a ventilated patient. Ventilator settings, however, are usually adjusted on the basis of arterial blood gases. Yet, arterial blood gases provide zero information about whether the respiratory muscles are being adequately rested. Consider synchronized intermittent mandatory ventilation, which has always been adjusted according to arterial blood gases. The failure of arterial blood gases to provide insight into work of breathing probably accounts for the gap of 20 years between the introduction of this mode and recognition of its harmful effects.[52–54]

Investigators recently have argued that calculations derived from the arterial pressure waveform provide a reliable continuous estimate of cardiac output (Fig. 48-19).[55–57] In patients with sepsis, Monnet et al[58] compared the accuracy of calculations based on the arterial pulse contour against a new transpulmonary thermodilution technique (the reference measurement) in detecting short-term changes in cardiac index (<1 hour). The contour technique was reliable in detecting a 15% increase in cardiac index induced by volume expansion (area under the receiver operating characteristic [ROC] curve, 0.87) or by norepinephrine (area under ROC curve, 0.92). Although promising, the ability of the arterial pressure contour to reliably estimate cardiac output needs further investigation in a more heterogenous group of ICU patients (not just sepsis) and over a longer period of observation (>1 hour).

Thinking in terms of ventricular preload, knowledge of end-diastolic volume is pivotal for logical assessment of hemodynamic performance in a critically ill patient.[59] No simple method is available, however, to measure end-diastolic volume. Many clinicians use central venous pressure to assess preload despite numerous studies showing that central venous pressure is extremely unreliable in estimating end-diastolic volume in critically ill patients.[60–65]

Different Techniques for Measuring the Same Physiologic Process

In the ICU, different techniques can be used to measure the same physiologic function. The resulting differing numbers, however, may suggest different clinical states. Arterial oxygenation can be assessed by measuring O_2 saturation with a pulse oximeter or partial pressure of oxygen (P_{O_2}) by blood-gas analysis. In a study of patients with acute respiratory distress syndrome (ARDS), change in Sp_{O_2} moved in an opposite direction to the change in Pa_{O_2} in 25% of the measurements. In some patients, a decrease in partial pressure of arterial oxygen (Pa_{O_2}) of 20 mm Hg was accompanied by a simultaneous increase in Sp_{O_2} of 20%.[66] Therapeutic decisions based on Sp_{O_2} alone differed from decisions based on Pa_{O_2} on 16% of occasions.

CLINICAL APPLICATIONS

The range of options for monitoring a ventilated patient is enormous and beyond the scope of this chapter. A few examples are provided. For a comprehensive review of the clinical

applications of ICU monitoring, the reader is referred to the companion book, *Principles and Practice of Intensive Care Monitoring*.[4]

Enhance Understanding of Pathophysiology

To properly interpret information—medical or nonmedical—a person must take into account the relevant context. To properly understand the results of a diagnostic test, a clinician requires a good understanding of pertinent pathophysiology.

Measuring pressure, flow, and volume during mechanical ventilation assists in the differential diagnosis of respiratory failure. The airway occlusion technique makes it possible to carefully characterize the mechanics of the lung, the chest wall, and the total respiratory system.[67–70] During a weaning trial, esophageal pressure and flow measurements can be used to partition patient effort into its resistive, elastic, and PEEPi components.[71,72] All three components are increased in weaning-failure patients, with PEEPi increasing the most. Therapy to decrease these abnormalities (such as bronchodilators or diuretics) may help expedite weaning outcome (Fig. 48-20).[73,74]

Recording expiratory muscle activity during spontaneous breathing helps differentiate PEEPi caused by dynamic hyperinflation from that caused by expiratory muscle activity (Fig. 48-21).[75–78] If PEEPi is mostly caused by dynamic hyperinflation, addition of external PEEP is likely to decrease work of inspiration.[71,79] If, however, an increase in PEEPi is caused by increased activity of the expiratory muscles,[80] addition of external PEEP will impose an additional elastic load. More importantly, it will also increase the operating lung volume.

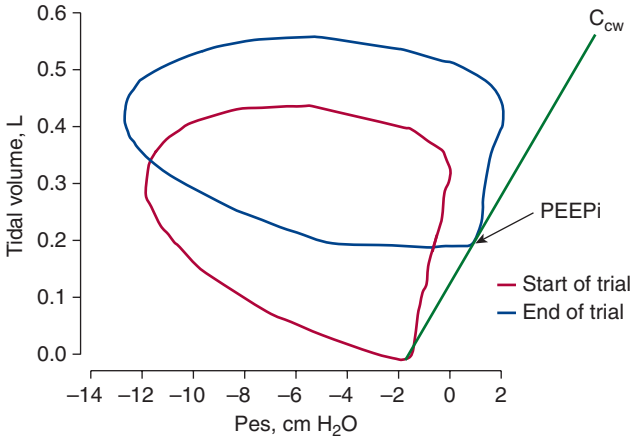

FIGURE 48-20 Esophageal pressure (*Pes*) versus tidal volume curves (Campbell diagrams of work of breathing) in a patient at the start (*red*) and end (*blue*) of a trial of spontaneous breathing. The *green line* represents the static compliance of the chest wall (C_{cw}) measured during controlled mechanical ventilation. At the end of the trial, the Pes-volume curve is displaced upward, indicating an increase in end-expiratory lung volume as reflected by the presence of intrinsic positive end-expiratory pressure (*PEEPi*).

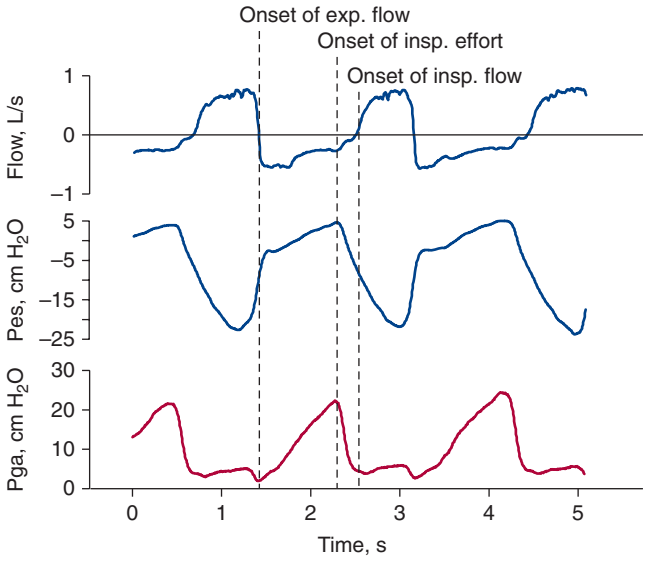

FIGURE 48-21 Flow, esophageal pressure (*Pes*), and gastric (*Pga*) pressure in a patient during a trial of spontaneous breathing. Dynamic intrinsic positive end-expiratory pressure (*PEEPi*) is estimated as the decrease in Pes between the onset of inspiratory (*insp.*) effort (*second vertical line*) and the onset of inspiratory flow (*third vertical line*). Estimation of the expiratory muscle contribution to swings in Pes and dynamic PEEPi is obtained by measuring the increase in Pga between the onset of expiratory flow (*exp.*; *first vertical line*) and the onset of inspiratory effort (*second vertical line*). (Used, with permission, from Parthasarathy et al.[78])

Aid with Diagnosis

Capnometry helps in detecting esophageal intubation.[81–83] The use of end-tidal CO_2 monitoring is based on the premise that CO_2 recorded at the end of a tidal breath reflects arterial partial pressure of carbon dioxide (P_{CO_2}). When the trachea of a patient with an intact pulmonary circulation is intubated, end-tidal CO_2 is recorded. When, however, the endotracheal tube is erroneously placed in the esophagus, end-tidal CO_2 is zero. Monitoring of end-tidal CO_2 has been compared with three other methods (auscultation, a negative pressure test using a self-inflating bulb, and transillumination) for verifying tracheal tube placement.[84] (The second approach, the negative-pressure test, uses a self-inflating bulb: If the endotracheal tube is in the esophagus, suction on the bulb causes the pliable esophageal wall to collapse and no air can be aspirated; if the tube is in the trachea, the semirigid walls prevent tube occlusion when suction is applied and air can be aspirated.) Monitoring of end-tidal CO_2 was found to be the most reliable (Fig. 48-22).

Persistence of expiratory flow throughout expiration, without return to zero, suggests PEEPi (Fig. 48-23); this suspicion can be verified by occluding the expiratory port of the ventilator immediately before the onset of the next breath.[85] Occlusion causes pressure in the lungs and ventilator circuit to equilibrate. The pressure displayed on the ventilator manometer is PEEPi.[86] The presence of PEEPi can help

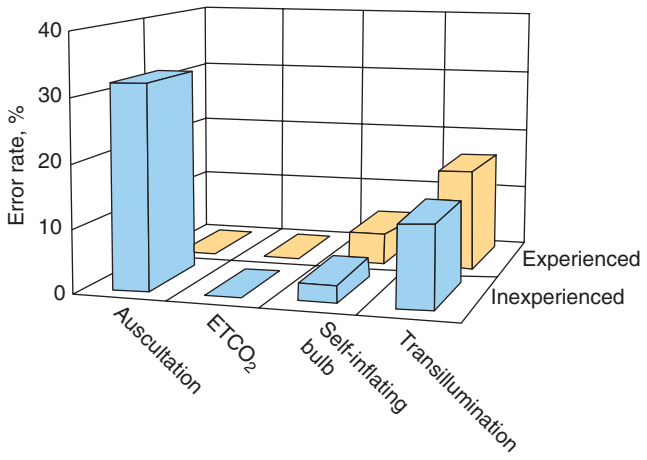

FIGURE 48-22 Error rates of experienced and inexperienced examiners in verifying the placement of a tracheal tube using four methods: *auscultation*, capnographic determination of end-tidal CO_2 ($ETCO_2$), negative-pressure test using a *self-inflating bulb*, and *transillumination* using a lighted stylet. Capnography was the most reliable method regardless of the examiner's experience. (Used, with permission, from Knapp et al.[84])

explain an unexpected drop in cardiac output or electromechanical dissociation (during cardiopulmonary resuscitation).[87] Steps to overcome PEEPi can decrease patient work of breathing and improve triggering of the ventilator.[86,88,89]

Guide Management

ASSESS THE RESPONSE OF DRUGS

Monitoring is essential with administration of therapeutic agents that can produce rapid and dramatic changes in a patient's condition. A physician would not dream of administering a potent, rapid-acting intravenous vasoactive agent (vasodilator, vasopressor, or inotropic agent) without monitoring arterial pressure. It would be unconscionable to perform cardiac resuscitation without ECG monitoring.

Measurement of airway resistance helps in assessing the response to bronchodilator therapy. In ventilator-dependent patients with COPD, delivery of albuterol from a metered-dose inhaler produces a decrease in airway resistance within 5 minutes; the effect is sustained for at least 60 minutes.[90,91]

During mechanical ventilation, pulse pressure (the gradient between systolic pressure and diastolic pressure) is maximal (PPmax) at end-inspiration and minimal (PPmin) during expiration. These respiratory variations in pulse pressure have been shown to reflect changes in left-ventricular stroke volume.[92] Accordingly, it has been reasoned that fluid responsiveness may be assessed by estimating the respiratory changes in pulse pressure (referred to as ΔPP) in terms of the following formula:

$$\Delta PP = \left[\frac{PPmax - PPmin}{(PPmax + PPmin)/2}\right] * 100$$

ΔPP was found to be reliable in identifying fluid responsiveness in sedated patients receiving mechanical ventilation; this variable, however, was inaccurate in spontaneously breathing patients and in patients ventilated with low tidal volume (<8 mL/kg).[93,94]

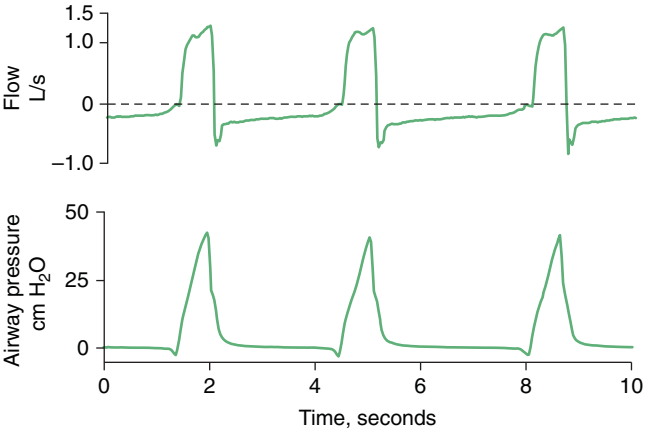

FIGURE 48-23 Flow and airway pressure in a patient being ventilated using assist-control ventilation. The failure of expiratory flow to return to zero at the onset of the successive mechanical breaths indicates the presence of intrinsic positive end-expiratory pressure (PEEPi).

OPTIMIZE VENTILATOR SETTING

Titrating FI_{O_2}. Pulse oximetry is commonly used when titrating FI_{O_2} in ventilated patients (Fig. 48-24). A Sp_{O_2} of 92% is a reliable target in white patients. In black patients, however, an Sp_{O_2} of 92% is associated with significant hypoxemia, and a higher target, 95%, is required.[95]

Adjusting Pressure Support. Tidal volume and respiratory rate are commonly used to set pressure-support ventilation.[96–100] A reasonable level of inspiratory effort is an inspiratory pressure-time product less than 125 cm H_2O·sec/min. Using this target, a respiratory rate of 30 breaths/min and tidal volume of 600 mL resulted in the fewest false classifications.[100]

Setting Positive End-Expiratory Pressure. In a patient with acute lung injury, the right level of PEEP is that which optimizes arterial oxygenation without causing O_2 toxicity or ventilator-induced lung injury.[101–104] Balancing the benefit of keeping the lung open (during tidal ventilation) against the risks of lung overinflation may require monitoring of the pressure-volume curve, lung morphology, and gas exchange.[105–110]

When loss of aeration has a focal distribution (atelectatic lower lobes coexisting with aerated upper lobes), a high level of PEEP can cause overinflation of already aerated areas and only partial recruitment of atelectatic areas.[111] In such patients, some experts recommend limiting PEEP to low levels (approximately 10 cm H_2O).[101] In patients who have

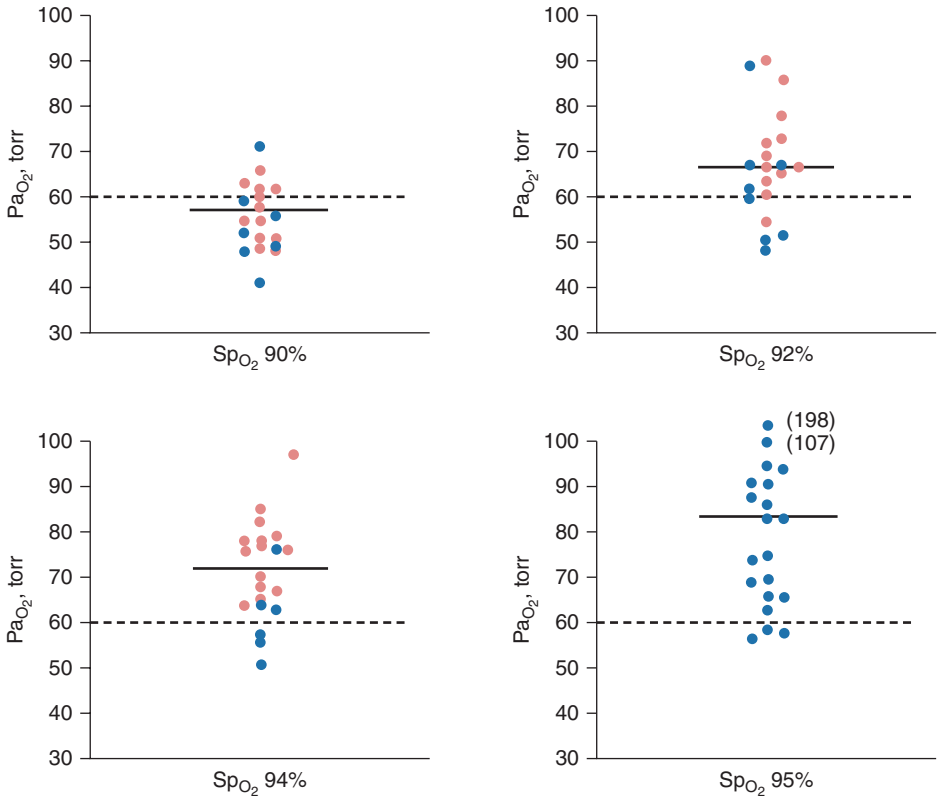

FIGURE 48-24 Values of arterial oxygen tension (Pa_{O_2}) at pulse oximetry oxygen saturation (Sp_{O_2}) readings of 90%, 92%, 94%, and 95%. Inspired oxygen concentration (FI_{O_2}) was adjusted to achieve a particular steady-state Sp_{O_2} value in a group of fifty-four critically ill patients. The *solid horizontal line* represents the mean Pa_{O_2} value obtained at each Sp_{O_2} target. The *orange* and *blue circles* represent values obtained in white and black patients, respectively. In white patients, a Sp_{O_2} target of 92% resulted in a satisfactory level of oxygenation, whereas a higher Sp_{O_2} target, 95%, was required in black patients. (Modified, with permission, from Jubran and Tobin.[95])

diffuse loss of aeration, the risk of overinflation with PEEP is low.[112] Thus, a higher PEEP can be used provided it does not cause the plateau pressure to rise above the upper inflection point of the pressure-volume curve.[101,113]

Assessing Patient Work of Breathing. Inspection of the airway pressure contour during assisted ventilation can help assess patient work of breathing. Excessive scalloping of the airway pressure tracing indicates increased work, such as that caused by insufficient inspiratory flow (Fig. 48-25). During assist-control ventilation, an increase in flow can decrease work of breathing by as much as 60% in patients with acute respiratory failure. Higher flow rates can also decrease inspiratory effort in stable patients with COPD.[114,115]

Continuous displays of pressure and flow have led to increased awareness that patient effort is frequently insufficient to trigger the ventilator.[75,88] During pressure support or assist-control ventilation, up to a third of patient efforts may fail to trigger the machine (Fig. 48-26). Such nontriggering has been shown to result from premature inspiratory efforts that are insufficient to overcome the elastic recoil associated with dynamic hyperinflation.[88] To trigger the ventilator, patient effort has to first generate a negative intrathoracic pressure to counterbalance the elastic recoil and then overcome the set sensitivity. The full consequences of wasted inspiratory efforts are not known. They certainly place an unnecessary burden on patients whose inspiratory muscles are already under stress. Such added stress can interfere with subsequent weaning.[116–118]

Avoid Complications

The heterogeneous lung involvement in ARDS puts some regions at risk of developing alveolar overdistension when a ventilator breath is delivered.[119–121] Plateau pressure is monitored as a surrogate for end-inspiratory alveolar pressure, and its monitoring may help to minimize lung injury.[122] Studies show that patients with ARDS who have plateau pressures greater than 32 cm H_2O have higher mortality.[113,123,124]

Daily radiographs in ventilated patients can reveal unsuspected or significant abnormalities.[125,126] Malpositioning of devices (endotracheal tubes, nasogastric tubes, and central venous pressure lines) and pneumothorax or pleural effusions are detected in 20% of patients.[127] Physicians had not anticipated these findings. The importance of early detection of abnormalities was underscored in a study by Steier et al.[128] Mortality was 7% when pneumothorax was diagnosed

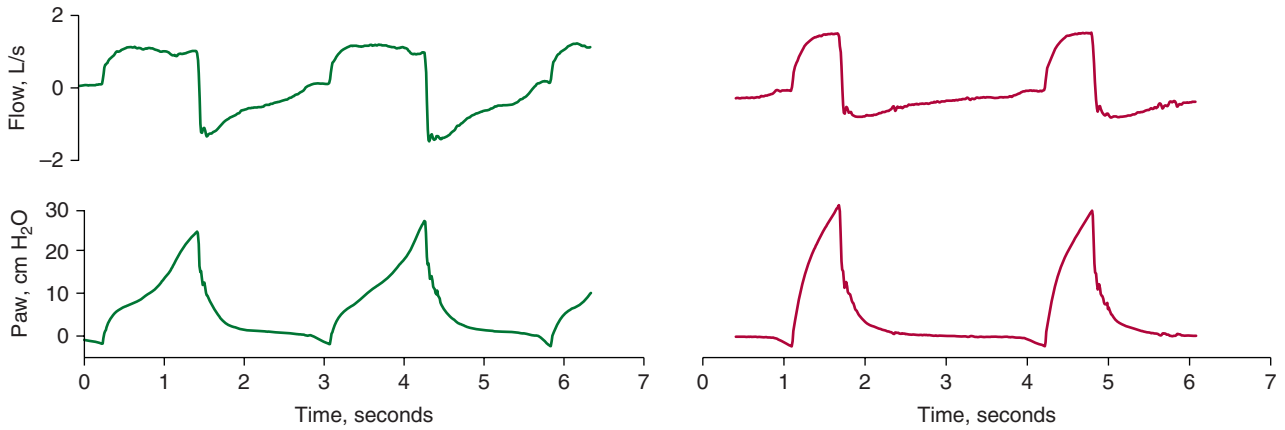

FIGURE 48-25 Flow and airway pressure (*Paw*) during assist-control ventilation at a flow of 30 L/min (*left panel*) and a flow of 60 L/min (*right panel*). On the *left panel*, the pronounced negative phase together with excessive scalloping of the Paw waveform indicates that the patient is making a strenuous effort to breathe as a result of the inadequate flow setting. On the *right panel*, the small negative phase and smooth rise and convex appearance of the Paw waveform indicate that the patient is making a slight inspiratory effort to breathe.

immediately. Mortality quadrupled when diagnosis (and treatment) was delayed.

Provide Alarms

Pulse oximetry can provide an early warning of hypoxemia. In 20,802 surgical patients, use of pulse oximetry resulted in 19-fold greater detection of hypoxemia (defined as an Sp_{O_2} <90%) as compared with patients in whom an oximeter was not used.[129] Myocardial ischemia was less common in the oximetry group than in the control group, twelve and twenty-six patients, respectively. The anesthesiologists reported that oximetry led to a change in therapy on one or more occasions in 10.5% of patients in the operating room and in 17% in the postanesthesia care unit.

An alarm on a ventilator may sound (or flash) because of a change in ventilator performance or patient clinical status. An abrupt increase in peak airway pressure can arise with endotracheal obstruction or ventilator malfunction. A decrease in peak pressure can arise with a leak in the circuit. An increase in the baseline airway pressure can signal malfunction of the exhalation valve (or inadvertent PEEP).[130,131]

The role of monitoring as a warning sign was highlighted in a study of anesthesia-related malpractice claims.[132] Of 1097 cases reviewed, negative outcomes were prevented in 32% by the use of additional monitors. The authors estimated that use of a pulse oximeter and capnometer would have prevented 93% of the mishaps.[132]

Assessment of Trends

Monitoring of physiologic variables over time helps in assessing a therapeutic response.[133] When vasopressor therapy is being titrated, continuous monitoring of arterial pressure is

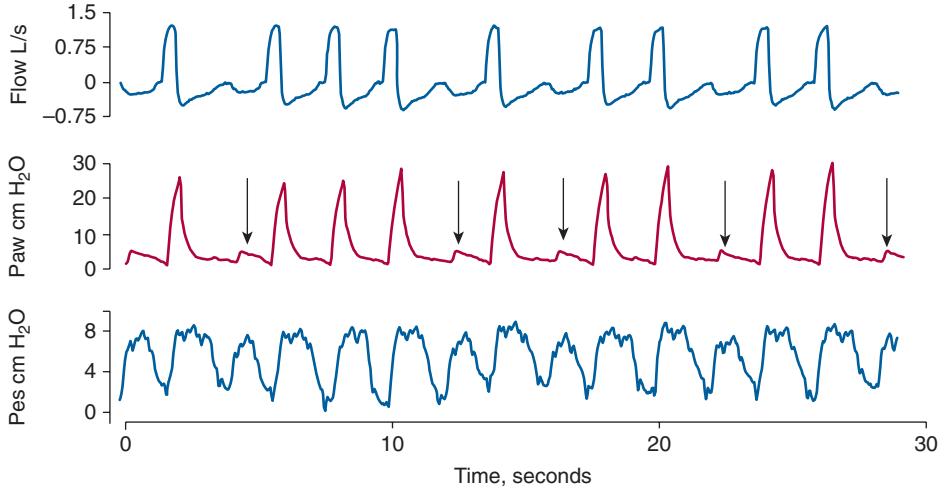

FIGURE 48-26 Flow, airway pressure (*Paw*), and esophageal pressure (*Pes*) in a patient receiving assist-control ventilation. The *arrows* indicate inspiratory attempts that failed to trigger the opening of the ventilator valve.

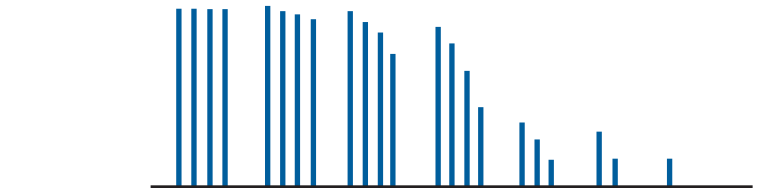

Receptor blockade (%)	60	70	75	77.5	80	85	90	95
T1 (%)	100	100	100	80	25	20	10	0
T4/T1 Ratio	100	0.9	0.75	0.6	0	0	0	0

FIGURE 48-27 Train-of-four stimulation consists of a series (train) of four electrical impulses delivered at a frequency of two stimuli per second. When neuromuscular blocking agents are not being used, the response to train-of-four stimulation is four strong twitches. As the receptors begin to load up with the neuromuscular blocking agent, four twitches are still present, although the response is weaker and a decrease is evident between the first and the fourth twitch. Comparison of muscular movement on the first (*T1*) and fourth twitch (*T4*) enables the calculation of a *T4/T1* ratio; this ratio can detect an earlier stage of receptor blockade than twitch loss. (Used, with permission, from Strange.[136])

essential. Monitoring the motor response to peripheral nerve stimulation helps avoid the accumulation of neuromuscular blocking agents (with risk of prolonged paralysis).[134,135] Train-of-four stimulation uses a series of four supramaximal stimuli delivered at a frequency of two stimuli per second (Fig. 48-27). The dose of a neuromuscular blocking agent is usually titrated to obtain no more than two visible muscle twitches in response to each train-of-four. If the patient fails to demonstrate any response with the train-of-four stimulation, the blocking agent should be discontinued temporarily or the dosage reduced.[135–137]

Changes in esophageal pressure over the first 9 minutes of a trial, quantified as a trend index, revealed sensitivity 0.91, specificity 0.89, positive predictive value 0.83, and negative predictive value 0.94 (Fig. 48-28).[74] The area under a ROC curve for the trend index (0.94) was greater than for first-minute measurement of esophageal pressure (0.44, $p < 0.05$) and tended to be greater than that for frequency-to-tidal volume ratio (f/V_T).

EFFECT OF MONITORING ON PATIENT OUTCOME

Because of expectation of improvement in patient outcome, monitoring is subjected to closer scrutiny than most diagnostic tests.[51] Although complications derived from use of a monitor are relatively easy to evaluate, few monitoring devices have been subjected to studies of their effect on mortality or other clinical outcomes. Those few studies have not revealed clearcut benefits. Three recently conducted randomized trials of the PA catheter (in 2714 patients and 120 ICUs) did not reveal improved outcome.[138–140] The negative results of these studies have led to a substantial decline in the use of the PA catheter (Fig. 48-29).[141]

In 20,802 surgical patients, Moller et al[129] found that pulse oximetry had no demonstrable benefit on the rate of postoperative complications. Accordingly, it is reasonable to ask whether monitoring has any role in the management of a critically ill patient. At first glance, the studies say no. Before reaching that conclusion, however, we need to scrutinize the data.

A randomized controlled trial is generally adopted as the most definitive method for evaluating the benefit of some intervention. In a typical trial, the effect of an intervention on some outcome is assessed in a well-defined patient population. Such trial designs are mostly used to assess the risks and benefits of a therapeutic agent. Using a randomized trial to assess the benefits of a monitoring device can be problematic because of poorly defined patient populations, complexity of the therapeutic intervention (because monitoring is also linked to treatment), and choice of the primary outcome.

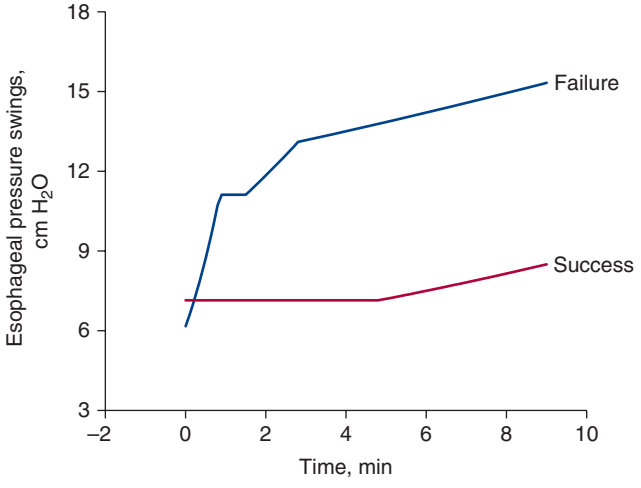

FIGURE 48-28 Change in esophageal pressure (Pes) swings, quantified using a nonlinear model, namely the multivariate adaptive regression spline (MARS) analysis, during the first nine minutes of weaning trials in weaning-failure patients (*blue line*) and weaning-success patients (*red line*). The mathematical technique was used to capture all of the data points in the two groups over the time span. The greatest rate of increase in Pes swings in the failure patients occurred during the first minute. The greatest difference in Pes swings between the failure (14.5 cm H_2O, 95% confidence intervals 18.9 to 11.2) and success groups (7.9 cm H_2O, 95% confidence intervals 11.8 to 0.8) was at the transition between the ninth and tenth minute. (Used, with permission, from Jubran et al.[74])

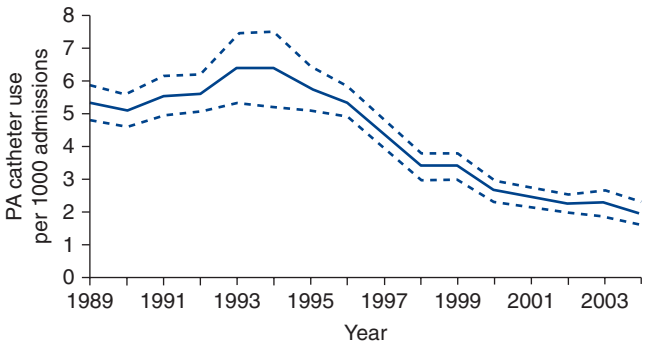

FIGURE 48-29 Pulmonary artery (*PA*) catheters placed per 1000 patients (*solid line*) and 95% confidence intervals around the annual rate of catheter utilization (*dashed lines*) in nine American states as part of a nationwide inpatient sample. Between 1993 and 2004, use of pulmonary artery catheterization decreased by 65%, from 5.66 to 1.99 per 1000 medical admissions. (Modified, with permission, from Wiener et al.[141])

Failure to Precisely Define Disease State

The first step in evaluating the effect of an intervention is to ensure a well-defined study population. Definition and categorization of disease states—the discipline of nosology—is especially difficult in critically ill patients.[142] (The reader is referred to a detailed discussion of nosology in Chapter 4.) The most precise way to define a disease is in etiologic terms (e.g., Legionnaire disease). Most randomized trials of monitoring techniques have been conducted in groups of patients identified in terms of a syndrome—that is, a condition defined on the basis of a constellation of symptoms and signs. A typical definition of sepsis is the following: temperature greater than 38°C (100.4°F) or less than 36°C (96.8°F), respiratory rate greater than 20 breaths/min or P_{CO_2} less than 32 mm Hg, and signs of hypoperfusion, among others.[139] (Note that the respiratory rate commonly listed as a criterion for sepsis falls in the middle of the normal range.) When a disease is defined in an imprecise manner, very different types of patients may be assigned to the two arms of a trial. This factor could be a major contributor to negative outcome of a study of a monitoring technique.

Complexity of Evaluating the Intervention

Evaluating the benefit and risk of any intervention in the ICU is challenging. The huge number of procedures and treatments typically used in any single ICU constitute confounding variables. These covariates contribute to considerable experimental noise in a trial, masking benefits that are truly present.

To illustrate these considerations, we discuss a hypothetical study designed to determine whether PA catheter monitoring improves survival in septic shock. In designing such a trial, the covariables shown in Figure 48-30 must be controlled for or taken into account.

PATIENT SELECTION: DISTINCTION BETWEEN TRUE INDICATIONS VERSUS STUDY INCLUSION CRITERIA

The choice of the most appropriate monitoring device is dictated by a patient's condition. To decide whether a monitor is indicated in a particular patient, the physician must balance potential benefits and risks. When wondering whether to insert a PA catheter in a patient with septic shock who is unresponsive to fluid and vasopressor therapy, a physician should consider three factors. One, will end-organ dysfunction proceed and become irreversible if therapy is not changed? Two, will large volumes of fluids, administered empirically but on an incorrect assumption that intravascular volume is depleted, predispose to hypoxemia should acute lung injury be present? Three, if a PA catheter is inserted, will the physician withhold fluids if the wedge pressure is normal?

The uncertain probability of organ dysfunction and its time course, the risks of monitoring, and the variable efficacy of therapy highlights the complexity of clinical decision making, even when the clinician is highly skilled and experienced. The above three questions, and other factors that impinge on the decision of whether a PA catheter is indicated in a particular patient, are omitted from the design of a randomized clinical trial. Instead, patients are selected on the basis of carefully defined eligibility criteria. The study is thus focused on a narrowly defined spectrum of patients who poorly reflect the more heterogeneous range of disease seen in everyday practice. As a result, the patients receiving a PA catheter in a randomized trial may bear little relationship to what an experienced and cautious physician does in everyday practice. A skilled physician is unlikely to insert a PA catheter in many of the patients assigned to the intervention arm of a trial, believing that the resulting information would have little likelihood of influencing patient management. If patients are entered into a trial and are randomized to the PA catheter arm, although a judicious physician would not insert a catheter in the same patients, the consequence will be to dilute any likely benefit from the catheter but at the same time increase the risk of complications.

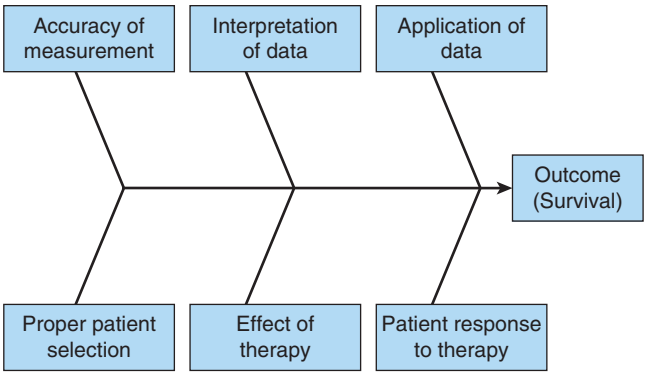

FIGURE 48-30 Factors that can influence the effect of a monitoring device on patient outcome, such as survival. See text for details.

In a study of a mixed group of medical and surgical patients, Connors et al[143] found that a PA catheter was more likely to be used in patients who were sicker and more likely to die. Richard et al[139] studied the benefit of a PA catheter in patients with shock and ARDS. Patients were eligible for monitoring with a PA catheter if their systolic blood pressure was equal to or greater than 95 mm Hg (on 3 mcg/kg per minute of dopamine), heart rate equal to or greater than 92 beats/min, Pa_{CO_2} equal to or less than 32 mm Hg while breathing spontaneously, and an elevated lactate level. We suspect most physicians would not insert a PA catheter in all (or even most) patients who meet these four criteria. In the study of Sandham et al[138] in high-risk surgical patients, 87% of patients who had a PA catheter inserted were not at high risk for death (as identified by New York Heart Association or American Society of Anesthesiologists classifications). In the study by Harvey et al[140] of 1041 medical and surgical ICU patients, patients were randomized to the PA catheter arm if the primary physician considered the patient as someone who "should" be managed with a PA catheter; precise criteria of what constitutes "should" were not given. Again, this study did not demonstrate a benefit from a PA catheter. But if a PA catheter is inserted in a patient in whom there is no clear indication for its use, would you expect the catheter to improve outcome? We expect all readers to answer no. Thus, the outcomes in the randomized trials by Richard et al,[139] Sandham et al,[138] and Harvey et al[140] were all preordained as negative before the first patient was enrolled.

ACCURACY OF THE MONITORS

Studies evaluating the impact of monitoring devices on outcome are predicated on the assumption that the clinical staff are employing the monitor in a knowledgeable manner and obtaining reliable readings. Reliability of PA catheter readings is highly dependent on catheter placement, calibration of the transducers, and interpretation of the data. Of 282 measurements of PA wedge pressure, Morris et al[144] found that 103 (36%) of the readings were inaccurate. Of 103 erroneous readings, eighty-nine were associated with technical problems, such as damped tracings, poor dynamic response, overinflation of the balloon, or incomplete wedging (Fig. 48-31). Technical problems with use of the PA catheter, or steps taken to correct them, were not taken into account in the randomized trials conducted by Richard et al[139] and Sandham et al.[138] Specifically, Harvey et al[140] state,"We did not assess the quality of use." Even with great care, these technical problems cannot be eliminated completely. For a simple device, such as a pulse oximeter, overall instrument failure was 7.2% among the sicker patients in the study of Moller et al.[129] Such operational problems are commonly not listed in reports of clinical trials.

INTERPRETATION OF THE DATA

Several studies reveal that many clinicians have limited skills in the accurate interpretation of data generated by a PA catheter.[47,145–147] In their survey, Iberti et al[47] found that almost half of physicians incorrectly interpreted a straightforward recording of wedge pressure. Another study revealed that physicians arrived at a wide range of wedge pressures for the same tracing.[148] If the wedge pressure is incorrectly and repeatedly read as low in a patient with ARDS, then continued administration of fluids is likely to result in an unfavorable outcome.

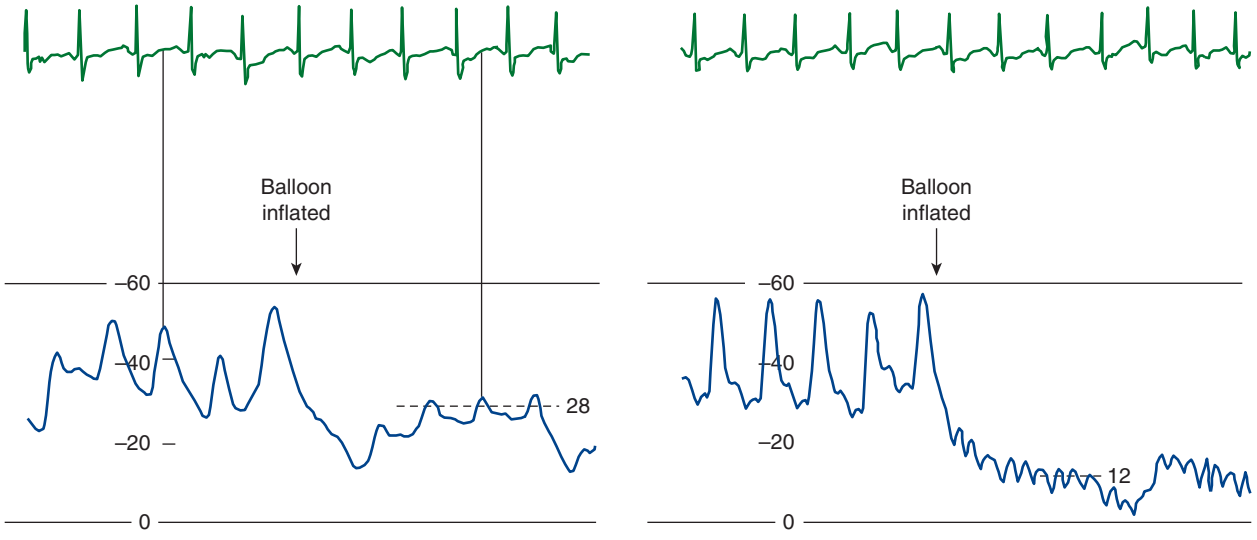

FIGURE 48-31 Simultaneous recordings of electrocardiogram (*ECG*) and pulmonary artery (*PA*) pressure to illustrate incomplete wedge pressure (*Ppw*). *Left panel.* With balloon inflation, wedge pressure falls to a value that approximates pulmonary artery diastolic pressure (*Ppad*). After balloon inflation, a single positive wave coincides with the T wave on the ECG—a pattern inconsistent with a left-atrial waveform. *Right panel.* Waveforms after the catheter has been retracted and the balloon reinflated. A large Ppad–Ppw gradient is evident and the tracing is consistent with a left-atrial waveform. Scale in mm Hg. (Used, with permission, from Leatherman and Marini.[20])

APPLICATION OF DATA IN CLINICAL DECISION MAKING

Even if data are accurate and properly interpreted, benefit will occur only if the physician applies the information logically in the management of patients. Some monitoring decisions can be made by simple rules of thumb (heuristics); these are easy to incorporate into an algorithm.[149,150] Simple rules take the *if-then* form. If serum glucose in a patient with insulin-dependent diabetes is high, then insulin should be administered. This strategy is straightforward because the probability of hyperglycemia is high, the consequences of untreated hyperglycemia are great, the risk of monitoring (drawing a blood sample) is low, the benefit of treatment is high, and the risks when insulin is properly administered are small.

The monitoring dilemmas that arise in most critically ill patients are complex and cannot be captured in an algorithm. Intensivists frequently have to make rapid decisions under conditions of considerable uncertainty, involving substantial risks and unpredictable benefit. To combine, integrate, and interpret diagnostic data in their decision-making process, intensivists employ a number of strategies of clinical reasoning.

Probabilistic Reasoning. Diagnostic uncertainty arises because data are insufficient or because the relationship between the data and the disease process is poorly understood.[150] To cope with uncertainty, physicians may use probabilities if available.[151] Probabilistic reasoning is based on the known sensitivity and specificity of a diagnostic (or monitoring) test. A physician forms an initial gestalt as to the likelihood of some condition, which is the *pretest probability*. Then, based on the known sensitivity and specificity of the test, the physician forms a new estimate of likelihood, the *posttest probability*. Take a physician who has no inkling as to whether a patient can (or cannot) tolerate a weaning trial. The pretest probability will be 50%. The physician then measures f/V_T and obtains a reading of 80. This reading has a likelihood ratio of 7.5 (that the patient will tolerate a weaning trial). Based on the nomogram of Fagan,[152] a likelihood ratio of 7.5 is associated with a posttest probability of 95% (if pretest probability is 50%). This means that when physicians are in complete doubt (50-50) as to whether a patient can be weaned, obtaining an f/V_T value of less than 80 will substantially decrease their doubt.

Unfortunately, the published data necessary for precise application of probabilistic reasoning are available for few diagnostic (or monitoring) techniques in the ICU. Because physicians cannot communicate in precise quantitative terms, they use expressions such as "most likely," "unlikely," and "rare." Consider a patient in septic shock who remains hypotensive despite fluid resuscitation and a moderate dose of a vasoactive agent (dopamine > 10 mcg/kg/min). A common cause of hypotension in such a patient is left-ventricular-dysfunction. To determine whether left-ventricular-dysfunction is present or absent, the physician measures the patient's cardiac index. Before measuring cardiac index, the physician forms a gestalt of the patient's likelihood of left-ventricular dysfunction (based on previous experience of patients with similar clinical characteristics). After inserting a PA catheter, measuring cardiac index, and based on the reported sensitivity and specificity of cardiac index, the clinician revises his or her assessment of the patient's likelihood of left-ventricular dysfunction. This scenario is idealistic, not realistic, because sensitivity and specificity of cardiac index for detecting left-ventricular-dysfunction in patients with septic shock have not been studied.[153,154]

Another problem arises with use of monitored data. Although data are generally recorded as continuous variables, clinicians typically view data in dichotomous terms. What is the breakpoint in cardiac index below which a patient is classified as having left-ventricular-dysfunction? Reports on cardiac index as a diagnostic criterion of left-ventricular-dysfunction usually present a range of possible values, such as 1.6 to 2.3 L/min/m^2, rather than a discrete value.[155] The threshold value of cardiac index that is best in distinguishing between the presence and absence of left-ventricular-dysfunction has never been determined. Is it an index of 2.2 L/min/m^2? Is it 2 L/min/m^2? Without a defined threshold value, one cannot attempt to measure the sensitivity and specificity of a diagnostic test.

A further layer of complexity arises with the choice of reference standard. All tests are inaccurate to varying degrees. Thus, the degree of accuracy of a diagnostic (or monitoring) test is measured against a reference test. Ideally, the reference standard should be measurable in concrete terms: histology or precise level of narrowing on angiography. For left-ventricular-dysfunction, however, the reference standard is based on clinical criteria. Studies suggest that a cardiac index of 2.2 L/min/m^2 is an important threshold in predicting the outcome of patients with acute myocardial infarction.[155] Will the physician use the same cardiac index threshold in deciding whether to start treatment with dobutamine in the above-described patient with sepsis who has failed dopamine therapy? Moreover, in making decisions in a particular patient, a clinician may decide to raise or lower the threshold value, taking into account aspects unique to a particular patient's condition. Because of dobutamine's chronotropic action on the heart, a physician may decide to withhold this drug in a patient with underlying coronary artery disease until the cardiac index falls to 1.8 L/min/m^2.

There is a deeper, more fundamental problem with probabilistic reasoning. This relates to its epistemologic grounding. (Epistemology is the branch of philosophy concerned with the study of the very foundation on which our knowledge rests.) On their own, data derived from randomized trials are unable to explain *why* a particular relationship exists. In contrast research in physiology, molecular biology, and many other fields has as its objective the elucidation of underlying mechanisms (explanations for why relationships occur). Tanenbaum[156] undertook an ethnographic study of the reasoning employed by physicians as

they made clinical decisions. She found that the clinicians were primarily realists (or determinists): They based decisions on a mental picture of a world of real relationships, real events. Data from mechanistic research enrich this mental picture, offering explanations (meaning) on which physicians can base clinical decisions. When physicians operate as realists, they conduct themselves as if they know what is really happening inside a sick person. Data from a randomized trial simply show that some relationship was observed, but provide no epistemologic basis for its occurrence, no understanding of cause and effect. In clinical decision making, realists image a disease process; probabilists play the odds.

Physiologic Reasoning. To attain greater confidence in diagnosis, clinicians employ physiologic (or causal) reasoning. As discussed under "Probabilistic Reasoning" above, the hope is to form a more coherent picture of cause-and-effect relationships in a given patient. This type of reasoning is particularly suited to the ICU, because monitoring is geared toward detecting changes in pathophysiology. Causal reasoning involves testing and validating (or refuting) apparent cause-and-effect connections.

Consider a patient with COPD and congestive heart failure who is being ventilated. A PA catheter is inserted and reveals a wedge pressure of 28 mm Hg. Based on probabilistic considerations, the likelihood of pulmonary edema is great. Using causal (physiologic) reasoning, wedge pressure is viewed as a reliable estimate of preload (left-ventricular end-diastolic volume). In this patient, the clinician judges the elevated wedge pressure to signify hypervolemia. The true advantage of causal reasoning becomes more clear when we learn that a 60-second interruption of positive-pressure ventilation caused this patient's wedge pressure to fall to 15 mm Hg. Probabilistic reasoning would steer us toward diagnoses such as hypervolemia or cardiac dysfunction. Physiologic (or causal) reasoning leads us to suspect that the high wedge pressure (28 mm Hg) is caused by PEEPi rather than hypervolemia or cardiac dysfunction.

Causal reasoning forms the bedrock for many diagnostic decisions made outside the ICU. Our understanding of the pathophysiology of critical illnesses, however, is too rudimentary to apply it when managing most ICU patients. The above example highlights the need for much more research into pathophysiologic mechanisms in critically ill patients. Data generated by randomized, controlled trials can never provide the information needed for causal reasoning—the type of reasoning that is dominant in the decisions made by physicians in their everyday practice.[156]

Deterministic Reasoning. Deterministic or categorical reasoning is used to reduce information overload. Deterministic reasoning applies a set of rules that take the form of *if-then* statements. For example, *if* a ventilated patient with COPD develops a sudden and equivalent increase in peak and plateau pressures, *then* a nonairway problem, such as a pneumothorax, should be considered. If a patient develops acute renal failure without proteinuria and the fractional excretion of sodium is less than 1%, then the renal failure is prerenal in origin.

Such *if-then* rules look simple and attractive. The difficult part is figuring out if the antecedent condition (the *if* part of the rule) has been met. When the developers of clinical protocols incorporate such rules into an algorithm, they deliberately eliminate contingencies that can influence the application of the rule. The elimination of such ambiguities means that the rule can be more precisely and concisely expressed on paper. But the elimination of context means that the rule is artificial and cannot be applied in a consistent manner during routine clinical practice.

An algorithm is available for treating hypokalemia in an ICU patient receiving diuretics. If serum potassium is 3.5 mEq/L and the patient is asymptomatic, the algorithm dictates not to give a potassium supplement. The context of everyday ICU practice, however, is more complex. If the patient has heart disease and is taking digitalis or undergoing cardiac surgery, most clinicians would administer potassium if serum potassium is 3.5 mEq/L to prevent life-threatening arrhythmias. Likewise, if a patient has cirrhosis, physicians would treat a potassium of 3.5 mEq/L to minimize the risk of hepatic coma. The problem of hypokalemia is further complicated if there is concurrent hypomagnesemia, which promotes potassium wasting. It would be difficult if not impossible to capture all such nuances in the few steps of an algorithm.

Research studies of monitoring devices have included algorithms in an attempt to control for variations in clinical practice. These attempts did not achieve their desired goals. Gattinoni et al[157] undertook a study to evaluate the benefit of directing fluid and pharmacotherapy to achieve a supranormal cardiac index (guided by a PA catheter). Survival was equivalent in the groups with supranormal and normal cardiac index. At first sight, the findings suggest that targeting therapy to a supranormal cardiac index does not improve outcome. Perhaps that is true. But such a conclusion cannot be rationally defended based on the presented data. The target of supranormal cardiac index was reached in only 46% of patients in that study arm. Canadian researchers strove for a similar goal.[138] They compared therapy based on predefined physiologic targets (guided by a PA catheter) versus therapy based on usual care (without a PA catheter). The O_2 delivery target in the experimental arm was reached in only 21% of patients at study entry and in 63% of patients after surgery. These two studies provide a vivid illustration of the problems that investigators face in achieving the physiologic objectives that are the true focus of their randomized trial. If the target is not being achieved, what exactly is being studied in these clinical experiments?

Casuistry. Physicians face many decisions that have never been the subject of a randomized, controlled trial. A physician with many years of experience will relate a current patient to previously similar cases that he or she has handled, paying close attention to how the present patient is similar to, or differs from, the previously managed cases. The physician

may also draw on knowledge gained from case reports and observational studies—the only type of literature that pertains to many problems in the ICU. Few randomized controlled trials have specifically addressed fluid management of patients with ARDS. A number of observational studies have been conducted,[158,159] and knowledge gained from such reports combined with previous experience guide decisions on fluid management in this setting.

Reasoning along these lines, primarily in terms of analogy, is referred to as *casuistry*. Casuistry literally means being concerned with concrete individual cases, as opposed to abstract generalities.[160,161] Casuistry involves reasoning based on precedent (previous example). It is the type of reasoning used in case law, and is the main foundation of the legal system. In deciding how best to manage a particular patient, a physician also needs to take into account a patient's personal preferences.

Tacit or Implicit Knowledge. Physicians make many decisions using tacit knowledge: the type of inexpressible knowledge in *knowing how* versus *knowing what*. Tacit knowledge is knowledge that cannot be articulated. It is implicit knowledge based in actions rather than in conscious thoughts.[162] For more than 80% of complex situations, cognitive psychologists have found that experts such as intensive care staff did not employ an analytical approach to decisions. Instead, they relied on tacit knowledge.[162]

The term *tacit knowledge* was introduced by Michael Polanyi, who pointed out that human beings know more than they can impart.[163] Tacit knowledge is acquired without the intervention of explicit reasoning. It suggests an activity that takes place below the level of conscious reasoning, whether by habit, by being deeply ingrained, or by instinct. By definition, its content is indefinable.

Examples of tacit knowledge include the surgeon's knowledge of the right amount of tension to place on a suture, knowing when to intubate a patient in respiratory distress, and knowing when to extubate a patient after completion of a weaning trial. The skill in performing bronchoscopy is another example. The physician knows how to position the bronchoscope spatially as if it were an extension of his or her fingertips, and how to serially weave the instrument to enter the posterior segment of right lower lobe bronchus. An added dimension is knowing how much pressure to exert, and sensing resistance, when performing a transbronchial biopsy. The physician cannot communicate this knowledge in explicit terms. Instead, the knowledge is something the physician feels and shows while performing the procedure.

The failure of the possessor of tacit knowledge to identify and communicate its content is often attributed to poor power of introspection. When a physician is asked to recount the mental steps involved in solving a complex problem, the reconstruction often sounds unconvincing, even naïve. An attending physician may decide not to extubate a patient who is breathing at a rate of 28 breaths/min and who has reasonable arterial blood-gas values. The fellow may appear puzzled by this decision. To explain his (or her) decision, the attending physician may use words such as "intuition" or "gut feeling." The word *intuition* is loaded with negative connotations. It is equated with random guessing, confused superstition, mystical thought, weird unfathomable emotion, and an excuse for prejudice. Yet, intuition, not explicit logical reasoning, lies at the heart of originality in science.

People are not born with some free-floating gift of intuition. Instead, the unconscious decisions and automatic actions that reflect tacit knowledge stem from years and years of experience and reflection in a particular field. Intuition is needed to know *when* is the right time to adapt (to judge when is a plan falling apart); to know *how* to adapt (hatching a scheme on the hoof); and in *evaluating* adaptive steps (spotting new steps that may cause problems subsequently). Tacit knowledge is exemplified by an experienced clinician who knows at what juncture it is prudent to insert a PA catheter in a patient who is septic, who remains hypotensive despite 20 mcg/kg per minute of dopamine, and who has started to exhibit a decrease in urine output. Improvisation in patient care requires considerable expertise; it is the antithesis of following a protocol.

Experts do not use guidelines or analytical reasoning when faced with familiar problems. Instead, they generate a single course of action—they do what normally works. An expert sees the world differently than does a novice. An expert spots things that other people miss: how things usually work, patterns, anomalies, fine details but at the same time the big picture, and soft underbellies for attack. The expert is not using tacit knowledge as a substitute for the explicit analytical method, but as an improvement over it.[162]

Consider the case of a patient who is admitted to the ICU with fever, respiratory distress, and hypotension. The resident examines the patient, but is unable to find an obvious source for the fever. Chest radiography and urinalysis are negative. The resident makes a presumptive diagnosis of septic shock. He begins therapy with vasopressors, fluids, and broad-spectrum antibiotics. The patient remains hypotensive. The next day, the attending physician hears a crunching sound over the apex, and suspects a Hamman crunch. At first, the physician is not convinced it is present, because the crunch is obscured by the noise of the ventilator. On closer listening, the crunch is synchronous with the heartbeat. The attending physician infers that the patient has an esophageal perforation, which is causing the sepsis. Surgical repair is successfully undertaken. The resident asks the attending physician, "How did you know what to look for?" "I don't know why," the physician replies, "I just sensed it." This is an example of tacit knowledge used by the attending physician. The attending answers, "I don't know why," because the physician is unable to recall the precise train of thought that inspired the physician to suspect mediastinal emphysema. In part, the attending physician's thinking is based on extensive experience, and the many similar cases the physician has seen in the past—an example of casuistry. The physician's inspired guess, diagnostic acumen, does not stem solely from tacit knowledge. It is also based on explicit knowledge. Hearing a crunching sound in the precordium is of no value

without the book learning that tells the physician what the sound signifies. The case exemplifies the intermingling of tacit and explicit knowledge.

The skills of an outstanding diagnostician are like those of the connoisseur, a refined ability to discern between nuances governed by a heightened sensibility (good taste). It is a mistake to imagine that the listing of a series of explicit steps in a protocol can substitute for the skills of a connoisseur.

CLINICAL JUDGMENT

To understand the contribution of the above five forms of reasoning, it is useful to consider each on its own. Expert clinicians, however, call on all these forms of reasoning, and blend them together without using each on an independent basis. The amalgam of these forms of reasoning constitutes *clinical judgment*—a term widely used but rarely explicated.

Clinical judgment refers to the totality of mental resources and cognitive processes that a physician uses in deciding what to do for a particular patient. A good judge is someone who examines different pieces of evidence; he or she compares critically and impartially the merits of each, and makes a decision as to where the truth lies. An experienced clinician blends tacit and explicit knowledge in the process of making clinical decisions. Such blending of knowledge cannot be reduced to, or captured in, a mathematical model that would apply universally in all critically ill patients. It is obviously impossible to control or standardize tacit knowledge and clinical judgment among the clinicians participating in a randomized controlled trial. The marked variation in degree of skill among participating physicians is an important unmeasurable factor that can confound the outcome of a trial. Recognition of this factor has led to calls for the inclusion of an extra arm in a clinical trial that reflects the usual care of the participating physicians.

CONFLATION OF THERAPY AND MONITORING

The fundamental goal of monitoring is to guide a clinician in management decisions. Thus, monitoring is inextricably linked to treatment. A monitoring device on its own never cured anyone. It can improve outcome only if it leads to more effective therapy. This link is not always recognized. Yet it hovers over all assessments of a monitoring device. The conflation of monitoring with therapy differs from the evaluation of diagnostic techniques in other areas of medicine; a test is judged by its diagnostic accuracy, not on the expectation that it will improve outcome.

Consider the use of hemodynamic monitoring in an unstable patient with septic shock. Therapeutic options include fluids, vasopressors, or inotropic agents. None of these agents directly correct the underlying problem. Each may also cause harm. When a supranormal cardiac index was used as a target for hemodynamic management in 762 critically ill patients, survival was no better than with usual care.[157] When high-dose dobutamine was used to achieve a high cardiac index, Hayes et al[164] found that treated patients had a higher mortality than the usual care group: 54% versus 34%. In a complex patient with septic shock, when initial hemodynamic therapy is unsuccessful, it is common to undertake invasive monitoring (often involving a PA catheter) to guide more aggressive therapy. An unsuccessful outcome in such patients may be the result of ineffective pharmacologic agents or complications caused by them. Yet, the results of such trials are commonly interpreted as evidence that hemodynamic monitoring is not effective.

PATIENT RESPONSE TO THERAPY

In medicine, we treat patients, not diseases. Patients have varying responses to therapy depending on their disease. Although the right therapy may be chosen (e.g., cefotaxime for meningococcemia), a patient may have an undesired response to the therapy that worsens outcome. A PA catheter may be inserted in a patient in septic shock to guide therapy. The patient may develop cardiogenic pulmonary edema (with fluid resuscitation), a life-threatening arrhythmia (with dobutamine), or digital ischemia (with norepinephrine). These adverse reactions can outweigh beneficial effects of the monitoring device (the PA catheter) itself. No monitoring modality is likely to improve outcome unless it is combined with a therapeutic intervention that has a good benefit-to-risk ratio.

Final Outcome

An outcome event is an occurrence (such as death) that may be modified after implementing some intervention (monitoring wedge pressure with a PA catheter). Outcomes research is defined by the statistical analysis of clinical data to determine whether particular interventions are associated with particular results. To discriminate between benefits and risks of an intervention, an adequate sample size is necessary. Sample size is calculated on the basis of baseline event rate, expected benefit, level of significance (α), and the power to detect a difference ($1-\beta$).[165] Studies evaluating the effect of monitoring on patient outcome often lack statistical power. Statistical power is especially important when complications are rare and the expected impact (of an intervention) is small. If the outcome under evaluation occurs frequently, fewer patients will be needed than if the outcome occurs infrequently. Moller et al[129,166] conducted a prospective, randomized trial of the effect of pulse oximetry on the rate of postoperative complications in 20,802 surgical patients. Hypoxemia (defined as a $Sp_{O_2} < 90\%$) was detected nineteen times more often in the oximeter group than in the control group ($p < 0.0001$). The primary goal of the study, however, was to determine whether the rate of postoperative complications was decreased. For this goal, statistical significance was not reached. The investigators concluded that it would take at least 500,000 patients to show a reduction in a rare event such as myocardial infarction and 1,900,000 patients to show a reduction in anesthesia-related deaths.

The American Society of Anesthesiologists introduced monitoring standards that mandated use of pulse oximetry in every patient undergoing anesthesia. Subsequently, Eichhorn[167] observed a threefold reduction in the incidence of major preventable intraoperative injury (ten in 757,000 vs. one in 244,000 anesthetics), yet the reduction did not reach statistical significance. Because the incidence of serious adverse events is low, it is estimated that an additional 6,545,605 cases would be needed to detect a significant reduction in major preventable intraoperative injury.[24,168] Given the necessary effort, would anyone suggest that it makes sense to undertake such a study to find out if pulse oximetry is helpful during anesthesia? If the study were negative, would anesthesiologists stop using this monitoring device? Unlikely.

When anesthesiologists were surveyed in the study of Moller et al,[129,166] 80% felt more secure when they used a pulse oximeter. Of 104 anesthesiologists, nineteen believed that the pulse oximeter helped them avoid serious complications (such as esophageal intubation, tracheal tube disconnection or displacement, anesthesia machine failure, and respiratory problems immediately after extubation). It is this mindset that has established pulse oximetry as an essential component of the standard of care despite a failure to achieve a $p < 0.05$ level of proven efficacy. The lack of concurrence between proof of efficacy in randomized trials of pulse oximetry and its requirement as part of the standard of care has major ramifications for all monitoring techniques.

When researchers evaluate the usefulness of a monitoring device, the selected outcome measure (mortality or complication rates) may be unrealistic. If benefit is expected to be small, an outcome based on mortality may not be sufficiently sensitive to detect it. Undertaking inappropriately designed studies may cause valuable tools to be discarded. At face value, the outcome of the study of Moller et al[129] should lead physicians to stop using pulse oximetry—at least in the operating room.

Authors commonly cite examples where intermediate outcomes (prevention of hypertension, hypoxemia, or ischemia; or suppressing premature ventricular contractions following myocardial infarction) were misleading. A widely cited study is the Cardiac Arrhythmia Suppression Trial (CAST) study. This consisted of a randomized trial to test the hypothesis that suppression of asymptomatic or mildly symptomatic premature ventricular contractions (PVCs) with antiarrhythmic agents in patients who have suffered a myocardial infarction improves survival.[169–172] It was believed that suppression of PVCs would prevent ventricular tachycardia and ventricular fibrillation and thus decrease mortality. Patients treated with antiarrhythmic agents (flecainide, encainide, or moricizine), however, had a higher mortality (8.0%, sixty-three of 755) than patients receiving placebo (3.5%, twenty-six of 743).

The increased mortality in the intervention arm of the CAST study is often interpreted as evidence that physiologic reasoning is unreliable, and that mortality is the only study outcome that reliably captures truth of efficacy.[49] Before accepting that conclusion, the data need to be closely scrutinized. A number of concerns arise. Mortality in the placebo group (3.5%) was much lower than expected.[173] The low mortality was partly a consequence of study design.[174,175] Only patients whose ventricular arrhythmias were suppressed during an open-label titration phase of the study were randomized to the active drug or placebo. Patients whose ventricular arrhythmias were not suppressed or who did not tolerate the pharmacologic agent were not randomized to either arm.[169,172] Thus, patients randomized into the study had a low risk for death for two reasons: The exclusion of patients who had died and exclusion of patients in whom arrhythmias could not be suppressed (with drugs) during the open-label titration (prerandomization) phase.[175] Of patients in the placebo arm, 80% had PVCs alone without having nonsustained ventricular tachycardia; moreover, more than half had a near-normal ejection fraction (above 40%).[172] There is further evidence that mortality in the placebo group is not generalizable. The CAST investigators undertook a subsequent analysis in the 318 patients who survived the open-label titration phase but who were not randomized to either arm of the study and the 942 patients who were randomized to the placebo arm.[176] Occurrence of death or a resuscitated cardiac arrest was higher in the nonrandomized patients (8.5%, twenty-seven of 318) than in the placebo group (4%, thirty-eight of 942).[176] In summary, the adverse effects of the antiarrhythmic agents in the CAST study may largely reflect the failure of the investigators to recruit representative patients into the placebo arm, insofar as the investigators excluded patients in whom they could not suppress their arrhythmias (a marker of increased mortality).[171,177–179] Certainly, it is inappropriate to use data from the CAST study to conclude that therapy guided by ECG monitoring (that is, physiologic reasoning) is not helpful.

CONCLUSION

Patients receiving mechanical ventilation are vulnerable to a host of complications and it is essential to spot these problems at the earliest possible time. Such complications are commonly associated with alterations in physiologic functions in different organ systems. By continuously recording many physiologic variables in real time, monitoring systems offer the possibility of alerting a physician to a significant change in a patient's status. The hope is that such a warning will provide an opportunity to interrupt a cascade of events sufficiently early in their evolution to avert a lethal catastrophe. Accordingly, expertise in the operation of monitoring systems plays a vital part in the intelligent use of mechanical ventilation. This expertise involves more than familiarity with the touch pads and screens of the machinery. Physicians must know the physiologic principles on which each monitor is based, appreciate the responsiveness and fidelity of the charted variables, be facile in troubleshooting a system, and evaluate monitored data in accordance with the canons developed for interpreting diagnostic tests. All these skills play a vital part in minimizing the ills that the ventilated patient is heir to—they form a consummation devoutly to be wished.

PRONE POSITIONING IN ACUTE RESPIRATORY FAILURE

Luciano Gattinoni
Paolo Taccone
Daniele Mascheroni
Franco Valenza
Paolo Pelosi

Approximately 35 years ago, the use of the prone position was proposed to improve arterial oxygenation in patients with acute respiratory failure (ARF).[1–3] The prone position, however, may have variable effects on gas exchange. Moreover, it has been suggested that, independent of gas exchange, the prone position may decrease the harm of mechanical ventilation, improving the outcome of patients with ARF. This chapter discusses the mechanisms affecting the changes in gas exchange consequent to the prone position in patients with ARF, and the effects of prone positioning on outcome of critically ill patients.

EFFECTS OF PRONE POSITIONING ON GAS EXCHANGE

The effects of prone positioning on gas exchange may result from a combination of the following mechanisms: (a) changes in regional lung inflation, (b) redistribution of ventilation, and (c) redistribution of perfusion. These three mechanisms apply to both the normal and diseased lung. In the diseased lung, however, these mechanisms are also affected by the underlying pathology. Moreover, because the underlying pathology is an evolving process, it is likely that the effects of positioning on arterial oxygenation will vary with time.

Regional Lung Inflation

METHODS OF INVESTIGATION

Most of the studies dealing with regional lung inflation in normal subjects were performed with radioactive xenon.[4,5] We used computed tomography (CT) to quantify regional lung inflation.[6,7] The CT scan provides a computer-reconstructed image that is composed of several hundred elementary units (voxels). Each voxel is characterized by a given level of absorption of X-rays, which mainly reflects the density of the material being studied. The density is usually expressed in CT numbers or Hounsfield units (H).[8] A density equal to 0 H characterizes a voxel composed of water, while a voxel with a density of −1000 H is composed of gas. A voxel with a CT number equal to −500 H has a composition of 50% gas and 50% tissue. By analysis of the CT numbers, we quantitatively describe the regional lung inflation of a single CT section, at the level of the lung base, that is representative of the entire lung.[6] The CT section is divided into ten levels along the vertical axis, each level including approximately 300 to 400 voxels (Fig. 49-1). The gas-to-tissue ratio, which is our index of regional lung inflation, was computed from the average CT number at each lung level.

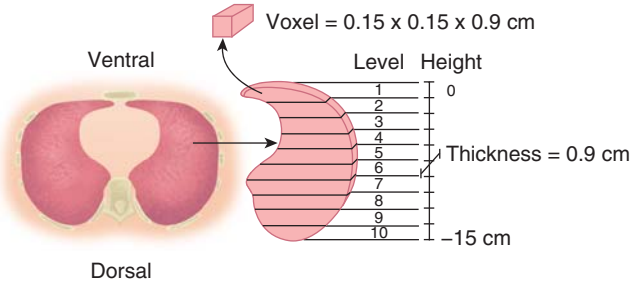

FIGURE 49-1 Regional analysis of the CT scan image. The vertical distance from ventral to dorsal surface (height) is divided into ten equal intervals. Ten lung levels are then obtained. Each level is composed of 300 to 400 elementary units (voxels), each characterized by a given CT number expressed in Hounsfield units (H). (Used, with permission, from Pelosi et al.[16])

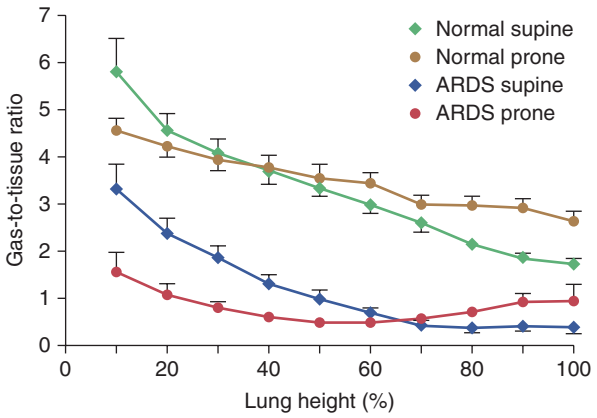

FIGURE 49-2 The gas-to-tissue ratio as a function of lung height in the supine (*diamonds*) and prone (*circles*) positions. The *green* and *brown* symbols refer to normal lungs ($N = 14$) and the *blue* and *red* symbols refer to lungs of patients with acute respiratory distress syndrome (*ARDS*) ($N = 20$). It is important to note that "height = 0" refers to the ventral surface in the supine position and to the dorsal surface in the prone position. The height scale direction is from nondependent (0) to dependent (100).

NORMAL LUNGS

Regional Inflation in the Supine Position. As shown in Figure 49-2, the regional inflation, expressed as the gas-to-tissue ratio, decreases along the vertical axis (from ventral to dorsal). Because the decrease is exponential, the rate of change of regional lung inflation with height may be characterized by a decay constant (K_d). The lower the value of the K_d, the higher the rate of the decrease of regional lung inflation along the vertical axis. The K_d in normal subjects is 13.6 ± 2.5 cm. At this distance from the ventral surface, the gas-to-tissue ratio is 37% of the gas-to-tissue ratio value computed at the ventral surface. In other words, the alveolar dimensions, in the dorsal regions, should be approximately one-third of those at the ventral surface.

Regional Inflation in the Prone Position. When a normal subject is shifted from supine to prone, the regional inflation distribution changes, increasing in the dorsal regions and decreasing in the ventral regions (see Fig. 49-2). The regional inflation decreases exponentially from dorsal to ventral for both supine and prone positions; however, the K_d is higher in the prone position compared with the supine position (K_d prone, 26.2 ± 2.2 cm; K_d supine, 13.6 ± 2.5 cm). This indicates that the regional inflation distribution is more homogeneous in the prone than in the supine position, and therefore the prone position does not simply reverse the regional inflation distribution. We confirmed these concepts in animal studies by means of CT scan.[9]

Mechanism of Vertical Inflation Gradient. The regional inflation is believed to depend on the local transpulmonary pressure (i.e., the absolute difference between pressure in the alveoli and pressure at the pleural surface [Ppl]). At functional residual capacity, alveolar pressure equals atmospheric pressure; thus, changes in transpulmonary pressure are caused by regional differences in Ppl. The Ppl gradient in normal subjects is approximately 0.2 to 0.3 cm H_2O/cm.[10] The nature of this pressure gradient, however, is still controversial and is mainly attributed to the following factors: (a) lung weight, (b) shape and mechanical properties of the chest wall, and (c) shape and mechanical properties of the lung.

The role of lung weight in normal subjects is considered a predominant mechanism by some investigators.[11–14] It was first stressed by Krueger et al,[15] who found that the normal Ppl gradient was very similar to the normal density of the lung (0.22 g/L). The lung-weight theory assumes that the lung behaves as a fluid and that the hydrostatic pressures are transmitted through the lung parenchyma as in a liquid (i.e., at a given lung height, the superimposed pressure [SP_L] is equal to the product of the height of the lung column and density). Estimating the SP_L with the CT scan, in normal subjects, we found an average SP_L gradient of 0.23 cm H_2O/cm,[16] which is similar to the Ppl gradient classically reported in physiology. Factors other than lung weight, however, may play a substantial role in determining Ppl. In fact, in the prone position, the decay of the regional inflation with height is less than in the supine position (i.e., the Ppl gradient is probably lower in the prone than in the supine position; see Fig. 49-2). If the SP_L was the only determinant of Ppl, the decay of the regional lung inflation would be similar in prone and supine positions. As shown in Figure 49-2, however, the regional inflation distribution, along the vertical axis, was different in the supine and prone positions. Our findings are in keeping with those of Mutoh et al[17] in normal dogs, in which the Ppl gradient was directly measured. Factors such as the thoracic lung shape and compliance should then be involved in determining the regional inflation changes with positioning. In addition, the prone position eliminates the compression of the lungs by the heart, which also contributes to a more homogeneous distribution of lung inflation.[18,19]

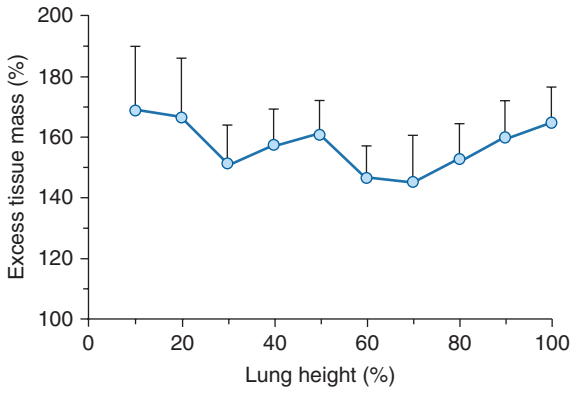

FIGURE 49-3 The distribution of excess tissue mass (i.e., the mass in excess of the expected normal mass) as a function of lung height. Data refer to thirty-four ARF lungs studied in the supine position. Zero on the abscissa refers to the ventral lung surface. (Used, with permission, from Gattinoni et al.[51])

LUNGS IN ACUTE RESPIRATORY FAILURE

Anatomic Changes during Acute Respiratory Failure. The early phases of ARF are characterized by lung edema. The edema causes a large increase in "lung tissue" and therefore in lung weight. In ARF patients, we found that lung weight, as measured by the CT scan technique, was two to three times greater than normal,[20] and this is consistent with the lung weight values reported in autopsy series.[21] We also found that edema (i.e., the amount of tissue mass in excess of normal [excess tissue mass]) does not accumulate preferentially in the dependent regions, and it is quite evenly distributed at each lung level (Fig. 49-3). The nongravitational distribution of edema was reported in a series of animal experiments using different techniques.[22,23] This homogeneous increase in lung edema has two important consequences for regional inflation. First, although ARF is characterized by a marked decrease in lung gas volume,[20] the total lung dimensions are similar to normal secondary to the increase in lung tissue mass (edema).[16] Second, the increased lung tissue mass leads to a dramatic increase in SP_L, which may be as high as 10 to 15 cm H_2O in the most dependent regions.[6,7,16]

Regional Inflation in the Supine Position. Figure 49-2 shows the behavior of regional inflation in patients with ARF in the supine position. As in the normal lung, the regional inflation decreases exponentially along the ventral–dorsal axis.[16] Two important differences, however, must be stressed. First, the regional inflation at the ventral surface is only half that of the normal lung. Second, the decay constant in the regional inflation with height (K_d) is almost half that of normal; that is, the rate of the decrease of regional inflation from the ventral to dorsal region is double that of the normal lung (K_d ARF = 6.9 ± 1.2 cm vs. K_d normal = 13.6 ± 2.5 cm). This suggests that in supine ARF patients at 0 cm H_2O positive end-expiratory pressure (PEEP), there is almost total alveolar collapse in the posterior half of their lungs, as confirmed by the CT scan image (Fig. 49-4).

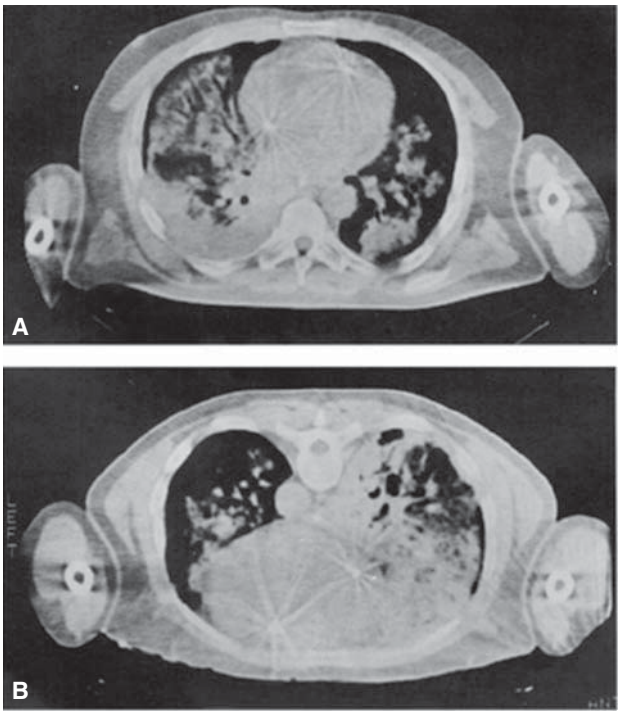

FIGURE 49-4 A representative CT scan image in supine (**A**) and in prone (**B**) positions. Note the typical redistribution of lung densities. Images taken 10 minutes apart, and at end-expiration apnea, with 10 cm H_2O PEEP. (Used, with permission, from Gattinoni et al.[6])

Regional Inflation in the Prone Position. Figure 49-2 shows the behavior of regional inflation in the prone position. As with normal subjects, the inflation gradient is reversed, and the regional inflation is greater in dorsal regions and lower in ventral regions. Once again, the dependent lung regions (ventral) are collapsed (see Fig. 49-4). As with normal subjects, regional inflation is more homogeneously distributed than in the supine position; however, exponential fitting of the experimental data did not reach a level of significance in all patients.

Mechanism of Vertical Inflation Gradient. The main difference in regional inflation between normal subjects and patients with ARF is the greater rate of decrease of regional inflation along the vertical axis in ARF lungs. This suggests that the Ppl gradient is higher in patients with ARF than in normal individuals.[16] The most likely explanation of the increased Ppl in ARF is increased lung weight; the overall lung shape, in fact, is not different between normal individuals and patients with ARF.[16] The thoracic–lung shape modifications when the patients are turned prone, however, probably change the Ppl gradient (i.e., the modifications of the lung and the chest wall shape may redistribute the forces acting at the pleural surface).

The relationships between lung shape modifications and distribution of regional lung inflation in ARF patients is discussed in "Mechanisms Involved in Arterial Oxygenation Changes in the Prone Position" below.

SUMMARY

In patients with ARF, lung densities redistribute from the dorsal to the ventral region when turned prone. Regional inflation decreases exponentially from the nondependent to the dependent lung region in both the supine and prone positions. The decay in regional inflation, both in normal individuals and in patients with ARF, is greater in the supine than in the prone position. This indicates that regional inflation is usually more homogeneously distributed in the prone position. The regional inflation gradient is secondary to the Ppl gradient. Lung weight is probably a major determinant in increasing the Ppl gradient in ARF. Thoracic–lung shape modifications from supine to prone, however, may produce a more homogeneous distribution of regional inflation in the prone position.

Distribution of Ventilation

As a general rule, ventilation relates to applied pressures, flows, and resistances according to the following equation:

$$DV = C \times (DP_{tp} - \dot{V} \times R)$$

where DV is variation in volume, C is compliance, DP_{tp} is transpulmonary pressure, $\dot{V}$ is flow, and R is resistance. It follows that regional ventilation depends on regional compliances, regional transpulmonary pressure swings, regional flow rates, and regional resistances.

NORMAL LUNGS

Distribution of Ventilation in the Supine Position. When a bolus of radioactive gas is inhaled by spontaneously breathing subjects in the supine position, ventilation is predominantly distributed to the dependent lung regions.[24] From available data, the major determinants of the distribution of ventilation appear to be: (a) the regional inflation distribution and (b) the pattern of diaphragmatic movement (active or passive).

Mead et al,[25] Otis et al,[26] and Pedley et al[27] proposed a lung model divided into two compartments: upper and lower. Regional inflation is greater in the upper (ventral) compartment and smaller in the lower (dorsal) compartment. The upper lung regions are closer to the flat portion of their pressure–volume curve, while the lower regions are on the steeper portion of the curve. Consequently, for a given applied pressure, ventilation is greater in the lower lung regions than in the upper regions.

In the supine position, a large portion of the lung is close to the diaphragm, which may vary its tension, shape, and position. During tidal spontaneous breathing, there is a greater displacement of the dependent hemidiaphragm, with consequent greater ventilation of the dependent lung.[28–30] Accordingly, in spontaneously breathing subjects, both regional inflation and diaphragmatic movement cooperate to distribute ventilation preferentially to the dependent lung. There are, however, three major conditions in which the ventilation is greater in the nondependent lung: (a) ventilation at low lung volume, (b) ventilation at high inspiratory flow rate, and (c) mechanical ventilation during anesthesia and muscle paralysis. The preferential ventilation of the upper compartment at a low lung volume is easily explained by the work of Otis et al[26] (i.e., at a low lung volume, the upper lung regions are probably shifted on the steeper part of the pressure–volume curve). At a high inspiratory flow rate, the accessory respiratory muscles appear to play a determining role in the redistribution of ventilation to the upper compartment.[31,32] During mechanical ventilation, particularly during anesthesia and paralysis, the diaphragm appears to play a major role in the distribution of ventilation.[33–35] In this situation, the diaphragm behaves as a flaccid membrane, which is faced with the vertical pressure gradient of the abdominal contents. The upper, nondependent part of the diaphragm moves passively and faces a lower abdominal pressure; thus, ventilation is greater in the nondependent lung regions.

Distribution of Ventilation in the Prone Position. Distribution of ventilation in prone position is still controversial. Indeed, some authors found a uniform vertical distribution of ventilation in spontaneously breathing subjects,[36] whereas others found a vertical gradient with either greater ventilation in the dependent (ventral) regions[4] or in the nondependent lung regions.[37]

No data are available concerning ventilation at low lung volumes or at a high inspiratory flow rate in the prone position. During mechanical ventilation in anesthetized paralyzed normal individuals in the prone position, Rehder et al[37] found that the distribution of ventilation was greater in the nondependent lung regions, where the passive upper position of the diaphragm faced a lower abdominal pressure.

Recently, in an animal study, we confirmed that the distribution of ventilation in the prone position is more homogeneous than in the supine position, and that in the prone position there is less lung strain once tidal volume is delivered.[9]

LUNGS IN ACUTE RESPIRATORY FAILURE

Distribution of Ventilation in the Supine Position. CT scan studies in patients with ARF have shown that ventilation is distributed preferentially to the nondependent lung because the dependent lung is usually collapsed and/or consolidated (see Fig. 49-4). We obtained CT scans at both end-expiration and end-inspiration in ten patients during the early phase of ARF.[38] In these patients, we, indeed, found that "ventilation" was preferentially distributed to the nondependent (ventral) lung regions. The pattern was in part modified by application of PEEP. With an increase in PEEP and reopening of the dependent lung regions, "ventilation" was more uniformly distributed (gas could reach the recruited dependent regions).

Distribution of Ventilation in the Prone Position. Few data have been published on the distribution of ventilation in patients with ARF placed in the prone position. Because regional inflation is more uniform in the prone position, similarly to the pattern in normal lungs, however, one would expect that ventilation should be more uniform in this posture. Vieillard-Baron et al showed that the prone position does improve homogenization of tidal ventilation by reducing time-constant inequalities.[39]

SUMMARY

In spontaneously breathing normal subjects, when supine, ventilation is preferentially distributed to the dependent lung regions, although prone position data are controversial. During mechanical ventilation, this pattern is reversed with preferential distribution of ventilation to the nondependent lung in both supine and prone positions. Accordingly, the main determinant of ventilation distribution is the regional inflation gradient and transdiaphragmatic pressures. In mechanically ventilated patients with ARF at low PEEP level, ventilation is preferentially distributed to the nondependent lung regions. In the prone position, we expect a similar pattern of ventilation distribution, because the collapsed areas move from the dorsal to the ventral regions. Tidal volume, however, is more homogeneously distributed in the prone position, because of a reduction in the slow compartment zones of the lung, and possibly because of a more homogeneous distribution of regional inflation.

Distribution of Perfusion

NORMAL LUNGS

Distribution of Perfusion in the Supine Position. The most widely accepted model that describes the pulmonary perfusion pattern is that described by West et al.[40] According to these investigators, the relationship between blood flow and pulmonary artery pressure, alveolar pressure, and venous pressure can be modeled as in a Starling resistor, where a collapsible tube traverses a closed chamber (the gas compartment) in which pressure (the alveolar pressure) may be varied at will. When the inflow pressure (pulmonary artery pressure) is lower than the chamber pressure (alveolar pressure), blood flow stops (zone 1). When the inflow pressure is higher than the chamber pressure, the flow through the system is governed by either the difference between pulmonary artery pressure and alveolar pressure (zone 2) or the difference between pulmonary artery pressure and venous pressure, when the outflow pressure (venous pressure) exceeds the chamber pressure (zone 3).

According to this "gravitational" view, perfusion should progressively increase down the lung. In the supine position, the lung should be characterized by perfusion in zone 2 and zone 3, increasing from ventral (zone 2) to dorsal (zone 3), because zone 1 conditions do not occur. Several authors, suggesting that factors other than gravity can determine the perfusion heterogeneity, have challenged the model of West et al.[41–45]

Distribution of Perfusion in the Prone Position. According to the gravitational theory, a perfusion gradient should exist from dorsal to ventral. Few data confirm this pattern in human subjects.[4] A perfusion gradient, however, could not be observed in the prone position in dogs;[44,46] regional pulmonary blood flows were positively correlated when measured in supine and prone position (and not negatively correlated, as expected according to the gravitational theory).

LUNGS IN ACUTE RESPIRATORY FAILURE

Distribution of Perfusion in the Supine Position. Whatever the determinants of perfusion in the normal lung, several physiologic and anatomic factors are likely to alter the perfusion distribution in ARF. Among these are (a) hypoxic vasoconstriction, (b) vessel obliteration, and (c) extrinsic vessel compression.

The effects of hypoxic vasoconstriction were evaluated in the lateral position using separate lung ventilation.[47] The inspiration of a hypoxic gas mixture by the dependent lung failed to redirect blood flow toward the nondependent lung, whereas diversion occurred in the supine position. This suggests that hypoxic vasoconstriction alone is not able to counteract the effects of posture on pulmonary blood flow.

Both macrothrombi and microthrombi have been found at various stages of ARF.[48] These anatomic alterations were associated with the appearance of filling defects when selective angiography was performed.[49] Unfortunately, data are not available regarding the distribution of these defects (homogeneous, dependent, or nondependent?), but obviously the presence of vessel obliteration will alter perfusion distribution. Nonthrombotic obliterative vascular disease may also occur in the early stage of ARF secondary to congestion or compression of vessels, and in the intermediate or late stages of ARF secondary to focal obstruction of small arteries and veins as a result of fibrosis.

Increased SP_L in ARF could also cause extrinsic vessel compression: The radiologic equivalent would be the "pruning" of vessels on selective angiography. In early ARF, we found (unpublished observation) that selective angiography was usually positive (filling defects and/or pruning) when the tip of the catheter was positioned in the dependent lung regions (dense areas on CT scan), and negative when it was in the nondependent lung regions. Moreover, we occasionally found changes in the selective angiography findings (from positive to negative) when the patients were turned from supine to prone, and the angiography was repeated in the same lung region.

All these data suggest that the pulmonary flow distribution is altered in ARF. If the compression mechanism and hypoxic vasoconstriction are operating, both should act mainly in the dependent lung regions (less aeration and higher SP_L), and the blood flow should partly be diverted toward the nondependent regions, as observed in cardiogenic pulmonary

edema.[50] This would partly protect against hypoxemia. In fact, it is not unusual to find 60% to 70% of airless lung (in the dependent regions) with a shunt fraction of 30% to 40%.[51] This indirectly proves that, in the supine position, part of the pulmonary blood flow is redistributed to the nondependent lung.

Distribution of Perfusion in the Prone Position. To our knowledge, few data are available regarding the distribution of pulmonary blood flow in patients with ARF mechanically ventilated in the prone position. Experimental evidence in dogs suggests that perfusion to the dorsal regions is greater than to the ventral regions in the prone position.[46] This occurrence might lead to a more even distribution of blood flow.[52] Endogenous nitric oxide plays a role in the regulation of regional pulmonary perfusion. In fact, after the inhibition of nitric oxide synthase by N(G)-monomethyl-L-arginine infusion, nitric oxide synthase messenger RNA expression and nitric oxide production were significantly higher in dorsal region as compared with ventral lung regions. In the supine position, lung perfusion was shifted to ventral regions during nitric oxide synthase inhibition, whereas in the prone position lung perfusion remained unchanged.[53] Moreover, acute changes of oxygenation consequent to positioning in patients with acute respiratory distress syndrome (ARDS) do not induce any short-term effect on pulmonary endothelin-1 net clearance or angiotensin-II net formation.[54] These data suggest that mechanisms other than gravity or hypoxic pulmonary vasoconstriction operate in the prone position to distribute blood flow.

SUMMARY

In the normal lung, blood flow is distributed according to gravity. Factors other than gravity, however, may play a role in governing regional perfusion. These factors seem prevalent in the prone position, where the vertical perfusion gradient may disappear. In the edematous ARF lung, available data suggest that pulmonary blood flow is partly diverted toward the nondependent, more aerated, regions. Vessel compression and hypoxic vasoconstriction may play a role in this pattern of blood flow distribution. In the prone position, during ARF, the nondependent, dorsal regions seem more perfused than the ventral regions. Consequently, in ARF, perfusion seems less dependent on gravity than in normal conditions.

Ventilation–Perfusion Matching

In the past, a number of investigators have used the multiple inert gas technique to study ventilation–perfusion ($\dot{V}_A/\dot{Q}$) relationships in different forms of ARF.[55–57] The general conclusions of these studies can be summarized as follows: although ventilation and perfusion are usually well matched in ARF lungs, a consistent portion of pulmonary flow traverses airless regions (true shunt), and low $\dot{V}_A/\dot{Q}$ compartments are scarcely represented.

The effect of prone positioning on regional shunt and aeration was studied in an animal model of acute lung injury using $^{13}N_2$ injection and positron emission tomography.[58] This study confirmed that supine position is associated with a high shunt fraction in the dorsal region (i.e., high perfusion and poor aeration), whereas prone positioning leads to a decrease of shunt fraction in the dorsal region, without a concomitant impairment of gas exchange in the ventral region. These effects were related to an increase in total gas content and a more uniform distribution of aeration in the prone position, because the increase in aeration in the dorsal region was not offset by loss of aeration in the ventral region. Moreover, in the prone position, perfusion resulted in less gravity dependence, because a substantial fraction of pulmonary blood flow was maintained in the dorsal region. In summary, this study demonstrated that prone positioning restores aeration while it preserves perfusion in the dorsal region of the lung, decreasing the regional and total shunt secondary to an increase in gas-exchanging pulmonary blood flow.

EFFECT OF PRONE POSITIONING ON CLINICAL OUTCOME OF PATIENTS WITH ACUTE RESPIRATORY FAILURE

Effects on Arterial Oxygenation

Over the last 35 years a series of reports appeared in the literature dealing with the use of the prone position as a tool to improve arterial oxygenation in patients with ARF. Over the years, several clinical studies on prone positioning have been conducted, including many retrospective studies,[1,3,59,60] prospective observational studies,[6,39,61–76] randomized clinical trials,[77–81] and meta-analyses.[82–86]

From these published data some generalizations may be made.

1. There is strong evidence that prone positioning is effective in improving oxygenation of patients with ARF. For this beneficial effect, the use of prone positioning is currently considered in the treatment of patient requiring injurious levels of fractional inspired oxygen concentration ($F_{I_{O_2}}$) and plateau pressure[87] or as a "rescue maneuver" for life-threatening hypoxemia. It must be pointed out, however, that (a) the degree of improvement is highly variable (from a few to hundreds of millimeters of mercury change in partial pressure of arterial oxygen (Pa_{O_2}), (b) a small fraction of patients do not show any improvement or even show a deterioration in arterial oxygenation while prone, and (c) the individual response to the prone position is hard to predict.
2. In the patients who respond, the improvement in gas exchange is usually progressive, and it may take hours to appear; moreover, some of these patients show a progressive decrease in arterial oxygenation if the prone position is maintained for long periods of time.

Thus, the long-term response to the prone position ranges from deterioration to great improvement, and it may be time dependent (slow improvement and slow deterioration).

3. The issue is further complicated when analyzing the effects of returning the patients to the supine position after they have been prone. Three different responses have been observed in patients who exhibited improved oxygenation in the prone position: (a) most of the patients display better oxygenation than in the original supine position, although the values are lower than in the prone position; (b) some patients return to basal supine oxygenation values when returned to the supine position (these patients are then considered "prone dependent"); and (c) some patients display improved oxygenation compared to both the previous supine and prone values.
4. When the same patient is turned several times, the effects of the maneuver may change in time (no improvement, whereas previous positioning in the prone position produced marked improvement or the reverse).

From the above description, it is obvious that the effects of positioning depend on the individual patient (i.e., the underlying pathology and pathophysiologic status, which may vary over time). Over the years, several authors have described the response to prone position in specific categories of ARDS[67,75] and patients without ARDS[76,88] and the improvement in oxygenation induced by inhaled nitric oxide.[61,62,64,65,70,74] The predictability of the oxygenation response to prone positioning, however, remains uncertain.[71]

MECHANISMS INVOLVED IN ARTERIAL OXYGENATION CHANGES IN THE PRONE POSITION

We can attempt to infer the mechanisms involved in arterial oxygenation changes when patients are turned to the prone position. We first discuss the mechanisms that may operate in the early period after positioning and then the mechanisms that are possibly time related.

Early Effects. An increase or decrease in Pa_{O_2} is caused by changes in regional lung inflation, ventilation distribution, and perfusion distribution. The effects on oxygenation (improvement or deterioration) are likely explained by a varying interaction between the mentioned factors in the different postures.

As previously discussed in the section "Regional Lung Inflation" regional inflation decreases from ventral to dorsal in the supine position, and from dorsal to ventral in the prone position. The rate of decrease in regional inflation, however, is steeper in the supine position than in the prone position (see Fig. 49-2). Because the decrease in inflation may be expressed in exponential form, this is equivalent to saying that the decay rate of regional inflation along the vertical axis (K_d) is lower in the supine position than in the prone position. This, however, refers to average values. In an individual patient, the pattern may be substantially different.

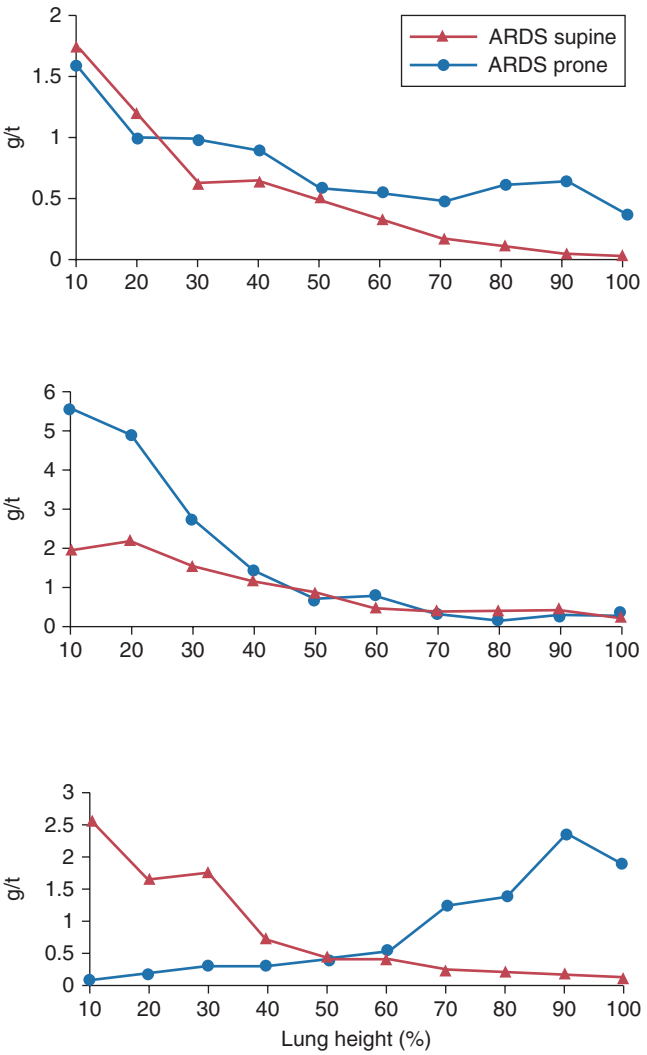

FIGURE 49-5 Different behaviors of regional inflation (gas-to-tissue ratio [*g/t*]) as a function of lung height in the supine (*red triangles*) and prone (*blue circles*) positions in three acute respiratory distress syndrome (*ARDS*) patients. Zero on the height scale refers to the ventral lung surface in the supine position and to the dorsal lung surface in the prone position. As such, the direction of the lung scale is always from the nondependent to dependent lung region (see text for further explanation).

In Figure 49-5, we report three ARDS patients who showed different patterns of regional inflation in the supine and prone positions. In the first patient (*upper panel*), regional inflation behaves as for the average population (see Fig. 49-2). The exponential fitting of the decay of regional inflation ($r = 0.91$) showed a K_d of 4.2 cm in the supine position. In the prone position, the decay of regional inflation was smoother, as reflected by the higher value of K_d, 14 cm (exponential fitting, $r = 0.97$). In this patient, Pa_{O_2} improved by 65 mm Hg on moving from the supine to the prone position.

The *middle panel* in Figure 49-5 shows the regional inflation pattern of a patient in which the decay of regional

inflation was significant in both the supine and prone positions ($r = 0.96$ and $r = 0.98$, respectively). In this case, however, K_d was lower in the prone position than in the supine position (4.3 and 9.4 cm, respectively). In this case, Pa_{O_2} deteriorated when the patient was turned from supine to prone (101 mm Hg when supine and 71.5 mm Hg when prone).

The *bottom panel* in Figure 49-5 refers to a very unusual patient. In this case, the low regional inflation areas in the supine position did not redistribute on switching to the prone position, and the pattern of regional inflation remained the same in the two positions. In this case, Pa_{O_2} did not change with alteration in position (61 mm Hg when supine and 68 mm Hg when prone).

We then tested the hypothesis that, in the individual patient, improvement in Pa_{O_2} on switching from supine to prone occurs when the decay in regional inflation is smoother (i.e., a higher K_d) in the prone position, whereas a deterioration in Pa_{O_2} occurs on switching from the supine to the prone position when the decay in regional lung inflation is steeper in the prone position (lower K_d). Plotting the individual K_d differences between prone and supine positions (DK_d) and the individual changes in Pa_{O_2} (DPa_{O_2}), we found a significant correlation between DK_d and DPa_{O_2} (Fig. 49-6). This suggests that the response in Pa_{O_2} is associated with a change in regional inflation: The position in which regional inflation is more homogeneous (higher K_d) is associated with a better Pa_{O_2}. When the regional inflation gradient along the vertical axis does not differ between the prone and supine positions (i.e., equal decrease from nondependent to dependent lung regions, whatever position is assumed), the Pa_{O_2} does not change. To state that the Pa_{O_2} changes are caused by regional inflation changes and not simply associated with them, however, we must assume that (a) ventilation behaves like regional inflation (i.e., it is more homogeneously distributed when inflation is more homogeneously distributed), and (b) perfusion is not changed when the position is changed (i.e., the relative perfusion of the dorsal and ventral regions does not change with position).

The question remains as to why in some patients regional inflation is more homogeneous in the prone position (and oxygenation improves in this position), while in other patients regional inflation is more homogeneous in the supine position (and oxygenation is better in this position). As previously discussed, regional inflation is dictated by Ppl, and this may, in turn, be influenced by SP_L and lung shape. Because SP_L is similar in the supine and prone positions,[6] it is possible that the postural changes in regional inflation are caused by the associated lung-shape variations. We attempted to quantify the variation in lung shape on switching from the supine to the prone position by dividing the lung area into two compartments (at 50% of the ventral–dorsal distance), the upper (U) and the lower (L) compartments, and calculating the upper-to-lower (U/L) ratio in the prone and supine positions. The difference in U/L ratio between the prone and supine positions (DU/L ratio) gives a quantitative estimate of lung-shape change. For example, when the DU/L ratio is zero, lung shape is unmodified, and the greater the DU/L ratio, the greater the upper compartment is in the prone position. We found that the DU/L ratio significantly correlated with both DK_d (Fig. 49-7) and DPa_{O_2} (Fig. 49-8).

This indicates that, when the U/L ratio is much lower in the supine position and much higher in the prone position, oxygenation will improve in the prone position. Consequently, we suggest that, according to these data, lung-shape modifications, as well as the modifications in regional inflation, may be predictive, in individual patients, of the early effects of positioning on arterial oxygenation.

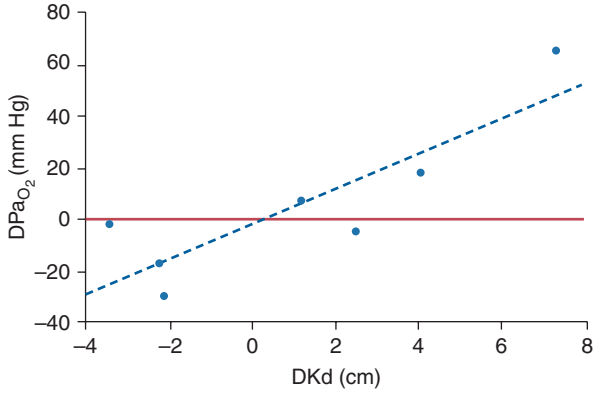

FIGURE 49-6 Relationship between changes in Pa_{O_2} (DPa_{O_2}) and changes in the regional lung decay constants (DK_d) between the prone and supine positions. Data are from seven patients with ARF (regional inflation was computed as weighted mean of the two lungs). Positive values of DPa_{O_2} indicate that the Pa_{O_2} is higher in the prone position, while negative Pa_{O_2} values indicate that Pa_{O_2} is higher in the supine position. When DK_d is close to zero (i.e., the decrease of regional inflation is similar in the prone and supine positions), the DPa_{O_2} is close to zero ($DPa_{O_2} = -1.7 + 6.6 \times DK_d$; $r = 0.86$; $P < .05$).

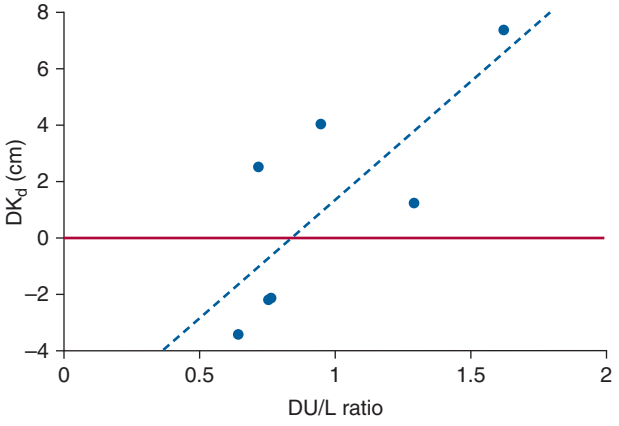

FIGURE 49-7 Changes in the regional lung inflation decay constants (DK_d) as a function of the changes of upper-to-lower lung ratio (*DU/L* ratio) between the prone and supine positions. ($DK_d = -7 + 8.3 \times$ DU/L ratio; $r = 0.77$; $P < .05$).

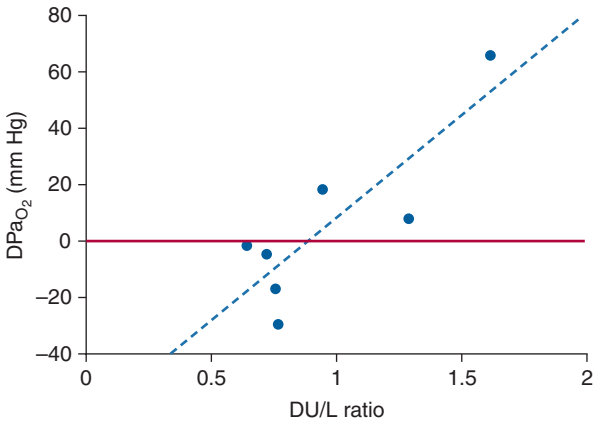

FIGURE 49-8 DPa_{O_2} as a function of the changes in upper-to-lower lung ratio (DU/L ratio) between the prone and supine positions ($DPa_{O_2} = -63 + 71.2 \times$ DU/L ratio; $r = 0.85$; $P < .05$).

Late Effects. When the positioning maneuvers are prolonged over time or are repeated several times during the course of ARF, the oxygenation response may be highly variable. No data are available with which to speculate on the possible mechanisms. We know, however, that with time edema may redistribute, lung pathology may progress from edema to fibrosis, and vascular characteristics may change. Further studies are needed to understand the time-related effects of positioning on arterial oxygenation.

Effects on Arterial CO_2. Recently there has been a paradigmatic shift of attention from changes in Pa_{O_2} to changes in partial pressure of arterial carbon dioxide (Pa_{CO_2}) consequent to prone positioning in patients with ARF. According to Pa_{CO_2} change, patients may be divided into two categories: those who show a decrease of Pa_{CO_2} secondary to prone position, and those whose Pa_{CO_2} does not change or even increases.

Before discussing the meaning of Pa_{CO_2} change, it is worth remembering that expected changes in Pa_{CO_2} are relatively smaller than changes in Pa_{O_2} because of the different slopes of the content/tension relationship. For a similar change in content, the change in tension of CO_2 (partial pressure of the gas) is expected to be approximately 12% of the change in Pa_{O_2}. This would result, for instance, in a change in Pa_{O_2} of 5 mm Hg versus a change in P_{O_2} of 40 mm Hg, implying not only more controlled measurements, but also greater accuracy.

That Pa_{CO_2} increases during the course of ARDS, in association with structural changes of the lung, has been known for many years.[77,78] Kallet et al found that an increase in dead space is a prognostic marker of ARDS mortality.[89]

We found that patients who display a decrease in Pa_{CO_2} in the prone position experience a greater survival (dose dependent) than do patients who do not show a decrease, or even show an increase in Pa_{CO_2}.[90] Moreover, we recently reported the decrease in Pa_{CO_2} during prone ventilation is associated with a higher lung recruitability as measured with CT scan.[91] Accordingly, the Pa_{CO_2} response to prone positioning may be associated to the underlying pathology: predominant recruitment in Pa_{CO_2} responders versus blood-flow diversion in nonresponders. Interestingly, only the changes in Pa_{CO_2} were associated with survival in this study, not the changes in Pa_{O_2}.

The Impact of Prone Positioning on Mortality

RATIONALE

Since the first report dating back to the 1970s,[1–3] the prone position has been proposed and used to improve oxygenation. The progressive recognition of the mechanism underlying this effect, however, led to the hypothesis that the prone position may decrease the danger associated with mechanical ventilation (ventilator-induced lung injury).[92] The hypothesis is based primarily on the observation that in the prone position there is a more homogeneous distribution of inflation, suggesting indirectly a more homogeneous distribution of stress and strain, which are likely the first triggers of ventilator-induced lung injury. In fact, in several animal models, it has been shown that the prone position decreases ventilator-induced lung injury or at least delays its progression.[9,93,94] CT scan studies in animals documented a decrease in regional strain in the prone as compared with the supine position.[9] Indeed, the possible favorable effects of prone positioning on outcome of patients with ARF should not be related to oxygenation changes, which were not found to be associated with outcome, but, instead, to changes in regional lung mechanics, by which forces applied by the ventilator should be more evenly distributed throughout the lung parenchyma.

RANDOMIZED CLINICAL TRIALS ON PRONE POSITIONING

To date, four major randomized, controlled trials (RCTs) have addressed the effect of prone positioning on outcome of adult patients with hypoxemic ARF.[77–80] Other minor published trials will not be discussed here, because they were characterized by major limitations (e.g., small sample size, inclusion criteria other than adult hypoxemic respiratory failure, application of prone positioning for less than 48 hours, patients cotreated with nonconventional ventilator modalities, and so on).[76,81,95–100] Table 49-1 lists the main characteristics of the four largest published trials. As shown, these trials exhibit large variations in term of enrollment criteria (acute lung injury or ARDS vs. hypoxemic respiratory failure vs. ARDS only), intensity of intervention ("early phase strategy" in the trials published earlier vs. "prolonged strategy" in the latest trials), and use of relevant cointervention (i.e., protective mechanical ventilation strategy). Despite the incorporation of the successively acquired scientific evidence into the newer protocols, none of these trials showed any benefit of prone positioning on the mortality of the general population of patients with

Enrollment period (years)	2004 to 2008	1998 to 2002	1998 to 2002	1996 to 1999
Enrollment criteria	ARDS with PEEP ≥5 cm H_2O	ARDS with four-quadrant infiltrates on CXR	Hypoxemic acute respiratory failure (413 ALI/ARDS pts)	ALI/ARDS with PEEP ≥5 cm H_2O
Stratified randomization for ARDS severity	Yes	No	No	No
Time after meeting enrollment criteria	<72 hours	<48 hours	>12 to 24 hours	Not prespecified
Last follow-up	6 months	Hospital discharge	90 days	6 months
Planned duration of prone positioning (average)	20 hours/day for 28 days	20 hours/day until weaning criteria	≥8 hours/day until weaning criteria	6 hours/day for 10 days
Actual duration of prone positioning (average)	18 hours for 8.3 days	17 hours for 10.1 days	9 h for 4.1 days	7 hours for 4.7 days
Protective mechanical ventilation	Yes (V_T ≤8 mL/kg of PBW)	Yes (V_T ≤10 mL/kg of PBW or ABW)	No	No
Trial ended early	No	No	Yes (slow enrollment)	Yes (slow enrollment)

Abbreviations: ABW, actual body weight; *ALI*, acute lung injury; *ARDS*, acute respiratory distress syndrome; *CXR*, chest X-ray; *PBW*, predicted body weight; *PEEP*, positive end-expiratory pressure; V_T, tidal volume.

acute lung injury or ARDS. In a post hoc analysis, however, of one of the first RCTs evaluating prone positioning,[77] we reported a reduction in 10-day mortality in the subgroup of patients with severe hypoxemia or with higher severity of illness. This finding was reinforced in the most recent RCT,[80] where the subgroup of patients with the most severe ARDS (stratified at randomization according a Pa_{O_2}/FI_{O_2} below 100) exhibited a trend toward a reduction in absolute 6-month mortality in the treatment arm of approximately 10%, a signal that did not reach statistical significance because of the small number of patients included in this subgroup. Notably, patients treated with prolonged prone ventilation demonstrated an increase in the rate of adverse events in this study (e.g., dislodgment of chest tube or endotracheal tube, desaturation, need for increased sedation and muscle relaxants, hypotension, or arrhythmias).

META-ANALYSES ON PRONE POSITIONING

A major limitation of the reported RCTs on prone positioning is the relatively small sample size, which could result in an underpowered study, particularly in the case of subgroup analysis. Because of the low incidence of ARDS, especially in its most severe form, several years of data collection are required, which prolongs the time needed to conduct an RCT on prone positioning.[101] Consequently, several meta-analyses have been performed to evaluate the effect of prone positioning in a larger population of patients.[82,84–86,102] Of note, most of these meta-analyses were conducted on a study level, reporting inconclusive results on primary and secondary outcomes in the unselected population of patients with hypoxemic ARF. This kind of meta-analysis, however, does not permit any subgroup stratification, whereas the body of knowledge derived from RCTs clearly suggests that prone positioning could be beneficial only in the subset of the most severely ill patients. To overcome this issue, two meta-analyses[83,103] with different trial inclusion criteria, have been conducted at a patient level, in collaboration with prone trialists, to determine whether prone positioning has a different impact on mortality depending on the extent of hypoxemia. In both of these studies, a threshold of Pa_{O_2}-to-FI_{O_2} ratio of 100 mm Hg was chosen, in line with the most recently published RCT.[80] Both meta-analyses support the hypothesis that prone positioning decreases mortality of patients with severe hypoxemia, whereas it has no beneficial effect in patients with less-severe hypoxemia (Fig. 49-9). Interestingly, a post hoc analysis using varying Pa_{O_2}-to-FI_{O_2} thresholds suggested improved mortality in the most severely hypoxemic group, using a Pa_{O_2}-to-FI_{O_2} ratio of up to 140 mm Hg to define this subgroup.[83]

We speculate that patients with severely hypoxemic ARDS derive benefit from prone positioning because it is only this subgroup of patients who have the physiologic prerequisites for prone positioning to work: They have a greater amount of edema, more widespread alveolar collapse, and higher lung recruitability.[104] In fact, the benefit of prone positioning on the respiratory system is greater recruitment of the dorsal region, which could lead a more homogeneous distribution of the stress and strain forces of mechanical ventilation, potentially decreasing the risk of alveolar injury by mechanical ventilation. This phenomenon is best observed when the aerated portion of the lung is small and when lung recruitability is high.[105]

Summary

The evidence derived from RCTs and recent meta-analyses clearly indicate that prone positioning should not be

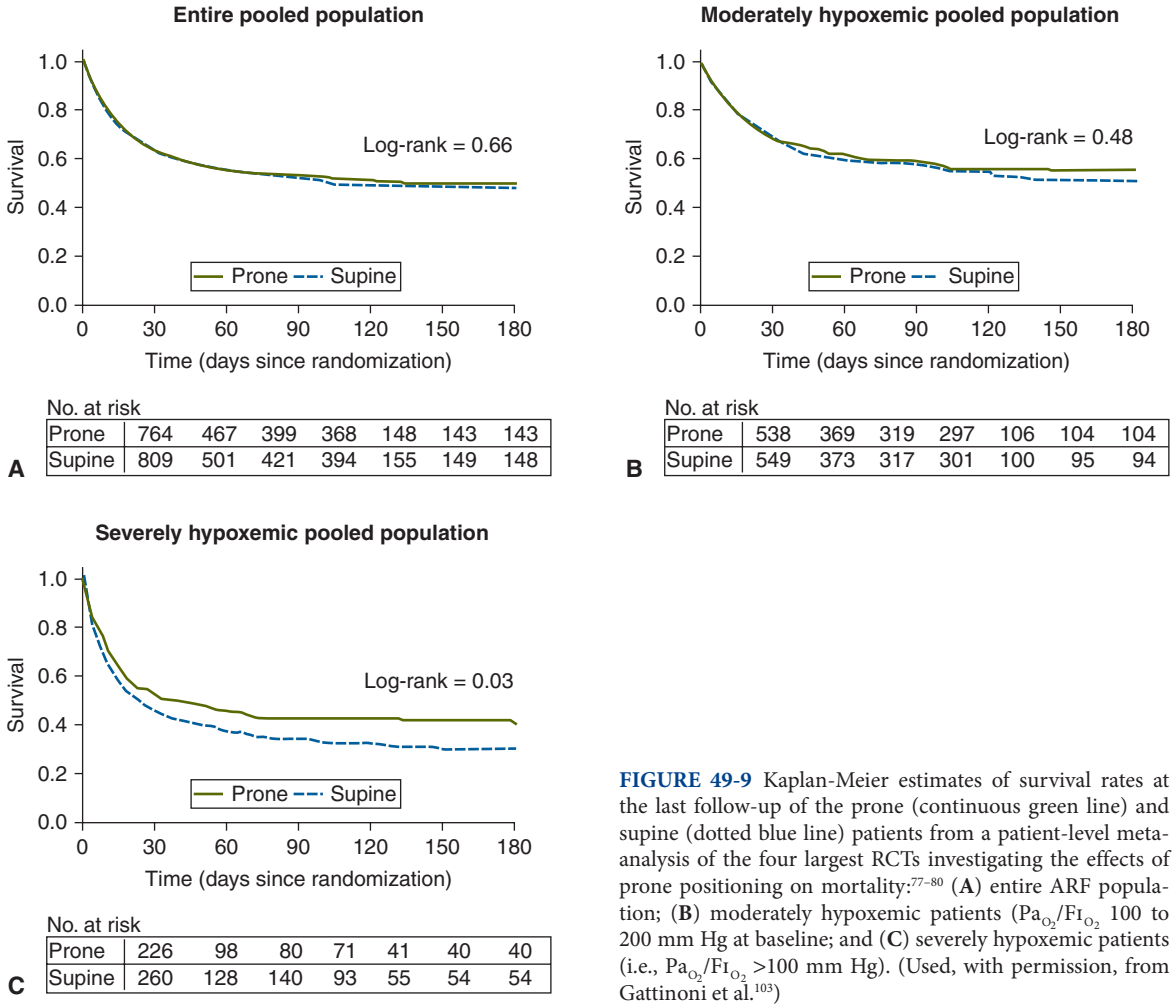

FIGURE 49-9 Kaplan-Meier estimates of survival rates at the last follow-up of the prone (continuous green line) and supine (dotted blue line) patients from a patient-level meta-analysis of the four largest RCTs investigating the effects of prone positioning on mortality:[77–80] (**A**) entire ARF population; (**B**) moderately hypoxemic patients (Pa_{O_2}/FI_{O_2} 100 to 200 mm Hg at baseline; and (**C**) severely hypoxemic patients (i.e., Pa_{O_2}/FI_{O_2} >100 mm Hg). (Used, with permission, from Gattinoni et al.[103])

implemented in patients with less-severe hypoxemic respiratory failure, a situation in which therapy produces useless and potentially harmful effects. Prone positioning, however, should be considered for the treatment of patients with severe hypoxemia, although great care and experienced personnel are required when performing this intervention. Future studies are needed to clarify practical questions facing the clinicians using prone positioning, such as the optimal duration of the therapy,[85] the validity of the Pa_{O_2}-to-FI_{O_2} threshold[83] in guiding therapy, and the real impact of adverse events. A currently ongoing trial targeting the enrollment of 460 patients with Pa_{O_2}/FI_{O_2} less than 150 mm Hg will provide additional data.[106]

PAIN CONTROL, SEDATION, AND NEUROMUSCULAR BLOCKADE

John P. Kress
Jesse B. Hall

Mechanically ventilated patients often require sedatives and analgesics, and in some circumstances may even require the addition of neuromuscular blockade. The myriad disease processes causing respiratory failure frequently elicit a sense of respiratory distress in these patients. In addition, therapies such as endotracheal intubation and positive-pressure ventilation bring about discomfort to a significant number of patients in the intensive care unit (ICU), and patients often receive these life support treatments after surgical interventions or medical conditions that themselves carry a burden of pain. Accordingly, most patients receive analgesics and/or sedatives while undergoing mechanical ventilation. Although many drugs are available to carry out the goals of pain control and, if necessary, sedation in the ICU, studies of the use of these agents were initially performed in other settings such as the operating room or procedure suite. However, accumulation of evidence directed at ICU patient outcomes—specifically patients undergoing mechanical ventilation—has increased over recent decades, and awareness of the complex pharmacology of sedatives and analgesics in critical care is now well established. At the same time, heightened awareness of the complications associated with the use of neuromuscular blocking agents has relegated their use to mostly short-term indications, such as general anesthesia in the operating room, with ICU use now reserved for a small population of patients, typically suffering from severe acute respiratory distress syndrome. The drugs used to achieve analgesia and sedation of mechanically ventilated patients are necessarily potent; however, the enduring effects when these drugs are used without discretion has impacted strategies for their administration.

RATIONALE

Recognition of the fundamental pathophysiologies of respiratory failure and the interaction of the mechanical ventilator and patient will allow goals of pain control, sedation, and neuromuscular blockade to complement the supportive goals of mechanical ventilation. An individualized strategy can then be executed, recognizing goals unique to each patient. This chapter discusses principles and goals of pain control, sedation, and neuromuscular blockade in mechanically ventilated patients, as well as review the drugs currently available to achieve these goals.

PAIN CONTROL

We begin our discussion with the analgesic agents because many patients experience pain to some degree, because inadequate control of pain is unfortunately a memory patients may have after ICU management, and because the ability of the patient to clearly indicate and quantify pain may be significantly impaired by respiratory failure and the devices employed to treat it. This last fact can lead to the unfortunate circumstance of pain in the mechanically ventilated patient presenting as agitation, which, if treated with sedatives alone, is often inadequately managed and leads to excessive drug administration.

Indications

The indications for analgesia during mechanical ventilation come directly from the multiple reasons for pain in these patients. Pain from surgical incisions or trauma is self-evident, but other indications for pain control are subtler. These include endotracheal suctioning or placement of invasive catheters such as arterial or venous lines. Preexisting problems such as skeletal fractures from metastatic cancer and prolonged immobility during bed rest[1] should be considered as other potential causes of pain. The mere presence of an endotracheal tube causes pain in some patients.

Pain may cause many adverse effects, including increased endogenous catecholamine activity, myocardial ischemia, hypercoagulability, hypermetabolic states, sleep deprivation, anxiety, and delirium.[2] Treating pain diminishes some of these detrimental effects.[3]

Assessing Adequacy

It is undeniable that pain occurs in some mechanically ventilated patients.[4–6] Failure to recognize that pain can cause agitation that may lead to inappropriate administration of nonanalgesic sedatives. Accordingly, an aggressive approach to managing pain has been strongly recommended by consensus opinions regarding sedation of mechanically ventilated patients.[7,8] Indeed, it is prudent to actively inquire for the presence of pain and begin the assessment of mechanically ventilated patients by postulating that pain is present as a symptom. The ability to accurately discern pain may be difficult because many ventilated patients are unable to convey its presence and clinical parameters such as changes in vital signs are often not reliable indicators.

In spite of such recommendations and vigilance, the management of pain in ventilated patients is inadequate in some cases.[5] Ineffective communication with patients may be at the root of this problem, because delirium in the ICU is common.[9] Concern over addiction to opiates,[10] adverse cardiopulmonary effects of analgesics, and arbitrary dose limits are other reasons for inadequate analgesia in ventilated patients.

Although attention to analgesia is important, it is similarly important to recognize that not all ventilated patients experience pain. A recent prospective observational study of 171 ICU patients described their self-reported experiences while in the ICU (34% of these were mechanically ventilated).[4] Only 40% of patients reported pain. The important message from this study is that pain, although common and distressing, is not universal. Accordingly, a concerted effort to determine whether or not a patient has pain is extremely important, lest unnecessary withholding or administration of analgesics occur.

Tools to categorize pain, such as scales or scoring systems, may be beneficial. In general, simpler scales are more effective because communication for many ventilated patients is limited. The visual analog scale, although not specifically evaluated in critically ill, mechanically ventilated patients, has very good reliability and validity.[11,12] This scale uses a self-reported measure of pain intensity that consists of a 10-cm line on paper with verbal anchors of "no pain" and "severe pain." A similar scale is the numeric rating scale. This scale also consists of a horizontal line with numeric markings 1 and 10 anchoring either extreme of the pain-intensity scale.[13]

Previous studies have shown that benzodiazepines may enhance the analgesic effects of opiates[14,15] and that opiate requirements are decreased in patients sedated with benzodiazepines compared with propofol.[16,17] Notwithstanding this interesting observation, it is imperative that sedative agents are not used in the place of analgesics.

Selection of Agent

Nonpharmacologic analgesic strategies are worth considering. For example, malpositioning of invasive catheters (an endotracheal tube impinging on the main carina) is a problem that may be easily remedied. Likewise, optimal patient positioning in bed may at least partially relieve low back pain, pain from chest tubes, and so on. In spite of appropriate attention to nonpharmacologic approaches, most patients require administration of pharmacologic agents. Opiates are given in most circumstances and are discussed below.

Opiates

Opiate receptors are ubiquitous, being found in the central nervous system as well as peripheral tissues. The two most clinically important opiate receptors are μ and κ. There are two subtypes of μ receptors, μ_1 and μ_2. Of these subtypes μ_1 receptors mediate analgesia, while μ_2 receptors mediate respiratory depression, nausea, vomiting, constipation, and euphoria. The κ receptors are responsible for such effects as sedation, miosis, and spinal analgesia. Several opiate drugs are available for clinical use and are discussed in detail below.

MORPHINE

Morphine is a commonly used opiate agent and is the drug with which all other opiates are typically compared. Administered intravenously, it has a relatively slow onset

of action (typically 5 to 10 minutes) because of its low lipid solubility, which delays movement of the drug across the blood–brain barrier. The duration of action after a single intravenous dose of morphine is approximately 4 hours. When given repeatedly, accumulation in tissue stores may prolong the effect. It is metabolized in the liver, undergoing glucuronide conjugation, and its active metabolite, morphine-6-glucuronide, may accumulate, particularly in renal failure. Elimination occurs in the kidney, so effects may be prolonged in renal failure. The primary central effect of all opiates is analgesia, which is mediated through the μ and κ receptors. Opiates have some anxiolytic properties, but no reliable amnesia.

FENTANYL

Fentanyl is a synthetic opiate. It has a very high lipid solubility, unlike morphine, leading to rapid movement across the blood–brain barrier and rapid onset of action. Redistribution into peripheral tissues leads to short duration of action after a single dose (0.5 to 1 hour). When fentanyl is given repeatedly and tissue stores become saturated, its clinical effect can be prolonged. Fentanyl has no active metabolites and does not release histamine.[18]

HYDROMORPHONE

Hydromorphone has pharmacologic properties similar to morphine with regard to onset of action. Because it has no active metabolites, however, the duration of action after long periods of hydromorphone administration may be less than that of morphine.

MEPERIDINE

Meperidine is a lipid-soluble opiate with rapid movement across the blood–brain barrier and a rapid onset of action (3 to 5 minutes). The higher lipid solubility leads to peripheral redistribution so that duration after a single dose may be shorter as compared with morphine (1 to 4 hours). Meperidine undergoes hepatic metabolism and renal elimination. Because metabolites of meperidine may accumulate secondary to the common organ dysfunctions that accrue in critically ill patients, and because these metabolites have neurotoxic effects that may cause seizures, there seems no reason to ever use this agent in the ICU patient (see below).[19]

REMIFENTANIL

Remifentanil is another synthetic, lipid-soluble drug with a rapid onset of action. It is quickly metabolized via hydrolysis by nonspecific blood and tissue esterases. As such, its pharmacokinetic profile is not affected by hepatic or renal insufficiency. It is given by continuous infusion because of its rapid metabolism and recovery time. When remifentanil is used during general anesthesia, available data suggest that postoperative respiratory failure is reduced, presumably because patients wake up more rapidly. It provides reliable short-term analgesia in patients with postoperative respiratory failure,[20] and may reduce ICU admissions by allowing extubation in the operating room.[21] Because of remifentanil's unique pharmacology, there is a potential for rapid tolerance to the drug.[22] This has been referred to as *hyperalgesia*.[23] Because remifentanil is eliminated from the body so rapidly and completely, it may lead to a circumstance where patients are left with no analgesia. Although further research is needed to more fully address this issue, it is important to acknowledge this potential problem when using remifentanil in the ICU patient.

Methods of Delivery

For most patients, intravenous injection of opiate analgesics is the preferred route. Intramuscular injections are discouraged because of pain related to the injection itself and unpredictable absorption in critically ill patients. Dosing strategies for intravenous administration of opiates include continuous infusions and intermittent dosing strategies. Intermittent dosing can be further divided into scheduled administration, administration on an *as needed* or *PRN* basis, and patient-controlled analgesia. Dosing given as needed may lead to fluctuations between inadequate and excessive analgesia. Patients alert enough to respond to their own pain needs may benefit from patient-controlled analgesia strategies,[24] although most ventilated patients are not alert enough to utilize a patient-controlled analgesia device. Transdermal opiates may be continued in patients who are chronically receiving such medications, although transcutaneous absorption is unpredictable during critical illness. Certainly, this route should not be used for treating acute pain in mechanically ventilated patients.

Toxicity

All opiates induce respiratory depression, which is centrally mediated and dose dependent. Depression is mediated by the μ_2 receptors in the brainstem medulla; the typical pattern is one of reduced respiratory rate but preserved tidal volume. The response to hypercapnia is decreased and the ventilatory response to hypoxia is obliterated. The depressed respiratory property of these drugs can be exploited in ventilated patients suffering from subjective dyspnea or coughing.

The hemodynamic effects of opiates in euvolemic patients are typically minimal. Hypovolemic patients with blood pressure sustained by sympathetic hyperactivity may suffer hypotension after the administration of opiates. Most opiates cause a decrease in heart rate because of decreased sympathetic activity. Although morphine causes histamine release, this does not usually cause hemodynamic compromise. Remifentanil may cause bradycardia and hypotension, particularly when administered concurrently with drugs having vasodilating properties, such as propofol. Hypertension after remifentanil, though described, is uncommon.

TABLE 50-1: COMMONLY USED OPIATES

	Morphine	Fentanyl	Remifentanil	Methadone
Typical starting dose	2 to 5 mg	25 to 50 mcg	0.025 to 0.1 mcg/kg/min infusion	5 to 10 mg
Onset	10 minutes	0.5 to 1 minute	3 to 5 minutes	10 to 20 minutes
Duration after single dose	4 hours	0.5 to 1 hour	NA; 5 minutes after 4-hour infusion	6 to 24 hours
Metabolism	Hepatic	Hepatic	Nonspecific tissue and plasma esterases	Hepatic
Elimination	Renal	Renal	Renal	Renal
Anxiolysis	+	++	++	+
Analgesia	++++	++++	++++	++++
Hypnosis	No reliable effect	No reliable effect	No reliable effect	No reliable effect
Amnesia	No reliable effect	No reliable effect	No reliable effect	No reliable effect
Seizure threshold	No effect	No effect	No effect	No effect
Reducing dyspnea	++++	++++	++++	++++
Cardiovascular effect	Venodilation	Venodilation	Venodilation	Venodilation
Respiratory effect	Hypoventilation	Hypoventilation	Hypoventilation	Hypoventilation
Common side effects	Ileus, nausea and vomiting, itching	Ileus, nausea and vomiting, itching	Ileus, nausea and vomiting, itching	Ileus, nausea and vomiting, itching

+, minimal effect; ++, mild effect; +++, moderate effect; ++++, large effect.

Gastrointestinal dysfunction in the form of pharmacologic ileus is common with the use of opiates in mechanically ventilated patients. Methylnaltrexone, a specific antagonist of μ_2 receptors in the gut, has been reported to attenuate opiate-induced gastrointestinal ileus in humans.[25,26] The utility of methylnaltrexone in critically ill, mechanically ventilated patients has not been tested.

Seizures are a toxicity unique to meperidine and occur as a result of its metabolite normeperidine, which is a central nervous system stimulant. Patients with renal failure and/or with prolonged use are especially prone to normeperidine accumulation. Because meperidine offers no significant advantage over other available opiates, its side-effect profile should largely preclude its use in critically ill patients.

Muscle rigidity occasionally occurs with synthetic opiates such as fentanyl and remifentanil. It is not seen with naturally occurring opiates like morphine. It is usually seen when high doses of these drugs are injected rapidly and may affect chest wall muscles. The mechanism of opiate-induced skeletal muscle rigidity, although not fully understood, is thought to involve supraspinal activity of the drugs in the striata and substantia nigra. In the most extreme cases, respiratory muscle rigidity makes ventilation impossible. Neuromuscular blockade, typically with succinylcholine, reverses this problem. Fortunately, this problem is extremely rare with the doses of opiates used in the management of ventilated patients in the ICU.

Dependence and withdrawal can be seen in patients receiving opiates for extended time periods when the drugs are discontinued. Patients who abuse opiates are at risk for this when hospitalized during critical illness. The signs and symptoms seen in withdrawal syndromes are mostly nonspecific and include pupillary dilation, sweating, lacrimation, rhinorrhea, piloerection, tachycardia, vomiting, diarrhea, hypertension, yawning, fever, tachypnea, restlessness, irritability, increased sensitivity to pain, nausea, cramps, muscle aches, dysphoria, insomnia, symptoms of opioid craving, and anxiety. Patients without previous illicit drug use may also experience opiate withdrawal when pharmacologically administered opiates given for extended time periods are suddenly stopped. Whether any preemptive strategies, such as downward titration or regular interruption of dosing, will attenuate or prevent opiate withdrawal is not known. Although apparently logical, use of long-acting opiates (e.g., methadone, transdermal fentanyl) to overcome this problem has not been studied in the ICU. Table 50-1 summarizes the pharmacologic properties of commonly used opiates.

SEDATION

Indications

Sedation needs vary widely in mechanically ventilated patients. Although nonpharmacologic approaches such as comfortable positioning in bed and verbal reassurance are reasonable initial considerations, treatment with sedative agents is frequently needed. Effective use of sedatives and analgesics in critically ill patients begins with an understanding of their various indications. Effective *analgesia* (discussed above) is extremely important and should be considered concurrently with sedation.

Anxiety occurs frequently in ventilated patients and is one of the most common indications for sedation. Anxiety may result from (a) uncertainty of one's surroundings, diagnosis,

or prognosis; (b) uncomfortable experiences such as the presence of an endotracheal tube or invasive diagnostic or therapeutic procedures; or (c) isolation from family and friends. Sedatives may be required to facilitate routine nursing care of ventilated patients. Procedures such as endotracheal suctioning, dressing changes, and repositioning regularly elicit distress requiring sedatives.

Dyspnea is common in ventilated patients and may be a source of distress requiring sedation. Excessive coughing may contribute to patient–ventilator dyssynchrony in some patients. Many patients requiring mechanical ventilation suffer from cardiopulmonary instability and impaired gas exchange. Abnormal elevations in oxygen consumption and carbon dioxide production may compromise such patients. Reduction of oxygen consumption can stabilize the balance between oxygen supply and demand.[16] Autonomic instability and elevated endogenous catecholamine activity are common in ventilated patients and may lead to hemodynamic changes (e.g., tachycardia or hypertension) that may elicit myocardial ischemia in some patients, particularly those at risk for coronary artery disease.[27]

Amnesia is often cited as an indication for sedation of ventilated patients. Certainly, for those patients mechanically ventilated during surgical procedures, the importance of amnesia is indisputable.[28] On the contrary, in ICU patients, the necessity of continuous amnesia is far less certain. Although amnesia for certain portions of critical illness requiring mechanical ventilation may seem logical (e.g., during invasive procedures), complete amnesia for extended periods during mechanical ventilation in the ICU has never been proven to confer benefit. Indeed, some data suggest that prolonged ICU amnesia may be detrimental to long-term neuropsychiatric recovery from critical illness.[29–31] It is clear, however, that complete amnesia is mandatory whenever neuromuscular blocking agents are administered.

The relationship between *delirium* and sedation is indisputable. Delirium—defined as an acutely changing or fluctuating mental state, inattention, disorganized thinking, and an altered level of consciousness that may or may not be accompanied by agitation—has been noted to have a wide incidence range in critically ill patients.[9,32,33] Hyperactive or agitated delirium may occur with anxiety as well as sepsis, fevers, encephalopathy (e.g., hepatic or renal), withdrawal syndromes (alcohol, tobacco, or other illicit drugs), or medications. Such hyperactive delirium is frequently treated with neuroleptic medications such as haloperidol.[34] A substantial fraction, however, of ventilated ICU patients exhibit an insidious, hypoactive form of delirium. Currently, it is unclear whether this form of delirium is an indication for any pharmacologic therapy.

Assessing Adequacy

The assessment of sedation adequacy requires a thorough awareness of the indications for sedation. Even when indications are clear, adequacy assessment is challenging because of its subjective nature. As such, a reliable instrument to categorize level of sedation is an important initial step. In view of that, several sedation scales such as the Ramsay Sedation Score,[35] the Sedation Agitation Scale,[36] and the Richmond Agitation-Sedation Scale (RASS)[37] have been developed. The Ramsay scale, described nearly 40 years ago, is often referenced in clinical investigations of sedation, even though it has never been objectively validated.[38] Accordingly, other sedation scales such as the Sedation Agitation Scale and RASS have been developed and tested for validity and reliability.[39] The RASS is perhaps the most extensively evaluated scale. It has been validated for ability to detect changes in sedation status over consecutive days of ICU care, as well as against constructs of level of consciousness and delirium. Because of their more precise scientific evaluations, the RASS and Sedation Agitation Scale should be viewed as preferable to the traditional Ramsay scale.

Ultimately, the evaluation of sedation adequacy is an individualized bedside maneuver. Guidance from nurses is useful, because they are often the first to notice changes in level of sedation. Theoretically, the optimal level of sedation would result in a state in which all indications for sedation are attended to, and the patient is fully communicative with bedside caregivers. This state of being awake and communicative while sedatives are being administered is ideal, and is possible in many patients. Unfortunately, for some, the stresses of respiratory failure and mechanical ventilation do not permit such a state.

Objective monitors of sedation level would be attractive tools for ventilated patients. The bispectral index monitor processes raw electroencephalogram signals into a discrete scaled number from 0 (absence of cortical activity) to 100 (fully awake). This monitor has been shown to track the level of consciousness under general anesthesia. There are some data that suggest a good correlation between the bispectral index and the sedation agitation scale[40] as well as the RASS;[39] however, problems such as electromyographic interference[41] have undermined the utility of this device for widespread use in the ICU.

Selection of Agent

After indications for sedation are established, the clinician must choose one or more agents to administer. This section outlines the various agents currently available and discusses the pharmacologic properties of each agent.

BENZODIAZEPINES

Benzodiazepines act by potentiating γ-aminobutyric acid (GABA) receptor-mediated inhibition of the central nervous system. The GABA receptor complex regulates a chloride channel on the cell membrane, and, by increasing the intracellular flow of chloride ions, neurons become hyperpolarized, with a higher threshold for excitability. The GABA receptor can be competitively antagonized with the

synthetic agent flumazenil, thereby reversing the pharmacologic effects of benzodiazepines. Midazolam, lorazepam, and diazepam are the three available parenteral benzodiazepines.

The onset of action of midazolam is rapid (0.5 to 5 minutes) and the duration following a single dose is short (approximately 2 hours). All parenteral benzodiazepines, including midazolam, are lipid soluble with a large volume of distribution, and are therefore widely distributed throughout body tissues. For all benzodiazepines, the duration of action after a single bolus depends mainly on the rate of redistribution to peripheral tissues, especially adipose tissue. Midazolam undergoes hepatic metabolism and renal excretion. One metabolite of midazolam (α-hydroxymidazolam) has active pharmacologic properties and is renally excreted. Accordingly, there seems little point to using midazolam in ICU patients who have kidney dysfunction. In the presence of normal renal function, α-hydroxymidazolam has a half-life of 1 hour. The pharmacokinetics of midazolam are very different when it is administered to critically ill patients, especially when given by continuous infusion for prolonged periods. Under these circumstances there is preferential accumulation of the drug in peripheral tissues, where metabolism is not possible. When drug infusions are stopped, the peripheral tissue stores release midazolam back into the bloodstream, leading to prolongation of clinical effect.[42] Obese and elderly patients may be even more prone to prolonged effects.

Intravenous lorazepam has a slower onset of action when compared to midazolam (5 minutes). This is the result of a lower lipid solubility that slows the drug's ability to cross the blood–brain barrier. The duration of action following a single dose is long (6 to 10 hours) and is proportional to the dose given. Because these data refer to healthy volunteers, applicability to critically ill patients is difficult. Lorazepam's longer duration of action is caused by lower lipid solubility with decreased peripheral tissue redistribution. The absence of renally excreted metabolites makes it the benzodiazepine of choice in patients with kidney failure.

Intravenous diazepam has a rapid onset of action (1 to 3 minutes) and a limited duration of action following a single dose (30 to 60 minutes). Like midazolam, these pharmacologic properties are caused by the high lipid solubility, which leads to rapid peripheral redistribution of diazepam and extended duration of action. As such, there is little point to ever using diazepam for ICU sedation.

The parenteral benzodiazepines have similar pharmacodynamic effects. All cause dose-dependent suppression of awareness along a spectrum from mild depression of responsiveness to obtundation. They are potent anxiolytic drugs and reliably produce amnesia;[43] lorazepam appears to produce the longest duration of antegrade amnesia. Another common feature of these drugs is their reliable anticonvulsant effect.[44] Rarely, benzodiazepines cause agitation. This paradoxical response typically accelerates as additional benzodiazepine is given; although rare, it has a propensity to affect elderly patients. All benzodiazepines induce dose-dependent depression of respiratory drive. This ventilatory depression, while less extreme than that seen with opiates, behaves in a synergistic manner with opiate-induced respiratory depression. A pattern of reduced tidal volume and slightly increased respiratory rate may help to discern a benzodiazepine effect from the pattern of slow, deep breathing typically seen with opiates. Benzodiazepines, like opiates, can obliterate the hypoxic ventilatory drive. They have minimal effects on the cardiovascular system of euvolemic patients, typically causing slight decreases in blood pressure without a significant change in heart rate. The effect is exacerbated in the presence of relative hypovolemia. In patients with elevated endogenous sympathetic drive, more profound decreases in blood pressure can be seen. Table 50-2 summarizes the pharmacologic properties of the parenteral benzodiazepines.

TABLE 50-2: PROPERTIES OF COMMONLY USED BENZODIAZEPINES

	Midazolam	Lorazepam	Diazepam
Typical starting dose	1 to 2 mg	0.5 to 1 mg	5 to 10 mg
Onset	0.5 to 2 minutes	3 to 5 minutes	1 to 3 minutes
Duration after single dose	2 hours	6 to 10 hours	1 to 6 hours
Metabolism	Hepatic	Hepatic (less influenced by age and liver disease)	Hepatic
Elimination	Renal	Renal	Renal

Respiratory effect	Hypoventilation	Hypoventilation	Hypoventilation
Common side effects	Paradoxical agitation	Paradoxical agitation	Paradoxical agitation

+, minimal effect; ++, mild effect; +++, moderate effect; ++++, large effect.

PROPOFOL

Propofol is an intravenous anesthetic with an alkylphenol molecular structure. Like benzodiazepines, it appears to act on the GABA receptor, although not at the same site as the benzodiazepines. The drug is hydrophobic and is prepared as a lipid emulsion, so it rapidly crosses the blood–brain barrier, leading to a rapid onset of sedation. High lipid solubility also allows for rapid redistribution to the peripheral tissues with a duration of action measured in minutes.[45] With prolonged infusions, duration may be increased slightly, although it is rare for the effect to last beyond 60 minutes from the time of infusion discontinuation. When the infusion is stopped, the peripheral tissue stores redistribute the drug back into the plasma, but usually not to clinically significant levels because of the drug's high lipid affinity. Propofol is ultimately metabolized predominantly in the liver. It has an elimination half-life of 4 to 7 hours and no active metabolites.

Propofol has predictable pharmacodynamic effects, acting as a hypnotic agent causing a dose-dependent depression of responsiveness and awareness. It is also a potent anxiolytic and amnestic agent.[45] Indeed, at high infusion rates, propofol is commonly used for general anesthesia. It appears to have effective anticonvulsant properties.[46] Propofol has no detectable analgesic activity and is not recommended as a sole agent for the initial management of mechanically ventilated patients, because pain control is important in some of these patients. The drug causes ventilatory depression and even apnea in some patients. Because apnea with propofol is unpredictable and not always dose dependent, it should not be used without readiness to secure the airway. The respiratory pattern with propofol is a decrease in tidal volume and a slight increase in respiratory rate. Propofol can cause significant decreases in blood pressure, especially in hypovolemic patients. Hypotension is mainly caused by preload reduction from dilation of venous capacitance vessels. There is mild myocardial depression that also contributes to hypotension.[47] The hemodynamic effect is generally more pronounced than with the benzodiazepines and it should be given cautiously to patients with cardiac disease. Hyperlipidemia is a unique side effect of propofol.[48]

As noted above, the drug is delivered in an intralipid carrier, and propofol 1% solution has 1.1 kcal/mL.[49] Therefore, parenteral lipid feedings must be adjusted to account for the calories administered with this drug. Triglyceride levels should be checked frequently and the drug stopped if hypertriglyceridemia is noted. Strict aseptic technique and frequent changing of infusion tubing is essential to prevent iatrogenic transmission of bacteria and fungi because propofol can support their growth.[50] A "propofol infusion syndrome," manifesting as dysrhythmias, heart failure, metabolic acidosis, hyperkalemia, and rhabdomyolysis, is a rare complication. It appears to be more likely to occur when high doses and/or concentrations of propofol are used.[51] An unpublished randomized, controlled trial of propofol in 327 pediatric patients reviewed by the Food and Drug Administration described a concentration-dependent increase in 28-day mortality in propofol-treated patients versus patients treated with other sedatives (4% mortality with sedatives other than propofol, 8% mortality with 1% propofol, and 11% mortality with 2% propofol).[52] Propofol has received media attention because of problems with national shortages[53] and reports of use of this agent as a drug of abuse[54,55]

FOSPROPOFOL

Fospropofol is a prodrug of propofol that has been introduced as a potential alternative agent for ICU sedation. The Food and Drug Administration approved the drug in 2008. It is metabolized in vivo to the active drug propofol, but the parent drug is water soluble with a much smaller volume of distribution than propofol.[56] The onset of action is on the order of minutes, just slightly longer than propofol. The potential implications of this characteristic include a lower propensity for accumulating in adipose stores during prolonged infusions, although thus far it has only been studied in Phase III clinical trials for colonoscopy, bronchoscopy,[57] or minor surgical procedures.[58] Contamination of fospropofol is less of a concern than propofol because of its water-soluble nature. Further study is needed to evaluate its utility in the ICU.

BUTYROPHENONES

Butyrophenones such as haloperidol may be used for sedation of mechanically ventilated patients. These drugs induce a state of tranquility, and patients often behave with a detached affect. Butyrophenones appear to antagonize dopamine, especially in the basal ganglia, although their exact site of action is not known.

The onset time of intravenous haloperidol is 2 to 5 minutes and the half-life is 2 hours. Starting doses of 1 to 10 mg are typically used with titration depending on the desired end point. The drug is metabolized in the liver.

These drugs are typically reserved for patients who are acutely agitated and hyperactive. A state of cataleptic immobility is occasionally seen. Haloperidol provides no amnesia, no effect on seizure activity, and minimal analgesia. Butyrophenones such as haloperidol are the drugs of choice for agitated delirium. A retrospective study reported an association between haloperidol in ventilated patients and a reduction in mortality,[59] but there are no confirmatory prospective trials. Currently, there is no convincing evidence for the use of antipsychotics in the treatment of ICU delirium. A small pilot study comparing haloperidol, ziprasidone, and placebo given to delirious patients in a preemptive manner found no differences in outcomes, although this study may have been underpowered to detect a difference.[34] A randomized trial comparing haloperidol to olanzapine showed similar reductions in delirium, but fewer extrapyramidal side effects with olanzapine.[60]

Haloperidol causes no significant respiratory depression.[61] This is an attractive feature of haloperidol, because most sedative or analgesic drugs cause respiratory depression.

Haloperidol is known to prolong the QT interval in some patients; it has been reported to result in torsades de pointes,[62]

although this problem is rare. The drug also mildly antagonizes the α_1 receptor and may decrease the neurotransmitter function of dopamine, resulting in mild hypotension.

Extrapyramidal effects are occasionally seen with these drugs, but are much less common with intravenous than with oral butyrophenones. When these complications occur, treatment with diphenhydramine or benztropine may be necessary. The neuroleptic malignant syndrome is another extremely rare problem, thought to result from central dopaminergic blockade leading to extrapyramidal side effects, muscle rigidity, and excess heat generation. It is a life-threatening complication, manifested by "lead pipe" muscle rigidity, fever, and mental status changes. Although data are limited, dantrolene, bromocriptine, and benzodiazepines are listed as possible treatment options.[63]

DEXMEDETOMIDINE

Dexmedetomidine is a selective α_2 agonist with both sedative and analgesic properties.[64] Patients receiving this drug are sedated when undisturbed, but they may arouse easily with minimal stimulation, particularly if they are not receiving opiates or other sedatives concurrently and do not have encephalopathy related to their critical illness. Dexmedetomidine is unique in that some patients transition from sedated to alert states quickly and easily without needing to discontinue the drug infusion, which permits frequent neurologic examinations. The drug is approved for short-term use (<24 hours) in patients initially receiving mechanical ventilation. Dexmedetomidine is analgesic sparing in postoperative patients.[65] Because it causes no respiratory depression, it can be continued after discontinuation of mechanical ventilation and extubation. Because it does not produce respiratory depression, it is not a desirable agent when this property is beneficial, such as the initial management of a ventilated patient in whom permissive hypercapnia is sought.

Side effects include bradycardia (on rare occasions of a severe nature[66]) and hypotension,[67] especially with hypovolemia or high endogenous sympathetic tone. Vasoconstriction and hypertension with increasing doses of dexmedetomidine also have been described.[68] Early studies with dexmedetomidine evaluated postoperative ICU patients[69]; however, more recent studies have targeted other types of patients receiving dexmedetomidine for longer periods of time. Pandharipande et al reported that dexmedetomidine resulted in more days alive without delirium or coma and more time at the targeted level of sedation than lorazepam.[70] Riker et al studied dexmedetomidine for longer-term ICU infusions and found that, compared to midazolam, it resulted in less ICU delirium and fewer days on the ventilator.[71] Table 50-3 summarizes the pharmacologic properties of the other commonly used sedative agents: propofol, haloperidol, and dexmedetomidine.

KETAMINE

Ketamine has a molecular structure similar to phencyclidine. Patients experience a state of mind in which perception is separated from sensation, a "detached from surroundings" or so-called dissociative state. While appearing unaware of their surroundings, patients keep their eyes open and maintain a protective cough reflex. They may behave with coordinated

TABLE 50-3: PROPERTIES OF OTHER SEDATIVE AGENTS

	Propofol	Fospropofol	Haloperidol	Dexmedetomidine
Typical starting dose	1 to 2 mg/kg	2 to 6 mg/kg	0.5 to 1 mg	0.5 to 1.0 mcg/kg over 10 minutes; 0.2 to 0.7 mcg/kg/hour infusion

movements that appear to be without purpose. The drug has profound analgesic properties without producing respiratory depression. The circulatory effects of hypertension and tachycardia, typically seen, reflect increased activity of the sympathetic nervous system. Some, but not all patients, experience amnesia after receiving ketamine. A recent study found ketamine to be an effective alternative to etomidate to facilitate intubation in the ICU. There was a significantly lower incidence of adrenal insufficiency with ketamine.[72] The side effects of emergence delirium and severe hallucinations limit ketamine as a mainstream agent for sedation and analgesia in mechanically ventilated patients. Indeed, this phencyclidine derivative is popular as an illicit drug of abuse.

BARBITURATES

Barbiturates such as thiopental and pentobarbital are potent agents that cause amnesia and unconsciousness. They have no role as sedatives in ICU patients because of a propensity to cause hemodynamic instability and prolonged accumulation in peripheral tissues secondary to lipid solubility. Thiopental is sometimes used to induce anesthesia to facilitate endotracheal intubation. These drugs may be used to induce a pharmacologic coma in patients with severe brain injury.

INHALATIONAL ANESTHETICS

Inhalational anesthetics are used often in the operating room to maintain general anesthesia in mechanically ventilated patients. These agents have analgesic, amnestic, and hypnotic sedating properties. These exhaled gases must be effectively scavenged because they are not metabolized to any significant degree. Delivery and scavenging are technically challenging problems, which has limited greatly the use of these agents outside of the operating room. While there are devices that can be attached to ventilator circuitry to recycle inhalational anesthetics,[73,74] these agents are largely restricted to the research setting and more data are needed before their widespread use in the ICU.

Strategies for Delivery of Sedatives in Critically Ill Mechanically Ventilated Patients

Because no single drug can achieve all of the indications for sedation and analgesia in the ICU, a combination of drugs, each titrated to specific end points, may be more effective. This strategy can allow lower doses of individual drugs and reduce drug accumulation. Both continuous intravenous infusion and intermittent bolus techniques have been advocated. Intermittent bolus strategies may lead to fluctuations in level of sedation and increase demands on nursing time, potentially distracting attention away from other patient care issues. The perceived benefits of continuous sedative infusions include a more consistent level of sedation with better patient comfort, though convenience is likely the greatest reason for its popularity.

Ideally, strategies for sedation and analgesia in critically ill patients should adhere to pharmacokinetic and pharmacodynamic principles. Unfortunately, ICU patients frequently exhibit unpredictable alterations in pharmacology so that precise guidelines for drug administration are not possible. For instance, when short-acting benzodiazepines such as midazolam and lorazepam are administered in the ICU, these drugs accumulate in tissue stores with consequent prolonged clinical effect. Other circumstances that confound prediction of pharmacologic behavior of sedatives and analgesics include altered hepatic and/or renal function, polypharmacy in the ICU with complex drug–drug interactions, altered protein binding, and circulatory instability. The multicompartmental pharmacokinetics typical in critically ill patients defy simple bedside pharmacokinetic profiling.[75] As such, titration of sedatives and analgesics against discernible clinical end points, while imprecise, is the most commonly utilized tool. Further confounding administration of sedatives in the ICU is the dramatic difference between extremes of sedation. Because oversedated patients are easier to manage than undersedated patients, clinicians may be heavy handed when sedating agitated patients.

The occasional ICU patient may require extraordinarily high doses of sedatives to achieve tranquility; such doses may be much greater than those quoted in the literature and recommended by drug manufacturers. Indeed, as discussed below in "Neuromuscular Blocking Agents," occasional patients may even require pharmacologic paralysis to achieve synchrony with mechanical ventilation.[76]

As sicker patients demonstrate improved outcomes in the ICU,[76–80] aggressive levels of sedation and analgesia are sometimes necessary. This is particularly likely for patients managed with unconventional ventilator strategies (e.g., permissive hypercapnia, low tidal volumes, prone positioning, and pressure-controlled ventilation), because these strategies may be inherently distressing to many patients. For selected patients, deep sedation may be the only practical option.

The use of deep sedation, however, carries a high price, because the neurologic examination is severely limited. Ideally, a head-to-toe daily assessment for the presence of organ failures should be routine for every critically ill patient. This is particularly so during resuscitative phases of care, when assessing the adequacy of end-organ perfusion and function is vital. The mental status examination is an important gauge of brain perfusion. Because brain injury is a devastating complication of critical illness,[81] acute cerebral dysfunction must be detected quickly and corrected if possible before permanent injury takes place. The veil of sedation severely handicaps clinicians' ability to serially follow a patient's neurologic condition.

A protocol-driven approach to sedation has been shown to alleviate many of the problems mentioned above.[82] Such protocols assure adequate analgesia and sedation using frequent assessments of patient needs with goal-directed titration of analgesics and sedatives. Alternatively, a routine protocol of daily interruption of continuous sedative infusions can reduce many of the complications of sedation in the ICU

setting, including duration of mechanical ventilation and ICU length of stay.[17] Such a strategy allows patients to spend some of their ICU time awake and interactive. This can allow earlier mobilization of intubated patients leading to improved independence of function and reduced ICU delirium,[83] as well as reduced drug administration and reduced diagnostic neurologic evaluations. Such protocol-driven sedation strategies allow a focused downward titration of sedative infusion rates over time, streamlining administration of these drugs and minimizing the tendency for accumulation.

Initially, the thought of decreasing or stopping sedatives in a critically ill patient who has been agitated may be unsettling. As such, clinicians may aggressively sedate patients early in their ICU course, and maintain the same level of deep sedation indefinitely. A daily holiday from sedatives can eliminate the tendency to "lock in" to a high sedative infusion rate. When sedative infusions are decreased or stopped, tissue stores can redistribute drug back into the circulation. Sometimes interruption of sedative infusions can lead to abrupt awakening and agitation. This must be anticipated by the ICU team to avoid complications such as patient self-extubation; if excessive agitation is noted, sedatives should be restarted. Although the attempt at waking and communication may fail on a given day, this does not portend inevitable failure on all subsequent days. When awakening patients from sedation, reaching the brink of consciousness, without precipitating excessive agitation may be ideal for some. Once objective signs of consciousness are demonstrated, restarting sedatives at half the previous dose and *as needed* is reasonable. Adjustments from this starting point can be individualized to patient needs.

It is clear that sedatives may impact the duration of mechanical ventilation.[17,84] Pairing sedation strategies, such as daily sedative interruption with spontaneous breathing trials, results in shortened ventilator, ICU, and hospital days[85] (Fig. 50-1).

Literature evaluating long-term consequences of recovery from respiratory failure and sedation suggests that post-ICU depression is common in patients who require mechanical ventilation during critical illness.[86] Posttraumatic stress disorder following recovery has been reported as well.[29,31] Some data suggest that lack of awareness related to sedation and/or underlying illness is associated with development of this disorder, and that preservation of awareness during mechanical ventilation may reduce this problem.[29,31,87]

NEUROMUSCULAR BLOCKING AGENTS

Indications

The use of neuromuscular blocking agents (NMBAs) during mechanical ventilation has decreased considerably in the last two decades. These agents remain a common tool to facilitate endotracheal intubation and assure immobility

during surgical procedures. The need for these drugs beyond their use to facilitate procedures is relatively rare in the ICU. Complications related to the use of NMBAs during critical illness have relegated these agents to use as a last resort, usually only for extreme derangements in cardiopulmonary physiology.

Indications for neuromuscular blockade include facilitation of mechanical ventilation in the rare patient who continues to have extreme *ventilator dyssynchrony* despite aggressive administration of sedatives and analgesics. Occasionally, a patient remains so dyssynchronous with the ventilator that effective ventilation is not possible and *severe derangements in gas exchange* ensue, leading to a need for neuromuscular blockade.

Papazian et al conducted a randomized trial in patients with severe acute respiratory distress syndrome (partial pressure of arterial oxygen-to-fractional inspired oxygen concentration ratio [Pa_{O_2}/FI_{O_2}] <150), in which patients received cisatracurium versus placebo in a double-blinded manner. Those receiving cisatracurium had a better adjusted 90-day mortality (hazard ratio [HR] 0.68 [0.48 to 0.98]; $P = 0.04$).[76] The mechanism(s) behind the survival benefit in this study is not known, but may relate to patients being more synchronous with the ventilator and hence avoiding alveolar overdistension or opening–closing cycles that lead to ventilator-associated lung injury.

Patients with *tetanus* may require neuromuscular blockade because of chest wall rigidity, which may prohibit effective chest wall excursion and ventilation. As mentioned above in the discussion of opiate toxicities, the rare occurrence of *skeletal muscle rigidity with high-dose synthetic opiates* may require neuromuscular blockade to permit ventilation. This problem is rare and muscle rigidity short-lived, so that neuromuscular blockade is necessary for only a short time. Lastly, circulation in patients with *severe hemodynamic instability* may become more compromised when respiratory distress demands even greater blood flow to the respiratory muscles from a circulation that cannot accommodate such demands. It is mandatory that patients given NMBAs receive drugs to assure amnesia while they are pharmacologically paralyzed.

Assessing Level of Blockade

Acetylcholine is released from synaptic vesicles at the terminal end of the motor nerve and binds to the postsynaptic end plate, propagating an electrical signal and leading to muscle contraction. Pharmacologic NMBAs bind to the acetylcholine receptor at the terminal end of the motor nerve. These agents can activate the acetylcholine receptor (depolarizing agents) or competitively inhibit the receptor without activating it (nondepolarizing agents). The depth of neuromuscular blockade from nondepolarizing agents is most accurately monitored with the use of a peripheral nerve stimulator. The use of a peripheral nerve stimulator in the ICU has been shown to reduce the amount of neuromuscular blocking drug used and shorten recovery of neuromuscular function and spontaneous ventilation;[88] however, with cisatracurium as the preferred ICU neuromuscular blocking agent (see below the section of Agents–Non depolarizing neuromuscular blocking agents), such monitoring may be unnecessary given the reliable clearance of this drug.[89]

Selection of Agent

DEPOLARIZING NEUROMUSCULAR BLOCKING AGENTS

Succinylcholine. Succinylcholine is the only available depolarizing NMBA. It has the most rapid and reliable onset of neuromuscular blockade, with paralysis sufficient to permit endotracheal intubation within 60 seconds of dosing. As such, succinylcholine is used only to facilitate endotracheal intubation but is not indicated for ongoing neuromuscular blockade in critically ill patients.

NONDEPOLARIZING NEUROMUSCULAR BLOCKING AGENTS

A number of nondepolarizing NMBAs are currently available. The pharmacology of the drugs commonly used during mechanical ventilation in the ICU is discussed below.

Pancuronium. Pancuronium is an older NMBA used during general anesthesia. It has a long half-life, with a duration of action between 60 and 90 minutes after a single intravenous bolus dose of 0.1 mg/kg. Its vagolytic side effect (typically results in a heart rate increase of approximately 10 beats/min), active metabolite (3-hydroxypancuronium), and reliance on renal clearance limit its attractiveness in critically ill patients.

Vecuronium. After the usual loading dose of 0.1 mg/kg, vecuronium typically lasts 30 minutes. Half of the drug is excreted in bile, so prolonged action may be seen in patients with liver dysfunction. In addition, one-third of the drug is excreted in the kidneys, so that accumulation in the setting of renal insufficiency may be seen. The active metabolite 3-desacetylvecuronium may lead to prolongation of effect with repeated dosing, particularly in patients with renal failure.[90]

Rocuronium. Unlike the other aminosteroidal nondepolarizing NMBAs, rocuronium has a rapid onset of action, typically within 60 to 90 seconds. It may be used to facilitate endotracheal intubation, as a substitute for succinylcholine, when the latter is contraindicated (e.g., burns, muscle tissue injury, and upper motor neuron lesions). The usual bolus dose is 0.6 to 1.0 mg/kg, with a duration of effect of 30 to 45 minutes, similar to vecuronium. The metabolite, 17-desacetylrocuronium, has minimal neuromuscular blocking activity.

Atracurium. Atracurium is a benzylisoquinolinium compound with a duration of action between 20 and 45 minutes. The initial loading dose is 0.4 to 0.5 mg/kg. The drug is usually given by continuous infusion in critically ill, mechanically ventilated patients at a dose of 10 to 20 mcg/kg/min. Atracurium is inactivated in plasma by ester hydrolysis and Hofmann elimination so that renal or hepatic dysfunction do not impact its duration of blockade. Atracurium may cause histamine release, and its breakdown product, laudanosine, has been associated with central nervous system excitation and seizures. Currently, it is rarely used in the ICU.

Cisatracurium. Cisatracurium is an isomer of atracurium and it has a similar pharmacologic profile to atracurium. The initial loading dose is 0.1 to 0.2 mg/kg and the duration of action is approximately 25 minutes. Like atracurium, this drug is inactivated in plasma by ester hydrolysis and Hofmann elimination. Cisatracurium does not cause histamine release. Because of its short half-life, it requires administration by continuous infusion. The usual dose is 2.5 to 3 mcg/kg/min. This drug is currently the most frequently used for neuromuscular blockade in mechanically ventilated ICU patients. Apart from succinylcholine and rocuronium use to facilitate endotracheal intubation, there seems little reason to ever use a neuromuscular blocking agent other than cisatracurium in the ICU.

Toxicity

In normal individuals, depolarization of skeletal muscle beds after administration of depolarizing NMBAs such as succinylcholine leads to release of intracellular potassium, typically resulting in an increase in serum potassium of approximately 0.5 mEq/L. Denervation of skeletal muscle from tissue injury, such as with burns or upper motor neuron lesions, may result in more dramatic rises in serum potassium with administration of succinylcholine.

The major toxicity with nondepolarizing NMBAs is prolonged weakness, which occurs by two separate mechanisms. The accumulation of a NMBA parent drug or its metabolites is seen with some agents (e.g., pancuronium and vecuronium), especially in patients with renal and/or hepatic dysfunction.[91] The second cause of weakness associated with NMBAs is known as *acute quadriplegic myopathy syndrome*. Patients with this syndrome manifest acute paresis, myonecrosis with increased creatine phosphokinase concentration, and abnormal electromyography. Electromyographic findings are consistent with denervation of skeletal muscle, which may progress to muscle atrophy and even muscle necrosis.

Complications of NMBAs have reduced, but not eliminated, their use in the ICU.[92] This is particularly noteworthy when corticosteroids are used in conjunction with NMBAs. Several studies suggest this combination is associated with a significant incidence of myopathy.[93] Table 50-4

TABLE 50-4: PROPERTIES OF COMMONLY USED NEUROMUSCULAR BLOCKING AGENTS

	Succinylcholine	Pancuronium	Vecuronium	Rocuronium	Atracurium	Cisatracurium
Type	Depolarizing	Nondepolarizing	Nondepolarizing	Nondepolarizing	Nondepolarizing	Nondepolarizing
Typical loading/ intubation dose	1.0 to 1.5 mg/kg	0.1 mg/kg	0.1 mg/kg	0.6 to 1.0 mg/kg	0.5 mg/kg	0.1 to 0.2 mg/kg
Continuous infusion? (dose)	No	No	No	No	Yes (10 to 20 mcg/kg/min)	Yes (2 to 3 mcg/kg/min)
Onset	60 seconds	3 to 5 minutes	3 to 5 minutes	1 to 2 minutes	3 to 5 minutes	3 to 5 minutes
Duration after loading dose	7 to 9 minutes	60 to 90 minutes	30 to 40 minutes	30 to 45 minutes	20 to 45 minutes	25 minutes
Metabolism	Plasma cholinesterase	Hepatic	Hepatic/biliary	Hepatic	Ester hydrolysis/ Hoffman elimination	Ester hydrolysis/ Hoffman elimination
Elimination		Renal	Renal/biliary	Biliary clearance of parent molecule from plasma		
Active metabolite?	No	Yes	Yes	Yes (minimal)	No	No
Cardiovascular effect	Supraventricular and ventricular rhythm disturbances with hyperkalemia	Vagolytic—tachycardia	None	None	Histamine release	No histamine release
Common side effects	Hyperkalemia	None	None	None	Histamine release	None

summarizes the pharmacologic properties of commonly used NMBAs.

IMPORTANT UNKNOWNS AND THE FUTURE

Currently available drugs for pain control, sedation, and neuromuscular blockade in mechanically ventilated patients all have important limitations. Given the availability of agents with fewer propensities to accumulate and impair neurologic evaluations or liberation from mechanical ventilation, the use of benzodiazepines in the ICU is falling out of favor. Novel approaches, such as inhalational agents and fospropofol, will require more research before they move into the mainstream.

Protocol-driven management of sedation and pain control can clearly improve patient outcomes, regardless of the agent administered. More experience with protocols and better understanding of potential limitations is needed to continue to optimize patient outcomes, both short-term and long-term. As such, further expansion of protocol-driven administration of sedation and analgesia should be evaluated, particularly in different ICU environments, such as general surgery, trauma, or neurologically injured patients.

Use of sedation scales and titration of drugs based upon goals described by these objective scales should allow optimization of sedation and analgesia. The impact of sedation and analgesia on delirium during critical illness must be further studied, given the magnitude of this problem in terms of prevalence and associated morbidity. The impact of neuromuscular blockade, sedation, and pain control on recovery following respiratory failure is poorly understood. Patients who require mechanical ventilation during critical illness suffer psychological and physical complications, and recovery may be slow and incomplete.[94–96] With recognition of psychological maladjustment, a few strategies achieving improved outcomes have been reported,[31,87,97] but more studies in this area are needed. Physical debilitation after respiratory failure and critical illness is well described, with most studies focusing on recovery from acute respiratory distress syndrome. Many of these patients suffer from critical illness-related polyneuropathy and myopathy.[98,99] Sedation strategies can allow patients to be more interactive in the ICU environment; this can encourage the opportunity for very early mobilization in the ICU[83,100,101] and reductions in functional impairment and deconditioning.

SUMMARY AND CONCLUSION

Pain control, sedation, and neuromuscular blockade are important components of the treatment of mechanically ventilated patients. Directing treatment to specific and individualized goals will assure that patient needs are met. All currently available agents for use in ventilated patients have limitations and complications related to their use. Rather than seeking an ideal drug, strategies of drug administration that focus attention on principles of sedative pharmacology in critical illness should be utilized. When these drugs are given to individual patients, recognition of specific goals will allow rational administration strategies to be implemented, which should lead to improvement in short- and long-term outcomes.

HUMIDIFICATION

51

Jean-Damien Ricard
Didier Dreyfuss

Humidification issues are overlooked by many clinicians in the intensive care unit (ICU). Because the need to heat and humidify inspired gases during mechanical ventilation is unanimously accepted, this process is considered the basic, supportive standard of care, about which there is no real debate. Yet, considerable controversy has surrounded central issues concerning humidification such as the level of adequate humidification and how to provide it, the influence of humidification devices on the incidence of ventilator-associated pneumonia, and certain patients and clinical situations and their requirements, such as the need for humidification during noninvasive ventilation. This may account for important differences in the practice of humidification between countries.[1,2] Fortunately, renewed interest has emerged over the past decade, as indicated by several clinical studies that have helped settle some controversies. This chapter will review the reasons for conditioning inspired gases by recalling the normal process of heating and humidifying air during spontaneous breathing, the physical principles of humidification, and the consequences of inappropriate conditioning. Devices to achieve this conditioning are covered and their advantages and potential drawbacks discussed. Finally, practical guidelines are provided.

RATIONALE

As mentioned in the next section, the upper respiratory tract is responsible for most of the conditioning of the inspired gases. Important features of this conditioning (reviewed by Irlbeck[3]) include heat, humidification, and filtration, in order to deliver to the lower respiratory tract a warm (32°C [89.6°F]), humid (95% relative humidity), and pathogen-free and particle-free gas. The last step is achieved in the lower respiratory tract. During invasive mechanical ventilation, the endotracheal tube bypasses the upper respiratory tract. This places the burden of supplying heat and humidity to the cold and dry medical gases on the lower respiratory tract, a task for which it is poorly suited.[4]

ANATOMY AND PHYSIOLOGY OF THE UPPER AIRWAY

The upper respiratory tract (nose, mouth, nasopharynx, oropharynx, laryngopharynx, and larynx, but mainly the nose) is responsible for most of the conditioning of inspired gas. Anatomic structure and physiologic function of the nose are

intimately linked. The highly vascular mucosa of the nose is ciliated and rich in mucosal glands and goblet cells. Three curved bony plates on the lateral side of each nasal cavity (the superior, middle, and inferior concha or turbinate bones), covered with a mucous membrane, ensure the important function of satisfactorily conditioning inspired gases. Their large surface area and position in relationship with the air current enable sufficient contact with the inspired gas. This mucous membrane also lines the paranasal sinuses, trachea, and bronchi but not the pharynx, which does not take part in the air-conditioning process.

PHYSICAL PRINCIPLES OF HUMIDIFICATION

Humidity can be defined as the moisture content of the atmosphere and by extension, water present as vapor in a gas mixture. Vaporization indicates the change of a liquid (or a solid) to a gas or vapor. There is no strict difference between the terms *gas* and *vapor,* although gas is generally used to describe a substance that appears in the gaseous state under standard conditions of pressure and temperature, and vapor to describe the gaseous state of a substance that appears ordinarily as a liquid or solid. Such a change of state requires a certain amount of energy or heat to overcome the van der Waals forces that bind the molecules together in the liquid state. They then escape the liquid as individual molecules of vapor. This amount of heat, specific for each substance, is known as the latent heat of vaporization of the substance.

Importantly, liquids can change to gases at temperatures below their boiling points. Vaporization of a liquid below its boiling point is called evaporation, and can occur at any temperature when the surface of a liquid is exposed in an unconfined space. Molecules of liquid that leave the surface of the liquid (because of sufficient kinetic energy) turn to vapor. They do so with their latent heat; the loss of heat causes the liquid's temperature to decrease. These molecules of vapor exert a certain amount of pressure known as vapor pressure. Vapor pressure is substance and temperature specific (i.e., each substance has a specific vapor pressure for each given temperature). At its boiling point, the vapor pressure of a liquid is equal to the atmospheric pressure. Therefore, vapor pressure of water at 100°C (212°F) is 760 mm Hg.

Measurements of humidity include absolute humidity and relative humidity. Absolute humidity is the mass of water vapor per unit volume of the gas mixture and is measured in milligrams of water per liter of gas (mg H_2O/L). Importantly, at any given temperature, a gas may contain only up to a certain amount of water vapor, corresponding to its maximal capacity at that temperature. Any extra water vapor will condense back into a liquid state. Relative humidity indicates the ratio of the actual water vapor content of the gas mixture to its total capacity at the given temperature. The amount of water vapor a gas can contain is directly proportional to the temperature of the gas (Fig. 51-1). For example, air with 50% relative humidity contains 22 mg of H_2O at 37°C (98.6°F), but only 8.5 mg of H_2O at 20°C (68°F).

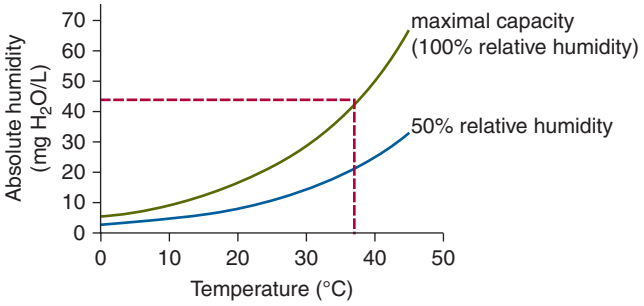

FIGURE 51-1 Absolute humidity (mass of water vapor) of air as a function of temperature at two relative humidities (100% and 50%). The *dotted lines* indicate the value of absolute humidity (44 mg H_2O/L) at core body temperature (37°C [98.6°F]) when air is fully saturated (100% relative humidity).

PHYSIOLOGIC PRINCIPLES OF HUMIDIFICATION

Physiologic humidification delivers inspired air at 37°C (98.6°F) and saturated with water vapor (100% relative humidity) to the lungs. Figure 51-1 indicates that in these conditions, the gas mixture contains 44 mg of H_2O per liter. The principle of humidification lies in the heat and humidity gradient that exists between the inspired gas and the respiratory tract.

As indicated above, humidification occurs first and mainly in the nose, then in the trachea and up to the second-generation bronchi. The large surface area of the turbinates, in combination with their irregular shape and protrusion into the nasal cavity that create a turbulent flow, enables a rapid transfer of heat from the mucosa to the inspired air. This heat gain is sufficient to allow water to evaporate from the mucosa into the inspired gas, enabling its humidification. As a result, inspired gas is warmed and humidified and nasal mucosal temperature decreases from 37°C (98.6°F) to 31°C (87.8°F).

During expiration, the opposite occurs. The gas leaves the alveolus at 37°C (98.6°F) with 44 mg/L of H_2O, and transfers heat to the cooler upper airway. As its temperature decreases, so does its maximal water content capacity. Condensation on the mucosa then occurs. At the end of expiration, approximately one-third of the heat and humidity has been transferred back to the mucosa.

Until the inspired gas has reached 37°C (98.6°F) with 44 mg/L water content, heat and water are lost from the respiratory tract. The point at which inspired gas reaches core temperature and 100% relative humidity is called the isothermic saturation boundary. It is usually situated in the second-generation bronchi. After this point, temperature and humidity of inspired gas remain constant, to ensure adequate gas exchange in the alveolus. Depending on climatic

conditions, the isothermic saturation boundary may move up or down the respiratory tract.

PATHOPHYSIOLOGY OF THE UPPER AIRWAY

Underhumidification

Underhumidification results from the bypassing of the upper airway that follows tracheal intubation and from the absence or inadequacy of conditioning of the dry, compressed, medical gas. Delivery to the lower respiratory tract of insufficiently warmed and humidified gas displaces the isothermic saturation boundary further down the bronchial tree. Moisture and heat loss ensues, inducing structural damages of the respiratory tract that may lead to physiologic and functional impairments with clinical repercussions.

EFFECTS OF MOISTURE LOSS

Moisture loss from the respiratory tract is, under normal conditions, a physiologic phenomenon (approximately 150 mL water) and contributes to the body's insensible water loss. The loss may be much greater if minute ventilation is increased, or if the gradient between the water content of inspired and expired air is large or both. This situation is encountered during mechanical ventilation and was first described during general anesthesia. In one of the first comprehensive studies on this topic, Burton described the reduction of mucociliary function after several hours of dry gas ventilation. When heat and humidity were added, mucociliary function was restored.[5] Numerous studies have been performed subsequently and exhaustively reviewed.[4] The adverse effects of inadequate humidification comprise structural damages such as loss of ciliary function, cilia destruction, damage to mucus glands, cytoplasmic and nuclear degeneration, cellular desquamation, mucosal ulceration, changes in tracheal cytology, and loss of surfactant. Such structural damage has functional repercussions: destruction of the mucociliary escalator, increase in sputum viscosity, increased airway resistance, decreased pulmonary compliance, reduced functional capacity, and increased pulmonary shunting. Clinical consequences include retained secretions, mucus plugging, atelectasis, increased work of breathing, hypothermia, and hypoxemia.[3] In clinical practice, the worst and most feared adverse effect of underhumidification is life-threatening endotracheal tube occlusion, which requires urgent endotracheal tube replacement (see section on effectiveness and outcome, below).

EFFECT OF HEAT LOSS

During general anesthesia, the amount of heat loss through the respiratory tract is very small in comparison with that of other sources (e.g., the operative field and skin). Two mechanisms may account for this loss. Heat is transferred from the respiratory mucosa to the inspired gases, and the amount depends on the patient's minute ventilation, the temperature gradient between the respiratory tract and the inspired gas, and the latter's specific heat. Given the very low specific heat of air, minimal heat is required to raise its temperature. The second and major mechanism by which heat is lost is vaporization (change of liquid water of the respiratory mucosa into vapor and its transfer to the inspired gas). Given the high specific heat of water, a significant amount of heat is required to raise the relative humidity of inspired gases. The amount of heat is further increased when the relative humidity of the inspired gas is very low (i.e., dry medical gas). These considerations may be important during prolonged surgery in infants and young children, keeping in mind that skin, operative site, and fluid administration are the major contributors to the heat loss.

Overhumidification

Because heat and moisture exchangers (HMEs) act passively (see below), they cannot deliver excessive heat or water to the respiratory tract. Consequently, the adverse effects described below are only possible with heated humidifiers and aerosol humidifiers and are now seldom encountered.[6]

EXCESS WATER

The volume of water that can be added to the airway mucosa depends on the state it is in. With heating and humidifying devices, water is in a molecular form (vapor) and is therefore unlikely to result in overhumidification, given the amount of water vapor contained in inspired gases. To significantly increase this amount would require excessive heating of the inspired gas (way above body temperature), thus causing thermal injury before overhydration. Effects of excess water have been reported in the past with the use of aerosol humidifiers,[7] but clinicians are now well aware of these side effects.

EXCESS HEAT

Reports of lung injury secondary to excessive heat are rare[6] and are related to the misuse of heated humidifiers.[8]

METHODS OF HUMIDIFICATION

Although many different types of humidifiers have been developed in the past, clinicians mainly use two types of devices to condition inspired gas during mechanical ventilation: heated humidifiers and HMEs.

Heated Humidifiers

The general working principle of heated humidifiers is to heat water contained in a humidification chamber that humidifies

FIGURE 51-2 Heated humidifier with a heated breathing circuit. Two temperature probes monitor gas temperature at the exit of the humidifier chamber and at the Y-piece before the endotracheal tube (*black arrows*).

inspired gas passing through it (Fig. 51-2).[9] Heating the water enables evaporation to occur, and the gas leaves the chamber saturated with water vapor. Evaporation depends on the surface area over which it occurs, the temperature of the liquid water, and the magnitude of the vapor pressure above the water surface. It can therefore be increased by augmenting the contact of inspired gas and water (larger humidification chamber), by raising the temperature of the liquid water, and by increasing the mass flow of gas above the water surface so as to decrease the vapor pressure. Once the inspired gas has left the humidifier, it cools along the breathing circuit before reaching the patient. Thus, the temperature one wished to achieve at the patient's level will not be reached. There are two ways to help overcome this problem. Inspired gas can be heated in the chamber to above the temperature one wishes to deliver to a patient, to take into account the heat loss across the circuit. Abundant condensation, however, will occur inside the tubing, providing an ideal reservoir for bacterial colonization[10,11] and will need to be drained, exposing health care workers to contaminated fluids and placing other patients at risk of cross-contamination.[12] To prevent this condensation (that results from the decrease in the temperature of the gas whose maximum vapor-carrying capacity is therefore reduced), breathing circuits can be heated by placing electric heater wires either in the wall or in the lumen of the circuit.

New devices are now servocontrolled by means of temperature sensors placed at the exit of the humidification chamber and just before the catheter mount (or flex tube). Because only the temperature is monitored (and not the humidity), however, these devices may become faulty in certain circumstances (see below).[13,14]

Heat and Moisture Exchangers

HMEs have undergone considerable development since their first description in the mid-1950s.[15] The basic principle of all HMEs lies in their capacity to retain heat and moisture during expiration and deliver these to the incoming dry medical gas during subsequent inspiration (Fig. 51-3).[16] This passive function has been achieved by different mechanisms. Metal elements of the first condensers were replaced by disposable foam, plastic, or paper. Increased moisture output was further achieved by coating the condenser element with a hygroscopic chemical (calcium or lithium chloride), which chemically adsorbs expired water vapor that is then returned to the inspired gas. These HMEs were called hygroscopic condensers. Derived from the field of filtration, hydrophobic HMEs were also used to heat and humidify inspired gas. The very large surface area of pleated, water-repellent ceramic of the first hydrophobic HMEs along with its low thermal conductivity enabled an important temperature gradient to develop within the HME that favored heat and moisture retention. Finally hygroscopic and hydrophobic elements were used in a single HME to create a "combined" HME. Hygrometric performance of these various HMEs differ considerably,[17] with hydrophobic HMEs exhibiting the lowest humidity outputs (with the attendant risk of endotracheal tube occlusion) and combined HMEs the highest, although recent measurements indicate that some purely hygroscopic HMEs provide levels of absolute humidity comparable

FIGURE 51-3 A combined (hydrophobic and hygroscopic) heat and moisture exchanger. *Dark arrows* indicate the presence of dripping wet condensation in the flexible tubing (the bright reflection seen on the wall of the tubing) suggesting that adequate humidity is being delivered by the heat and moisture exchanger (see text for details). Note that the heat and moisture exchanger is positioned vertically above the endotracheal tube, thus limiting the amount of secretions refluxing from the tube to the heat and moisture exchanger.

to those of combined HMEs.[18,19] New devices have been designed to boost the humidifying performance of HMEs,[20] although their actual clinical benefit is uncertain.

APPLICATION

Based on the above principles, supplying heat and humidity to inspired gases is mandatory when the upper airway is bypassed during tracheal intubation. This supply must be provided as soon as the patient is connected to the ventilator, either by an HME or by a heated humidifier. Apart from certain specific situations (see "Practical Steps" below), both HMEs and heated humidifiers serve equally well. Despite this, practices differ considerably among countries.[1,21] Rationalizing the choice of a given humidifying device should help decrease costs in mechanical ventilation without impeding quality of care.

EFFECTIVENESS AND OUTCOME

Several important aspects must be taken into account when analyzing the effectiveness and outcomes of inspired gas conditioning, including:

- The avoidance of endotracheal tube occlusion (the worst and most feared complication of inadequate gas conditioning). This aspect is directly linked to the performance of the humidifying device in terms of heat and humidity delivery;
- The avoidance of spreading microorganisms (especially multidrug-resistant organisms). This is directly linked to the humidifying device's capacity to prevent contamination of the respiratory tubing (Fig. 51-4 and Fig. 51-5);
- The addition of minimal resistance and dead space;
- The practicability of use of the device;
- The minimal maintenance necessary to ensure optimal use of the device; and
- The minimal cost associated with the purchase and the long-term use of the device.

Using this list, one can define the characteristics of the ideal humidifier: a device that provides adequate levels of humidification whatever the ventilator and patient conditions; one that does so automatically; one that is safe to operate (i.e., is electric-shock free, with no or a limited number of connections that can become faulty); one that protects the environment from the patient's pathogens; one that is easy to use; and one that requires low maintenance and is inexpensive.

Ensuring Adequate Humidification

The adequate level of humidification can be defined as a level at which there is no excessive heat or water loss by the respiratory tract. The difficulty arises when one tries to set the minimum value of absolute humidity a device should deliver.

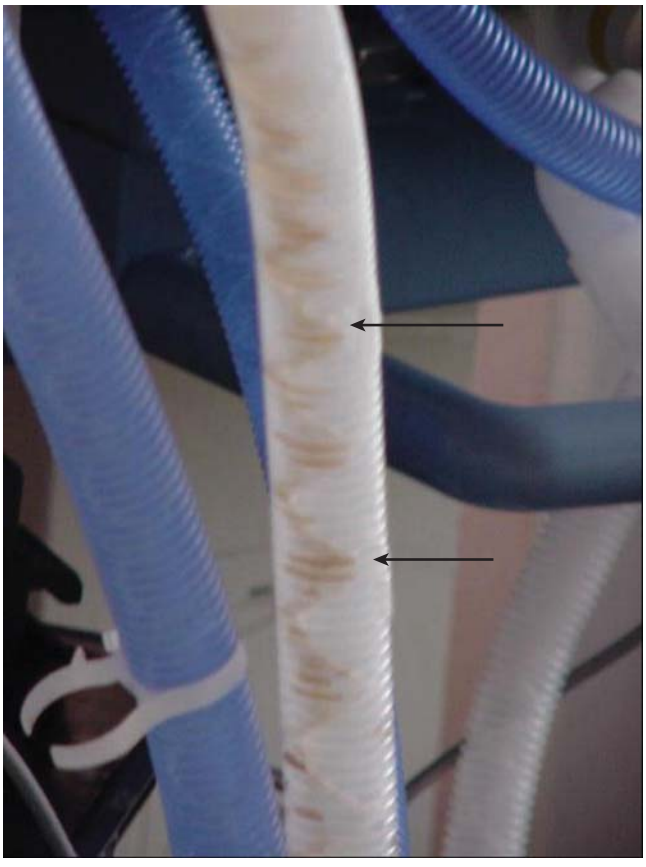

FIGURE 51-4 A heavily contaminated breathing circuit.

This may be useful when selecting and comparing different devices. Although ranges as wide as 25 to 35 mg H_2O/L have been suggested in the past,[22] the figure of 30 mg H_2O/L is recommended today.[24] That is, a clinician wishing to select an appropriate humidifying device should make sure that the device delivers at least 30 mg H_2O/L of absolute humidity.

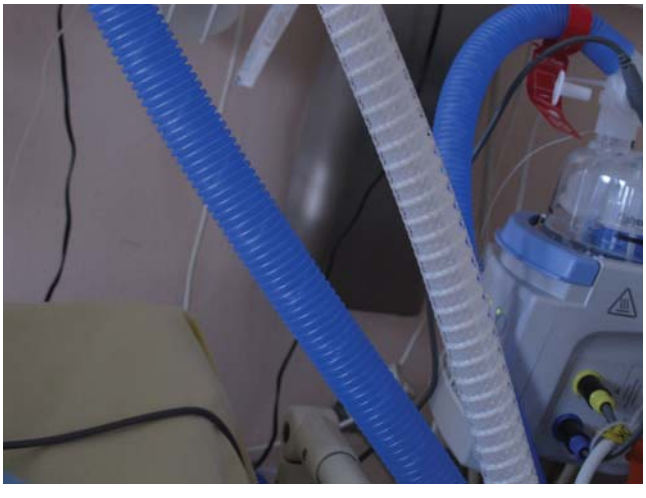

FIGURE 51-5 A dual heated respiratory circuit. The new generation expiratory limb (*white tubing*) allows water vapor to diffuse through the tubing wall, thus minimizing condensate formation in the limb.

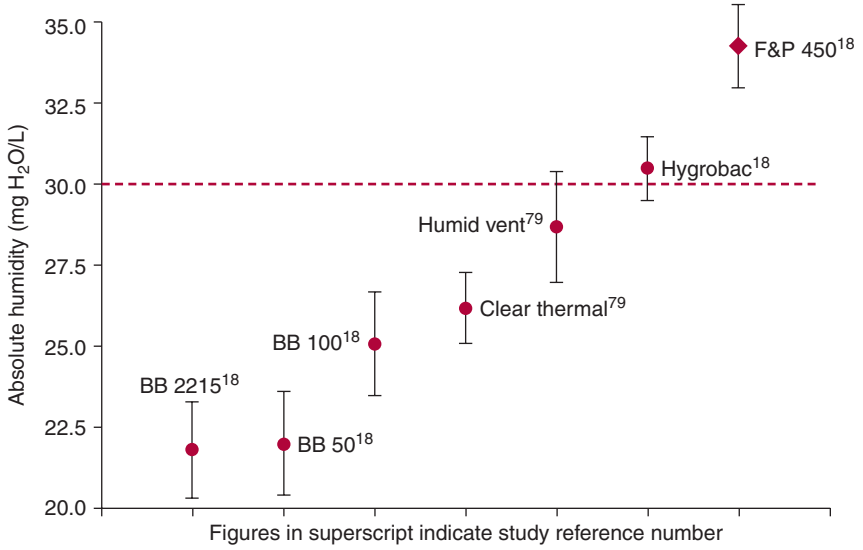

FIGURE 51-6 Values of absolute humidity delivered by several heat and moisture exchangers and one heated humidifier. The *dotted horizontal line* delineates the minimum value of humidity (30 mg H_2O/L) a device should deliver. Note the discrepancies that exist among heat and moisture exchangers (*red circles*). The HMEs exhibiting the lowest values of absolute humidity are those most strongly associated with endotracheal tube occlusions. The heated humidifier (*red diamond*) exhibited the highest value for absolute humidity.

A recent study indicates that this output is not achieved by all available HMEs.[23]

In the past, HMEs and heated humidifiers were not equivalent in terms of humidity output. Back in the late 1980s, several studies alerted clinicians to the risk of endotracheal tube occlusions associated with the use of HMEs.[24–27] These studies, however, all used purely hydrophobic HMEs, whose measured performance displayed low values of absolute humidity.[17,18,28,29]

Although heated humidifiers indisputably deliver greater values of absolute humidity than HMEs[17,28,29] (Fig. 51-6), there is to date no evidence of any benefit of these greater values in terms of clinical outcome, including endotracheal tube occlusion. Table 51-1 displays the incidence of endotracheal tube occlusion reported in recently published studies. It is important to note that: (a) endotracheal tube occlusion rates have drastically dropped in comparison with earlier studies;[25–27] (b) endotracheal tube occlusion is also reported with the use of heated humidifiers; and (c) the incidence of endotracheal tube occlusion no longer appears to be greater with HMEs than with heated humidifiers. In one study, the incidence was greater with heated humidifiers than with HMEs.[30]

The reasons for this unusually high rate of endotracheal occlusions deserve particular attention. As indicated above (see "Methods of Humidification" above), new heated humidifiers are servocontrolled. Because the temperature of the incoming gas mixture has a direct effect on the heating mechanism of the plate that warms the humidification chamber, if the temperature is too high, the plate no longer heats, resulting in very low levels of absolute humidity,[13,14] sometimes below 20 mg H_2O/L.[13,14] These very low values, well below the 44 mg H_2O/L expected with these devices, are encountered when the temperature of the gas exiting the ventilator is high and/or when the ambient temperature is high.[13,14] It is notable that depending on the type of ICU ventilator, the output ventilator temperature may vary from 26°C to 35°C (78.8°F to 95°F).[13,14] An automatic compensation system has been designed that seems to be effective in overcoming this worrisome problem.[14,31] This system is available on some, but not all, heated humidifiers. If not, HMEs should be used.

Abbreviations: ETT, endotracheal tube; *HH*, heated humidifier; *HME*, heat and moisture exchanger.

Resistance

Both types of humidifying devices (HMEs and heated humidifiers) marginally increase resistance to flow in the respiratory circuit[32–35] with no impact on auto–positive end-expiratory pressure, even in patients with chronic obstructive pulmonary disease (COPD).[36] Thus, resistance to flow of humidifying devices during invasive mechanical ventilation is not a major problem clinically.

Dead Space

Because of their internal volume, HMEs increase dead space in the ventilator circuit.[35,37,38] This increase is directly proportional to the internal volume of the HME, which may vary between 30 mL and 95 mL.[38] The impact of dead space on work of breathing and arterial CO_2 depends on the mode of ventilation and tidal volume used. During volume-assist control ventilation, internal dead space will only influence Pa_{CO_2} and pH: the smaller the tidal volume used (in combination with an HME with a large internal volume), the greater the impact on arterial CO_2 and pH.[39,40] During invasive and noninvasive pressure-support ventilation, use of HMEs may increase work of breathing in COPD and in difficult-to-wean patients.[34,41–45] This increase in work of breathing, however, is easily overcome by increasing the level of pressure support by 5 to 10 cm H_2O.[34,41,43,44]

Microbiologic Outcome

NOSOCOMIAL PNEUMONIA

The problem of nosocomial infection related to respiratory equipment is not new, and older inhalation therapy equipment posed a considerable challenge in ICUs in the past.[46–49] Similarly, it has been suggested that contamination of respiratory tubing used with heated humidifiers may be a risk factor for ventilator-associated pneumonia.[11,50] This hypothesis stemmed from the rapid and considerable bacterial colonization of respiratory tubing encountered with use of heated humidifiers.[10–12,51] Because HMEs prevent bacterial contamination of respiratory tubing,[52,53] the question arose as to whether, or not, the incidence of ventilator-associated pneumonia was greater with heated humidifiers.[54] There is now overwhelming evidence that the method of humidification does not influence occurrence of ventilator-associated pneumonia.[30,52,55–58] This is not very surprising considering the pathogenesis, mainly the silent aspiration of contaminated gastric and oropharyngeal secretions.[59] Consistent with this reasoning, the incidence of ventilator-associated pneumonia is not affected by the duration of use of HMEs, whether changed every 48 hours,[60] 72 hours,[18] or only once a week.[61] Similarly, the type of HME does not influence the rate of ventilator-associated pneumonia.[62,63] Despite these facts, some have recently recommended they be preferred to heated humidifiers to prevent nosocomial pneumonia.[64]

CROSS-CONTAMINATION

Although use of heated humidifiers is not associated with a greater incidence of ventilator-associated pneumonia, these devices do have the potential for cross-infection.[12] Craven et al studied ventilator-circuit colonization during the first 24 hours after a circuit change. They found a rapid colonization: 33% of circuits were colonized at 2 hours, 64% at 12 hours, and 80% at 24 hours. The median level of colonization at 24 hours was 7×10^4 organisms/mL.[11] Bacteria isolated in respiratory tubing condensates correlate with the microorganisms found in patients' tracheobronchial secretions.[11,51,55] These highly contaminated condensates should therefore be handled as infectious waste and regularly emptied.[11] Repeating these septic maneuvers several times a day increases the risk of cross-infection, especially when patients are colonized with multidrug-resistant bacteria.[65]

Preventing respiratory tubing contamination confers on HMEs a great advantage over heated humidifiers.[19,52,55] Attempts have been made to reduce formation of condensation in the circuits by heating both the inspiratory and the expiratory limb of the circuit. Such equipment needs to be evaluated in the clinical setting. A preliminary report found that condensation still occurred in up to 50% of patients ventilated with these heated circuits,[65] leading to substantial bacterial colonization (see Fig. 51-4). A modified expiratory limb enabling evaporation through the wall of the circuit considerably decreases occurrence of condensation in the circuit (see Fig. 51-5).

Practicability and Maintenance

For obvious reasons, HMEs are far easier to handle than heated humidifiers. They require no maintenance and several studies indicate that they reduce staff work load.[52,56,66] Several technical improvements brought to the new heated humidifiers (servocontrol, automatic water-filling system, heated respiratory circuits, and so on) have considerably reduced the time required to check and operate them.

Safety

Clinicians are well aware of the hazards associated with HMEs (mainly endotracheal tube occlusion),[1] but may be less aware of the hazards associated with heated humidifiers. Some recently described hazards deserve particular attention. Burns to the patients and breathing circuit meltdowns have occurred in the past because of heated wires.[67–69] More frequent and more recent is the risk of ventilator shutdown because of rain out from heated humidifiers.[70–72]

Costs

Several studies have compared the costs of humidification with HMEs with those of heated humidifiers.[52,54–56,66,73,74] All conclude that considerable cost savings can be achieved by using HMEs, not only because heated humidifiers are

expensive to buy, but also because they are expensive to run (especially because of the price of heated respiratory tubing). Costs can be further reduced by extending the use of HMEs; several studies indicate that these devices may be used without change for up to a week (see below).[56,61,75]

PRACTICAL STEPS

Invasive Mechanical Ventilation

An algorithm for heating and humidifying inspired gases during invasive mechanical ventilation is proposed in Figure 51-7.

WHICH DEVICE FOR WHICH PATIENTS

There are very few and rare contraindications to the use of HMEs. Because they act passively, the amount of heat and moisture they deliver to the inspired gases depends on the amount of heat and moisture they retain during expiration. Therefore, patients with profound hypothermia or important bronchopleural fistulas should preferably be ventilated with a heated humidifier. In addition, a heated humidifier may be preferable in patients ventilated for acute asthma or acute respiratory distress syndrome, in whom a drastic decrease in tidal volume induces extreme respiratory acidosis (to avoid increased dead space with HMEs).[39,40] A heated humidifier can be used until the patient's respiratory condition improves sufficiently to enable the use of an

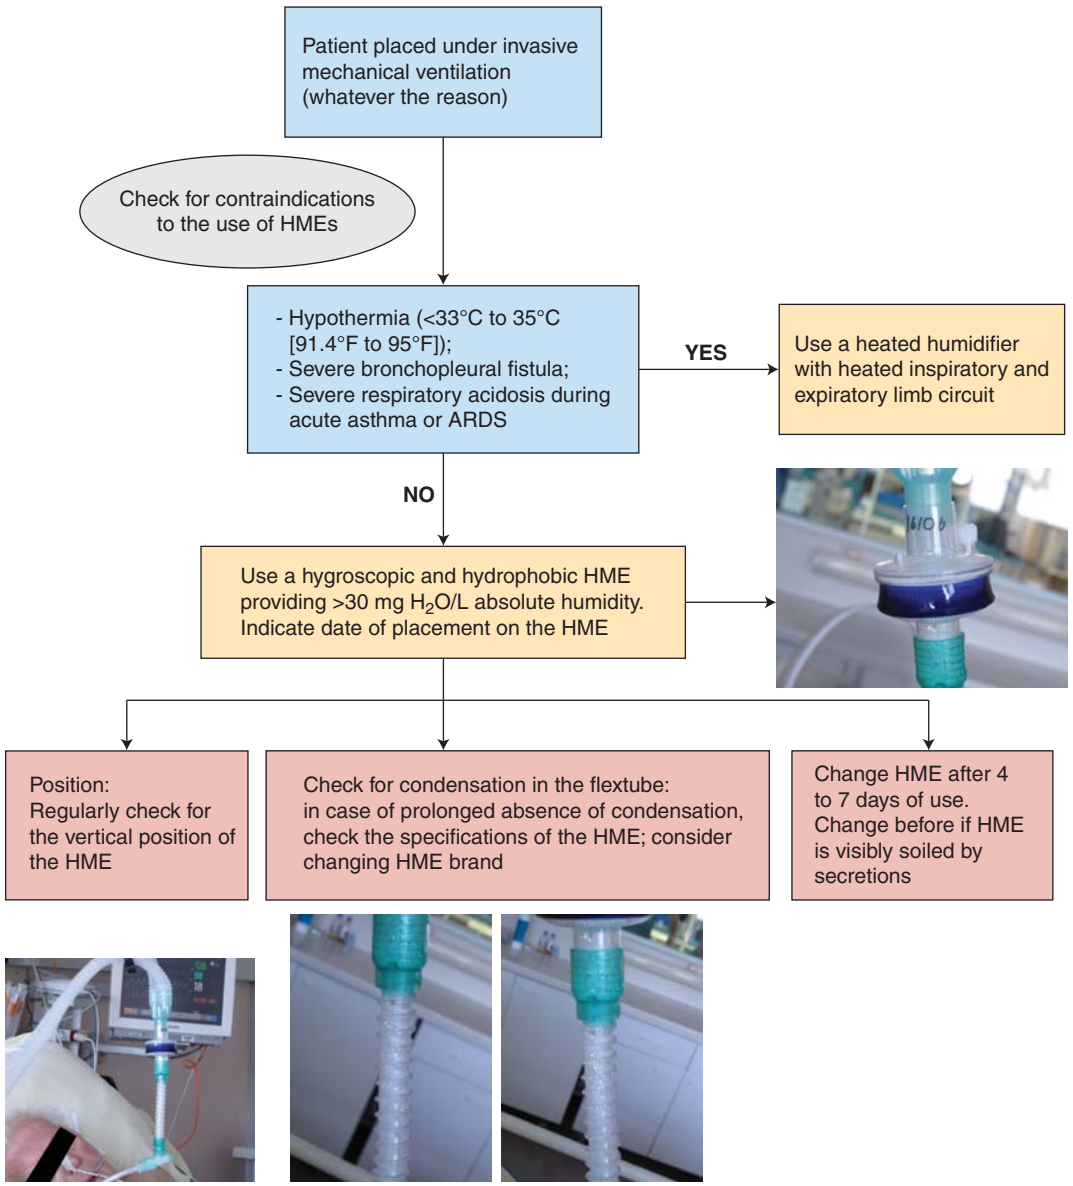

FIGURE 51-7 Algorithm for heating and humidifying inspired gases during invasive mechanical ventilation. *ARDS,* acute respiratory distress syndrome; *HME*, heat and moisture exchange.

HME. Apart from these specific situations, HMEs should be considered first to heat and humidify inspired gases of all ventilated patients. They are as effective as heated humidifiers, and are much cheaper and much easier to use. Importantly, medical as well as surgical patients can benefit from them.

Despite the former practice of restricting their use to patients without a history of respiratory disease and only for the first 5 days of mechanical ventilation,[74,76] several studies have clearly shown that they may be used in any ventilated patient, even in patients with COPD and for any length of mechanical ventilation. Because patients with COPD represent the most important subgroup of ventilated patients in the United States,[77] and because their duration of ventilation is longer than that of other patients,[77] adequate humidification is probably more critical in such patients than in patients ventilated for shorter periods. Numerous studies show that long-term mechanical ventilation can be safely conducted in such patients with HMEs.[19,55,56,75,78–80] Three studies have specifically compared humidity output of HMEs in patients with and without COPD and consistently found that the measured values for absolute humidity were very similar (Fig. 51-8).[19,75,80]

FREQUENCY OF HEAT AND MOISTURE EXCHANGE REPLACEMENT

There is now considerable evidence that HMEs may be used for longer than the 24 hours recommended by manufacturers.[18,19,56,60,61,73,75,79–82] Compelling results stem from rigorous clinical evaluation[56,60] or extensive bedside measurement of humidity delivery.[18,19,61,75,79–81] Figure 51-9 shows that humidity delivery of a combined HME (Hygrobac, DAR, Mirandola, Italy) used for 7 days without change was remarkably stable throughout this period. Progressive clogging of the device with tracheal secretions (that seriously increase resistance to airflow) could have been a drawback. Repeated measurements of the resistance of the HME over 7 days indicate that this phenomenon did not occur (Fig. 51-9).[75]

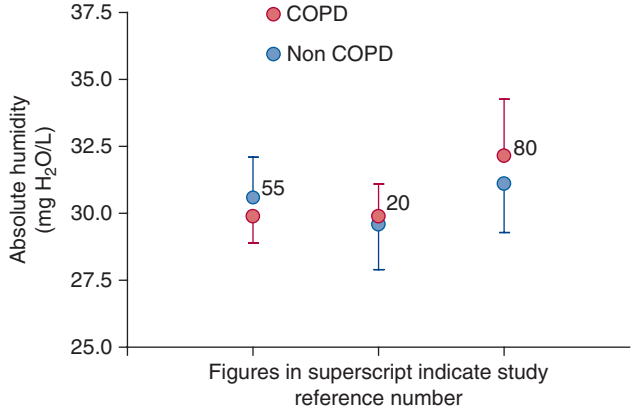

FIGURE 51-8 Comparison of the absolute humidity delivered by heat and moisture exchangers in patients with and without chronic obstructive pulmonary disease (COPD). Values are similar, indicating that these devices are suitable for patients with COPD undergoing mechanical ventilation.

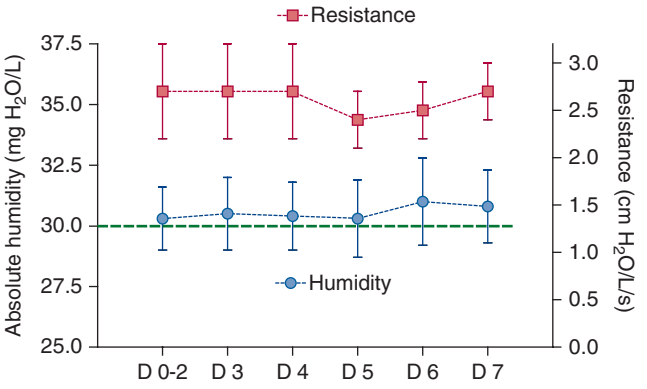

FIGURE 51-9 Absolute humidity (*left Y axis*) and resistance (*right Y axis*) measured over time in combined heat and moisture exchangers used for 7 days without change. Note the perfect stability of the humidity output and the lack of increase in resistance over time. (Adapted, with permission, from Ricard et al.[53])

Keeping the HME vertically above the tracheal tube (see Fig. 51-3) (and having nurses and doctors repeatedly check the position of the HME) prevents secretions from refluxing from the tracheal tube and obstructing the HME.[19,75] Use of HMEs may be extended in both medical patients (including those with COPD[19,75,79,80]) and surgical patients.[18,61,73,82] This practice is now widely accepted,[83] and recommendations have been made to change HMEs only once a week.[64] In our own published[75] and unpublished experience,[75] we have been changing HMEs only once a week since 1997, and have not encountered endotracheal tube occlusions.

Noninvasive Mechanical Ventilation

The question of heat and humidification requirements during noninvasive ventilation has gone unanswered until very recently. The 2001 International Consensus Conference on Noninvasive Ventilation made no recommendation as to whether a humidifying device should be used or not.[84] This absence stems from the uncertainties regarding the level of humidification required during noninvasive ventilation (given the fact that the upper airways are not bypassed) and that can be achieved during noninvasive ventilation with HMEs and heated humidifiers.

This aspect has received attention in a recent study that compared the water content of gas delivered obtained during noninvasive ventilation with either an HME or a heated humidifier, and the comfort or discomfort experienced by healthy subjects.[85] In the absence of humidification, water content was very low when an ICU ventilator was used (5 mg H_2O/L), but equivalent to ambient air hygrometry with a turbine ventilator at minimal fractional inspired oxygen concentration (FI_{O_2}) (13 mg H_2O/L). HME and heated humidifier had comparable performances (25 to

30 mg H_2O/L) although HME's effectiveness was reduced with leaks (15 mg H_2O/L). During continuous positive airway pressure, dry gases (5 mg H_2O/L) were less tolerated than humidified gases. Gases humidified at 15 or 30 mg H_2O/L were equally tolerated. These data indicate that in favorable conditions, HME and heated humidifiers provide equivalent comfort to the patient through similar water content to the inspired gases.

This study contrasts with some physiologic studies of the influence of the humidifying device on respiratory variables. In a randomized crossover study in nine patients receiving noninvasive ventilation for moderate to severe acute hypercapnic respiratory failure, a significant increase in work of breathing was found with HMEs in comparison with heated humidifiers), although this did not significantly impact the partial pressure of arterial carbon dioxide (Pa_{CO_2}).[44] The dead space of HMEs is obviously responsible for these observations and a recent study showed that use of an HME with a very small dead space does not alter respiratory variables, compared with heated humidifiers.[86]

The question that arises is whether the choice of a given humidifying device during noninvasive ventilation affects outcome, especially the intubation rate. To address this issue, a large multicenter randomized trial tested the hypothesis that the use of HMEs would increase intubation rates.[87] During 13 months, 247 patients were randomized to noninvasive ventilation either with an HME or a heated humidifier. The intubation rate (failure of noninvasive ventilation) was higher with a heated humidifier than with an HME, although the difference did not reach statistical significance (37.6% vs. 30.6%; $p = 0.31$). Mortality tended to be higher in the heated humidifier group (21.5% vs. 14.1%; $p = 0.18$). Pa_{CO_2} tended to be lower in the heated humidifier group (66 vs. 72 mm Hg; $p = 0.08$).[87] These preliminary results suggest that the observed increases in work of breathing, minute ventilation, and Pa_{CO_2} in carefully conducted physiologic studies (but on a small number of selected patients) may only play a marginal role in the clinical setting. Taken together, it can now be stated that noninvasive ventilation can be safely and efficiently performed with HMEs, provided attention is given to minimize leaks and that a small internal volume HME is chosen.

Adjustments at the Bedside and Troubleshooting

Assessing humidification at the bedside is desirable, if not essential, for at least two reasons: (a) a life-threatening tracheal tube occlusion[24] may occur without any precursory clinical signs of insufficient humidification; and (b) devices may not deliver, in some instances, the heat and humidity that is expected of them, because they are either malfunctioning[14] or performance in the clinical setting does not attain that stated by the manufacturer.[14,80]

Such assessment raises two questions: (a) Is the device delivering enough heat and humidity (according to the standards)? (b) Is the amount of heat and moisture delivered appropriate for a given patient?

ASSESSING HEAT AND MOISTURE EXCHANGERS AND HEATED HUMIDIFIERS AT THE BEDSIDE

A simple means of evaluating the humidity delivered by a given device is to assess the amount of condensation seen in the flexible tubing that connects either the Y-piece (when using a heated humidifier) or the HME to the endotracheal tube.[14,17,88] Indeed, the amount of condensation seen in the flexible tubing is positively correlated with the absolute humidity measured at the bedside.[14,17] If the tubing remains constantly dry over time, or only very few droplets of water are seen, then absolute humidity delivered by a device is probably below 25 mg H_2O/L, and the patient is at risk of endotracheal tube occlusion. When numerous droplets are seen in the tubing or if it is dripping wet, the device is probably delivering sufficient absolute humidity to prevent endotracheal tube occlusion.[17]

ASSESSING ADEQUACY OF INSPIRED GAS CONDITIONING

Although it is conceivable that some patients have special humidification needs, the prevailing literature indicates that heated humidifiers and HMEs equally meet humidification requirements in the vast majority of ventilated patients. Therefore, monitoring the characteristics of secretions (thick and tenacious, or watery and abundant) as a guide to insufficient or excessive humidification may be of limited value, because changes in mucus characteristics may be entirely caused by the patient's condition (respiratory status, fluid balance, and so on), and not a consequence of the humidifying device. It has been shown that air humidification with either an HME or a heated humidifier has similar effects on mucus rheologic properties, contact angle, and transportability by cilia in patients undergoing mechanical ventilation.[89]

IMPORTANT UNKNOWNS

The preliminary results showing a trend toward higher intubation and mortality rates following noninvasive ventilation with a heated humidifier[87] strongly bring into question the use of these devices during noninvasive ventilation, at least in patients for whom Pa_{CO_2} is not the main problem. A question unanswered until recently was whether a humidification device was necessary in every single patient undergoing noninvasive ventilation. The above-mentioned study by Lellouche et al[85] provides some important clues. If an ICU ventilator is used, then additional heat and moisture is essential to ensure subject comfort, and this can be achieved equally by an HME or a heated humidifier. When a turbine ventilator is used, the hygrometry obtained is close to that of ambient air, and one should ask whether inspired gases are too dry or not. Unfortunately, because this study was conducted in healthy

subjects, it remains unknown if its results are applicable to the clinical setting. One can legitimately hypothesize that the level of humidification that provides comfort to a healthy subject differs from that required for a patient with COPD suffering from acute respiratory failure.

THE FUTURE

In the field of acute respiratory failure management, underhumidification is no longer the main threat associated with invasive or noninvasive mechanical ventilation. The challenge now facing clinicians is the appropriate management (in terms of humidification) of a much larger population of patients that breathe spontaneously but require additional oxygen. Despite the millions of patients receiving external oxygen every day around the world, little data are available on their needs in terms of humidification. If very low flows of oxygen do not seem to be associated with marked discomfort, recent data indicate that cold-water bubble humidifiers perform poorly during oxygen therapy.[90] Additional heat and moisture, provided by a heated humidifier, only partially relief the dryness of mouth provoked in patients by dry oxygen.[90] Little is known when higher flows are used with a face mask. A new technique, called *high-flow nasal cannula oxygen*, has arisen from the neonatal and pediatric experience with very high-flow oxygen therapy. It combines a heated humidifier and an air-oxygen blender allowing flows up to 60 L/min with 100% FI_{O_2} (Optiflow, Fisher & Paykel, Auckland, New Zealand). One must bear in mind that patients' inspiratory flow during respiratory distress may exceed 60 L/min.[91] Thus, conventional oxygen therapy, even at its maximum flow (15 L/min), will cover only a small fraction of a patient's inspiratory flow in terms of oxygen and humidification. With a high-flow nasal cannula, better matching between an adequately heated and humidified oxygen flow and a patient's inspiratory demand is obtained. Promising results have been reported with this technique in ICU patients in acute respiratory failure,[92,93] as well as in patients presenting to the emergency department with hypoxemic respiratory failure.[94]

SUMMARY AND CONCLUSION

Adding heat and moisture to the inspired gas during invasive mechanical ventilation is mandatory. This can be efficiently achieved either by heated humidifiers or by HMEs. Although hygrometric performance of combined HMEs is slightly lower than that of heated humidifiers, they are clinically as efficient and do not cause more endotracheal tube occlusions. They may be used in the vast majority of medical (including COPD) and surgical ICU patients and for the entire duration of mechanical ventilation. Specific situations, however, such as menacing respiratory acidosis during mechanical ventilation of patients with acute asthma or very severe acute respiratory distress syndrome, require the use of a heated humidifier until the respiratory condition improves sufficiently to enable the use of an HME. Use of heated humidifiers does not increase the risk of ventilator-associated pneumonia, nor does prolonged use of HMEs. However, because circuits get rapidly contaminated with heated humidifiers (unlike HMEs), they carry the potential for cross contamination. Finally, costs of mechanical ventilation are greatly reduced with the use of HMEs.

AIRWAY SECRETIONS AND SUCTIONING

Gianluigi Li Bassi

Retention of airway secretions in patients on invasive mechanical ventilation constitutes a common problem associated with several complications. Therefore, secretion management represents a great challenge for respiratory therapists, nurses, and physicians, particularly in the patient with underlying airways disorders. This chapter discusses management of airway secretions in mechanically ventilated patients, focusing on physiology of mucus production, clearance, and the most common treatments, both pharmacologic and nonpharmacologic, to enhance removal of retained secretions. Although adequate humidification of the inspired gas plays a primary role on mucus clearance, the reader is referred to Chapter 51 for a comprehensive discussion of this topic.

PHYSIOLOGY OF AIRWAY SECRETION AND CLEARANCE

The lungs are exposed daily to 10,000 to 12,000 L of inhaled air, which potentially carries pathogens and noxious particles. Nevertheless, airways are efficiently protected by the airway lining fluid, which constitutes a physical barrier and a medium with antimicrobial and immunomodulatory properties. The airway lining fluid is a biphasic layer formed by a gel-phase (mucus), mainly consisting of water (97%), with proteins, lipids, electrolytes, and cellular debris making up the remaining 3% of its weight. By contrast, the inner layer is a low-viscosity sol-phase that mainly provides lubrication for continuous ciliary beating.

The main components of mucus are mucins. These are large (up to 3×10^6 Daltons per monomer) heavily glycosylated proteins that provide a tangled network necessary to entrap any particles inhaled during ventilation. Two different types of mucins have been identified: (a) cell-tethered and (b) secreted mucins. Cell-tethered mucins present several functions in cellular adhesion, pathogen binding, and cellular transduction. We focus on secreted mucins, because detailed description of membrane-bound mucins goes beyond the scope of this chapter.

Four genes coding for airway-secreted mucins have been identified and map to chromosome 11p15.5[1] and 12q12.[2] As depicted in Table 52-1, the genes can be found in different

TABLE 52-1: GENES CODING FOR SECRETED MUCINS IN THE AIRWAYS

Gene	Chromosomal Locus	Tissue Distribution	Airways Predominant Distribution
MUC2	11p15	Lung, conjunctiva, middle ear, stomach, small intestine, colon, nasopharynx, prostate	Surface goblet cell Duct of submucosal glands
MUC5AC	11p15	Lung, conjunctiva, middle ear, stomach, gallbladder, nasopharynx	Surface goblet cell
MUC5B	11p15	Lung, sublingual gland, laryngeal submucosal, esophageal glands, stomach, duodenum, gallbladder, nasopharynx	Surface goblet cells Submucosal glands
MUC19	12q12	Lung, salivary gland, kidney, liver, colon, placenta, prostate	Submucosal glands

organs; MUC5AC and MUC5B are the ones most commonly expressed in human airways.[3,4] Mucin genes comprise a single large central domain (approximately 10 kb) that encodes for serine-rich, threonine-rich, and proline-rich regions, which are the sites of *O*-linked glycosylation of mucins. Importantly, linked glycans present an extraordinary diversity[5] among species and even within species; this feature provides the highly efficient binding capability between mucus and almost any particle and/or pathogen deposited on the airways. The 5′ and 3′ genomic regions encode for the von Willebrand factor-like proteic regions, rich in cysteine,[6] which allow the disulfide bonds between mucin monomers to form the ultimate polymeric structure.

Airway Secretory Cells

The airways comprise ciliated and secretory cells, structured in a pseudostratified epithelium up to the main bronchi and as a simple cuboidal epithelium toward the peripheral airways. Mucus production in normal airways is low, approximately 10 to 100 mL/day; hence, airways are covered by a thin layer (approximately 5 µm) of mucus (Fig. 52-1B). In humans, MUC5AC is mainly produced by goblet cells[7] in the proximal airways, whereas goblet cells throughout the airways and submucosal glands mostly produce MUC5B.[8]

In healthy airways, epithelium goblet cells are outnumbered nearly fourfold by ciliated cells (Fig. 52-2A). Goblet cells contain cytoplasmic granules (see Fig. 52-1C), in which mucin polymers are firmly packed. When the polymers are secreted, the mucin polymers increase in size by 500 times their packed volume[9,10] secondary to hydration.

In airways with an internal lumen equal to or greater than 2 mm, mucus is largely produced by submucosal glands (see Fig. 52-2B and D). Mucus produced by the gland is drained through several tubules into the main duct, which finally narrows into a ciliated duct opening into the airways.[11] The submucosal gland is formed by mucus cells and serous cells. Gland serous cells secrete a low viscosity compounds with antiinflammatory and antimicrobial properties.

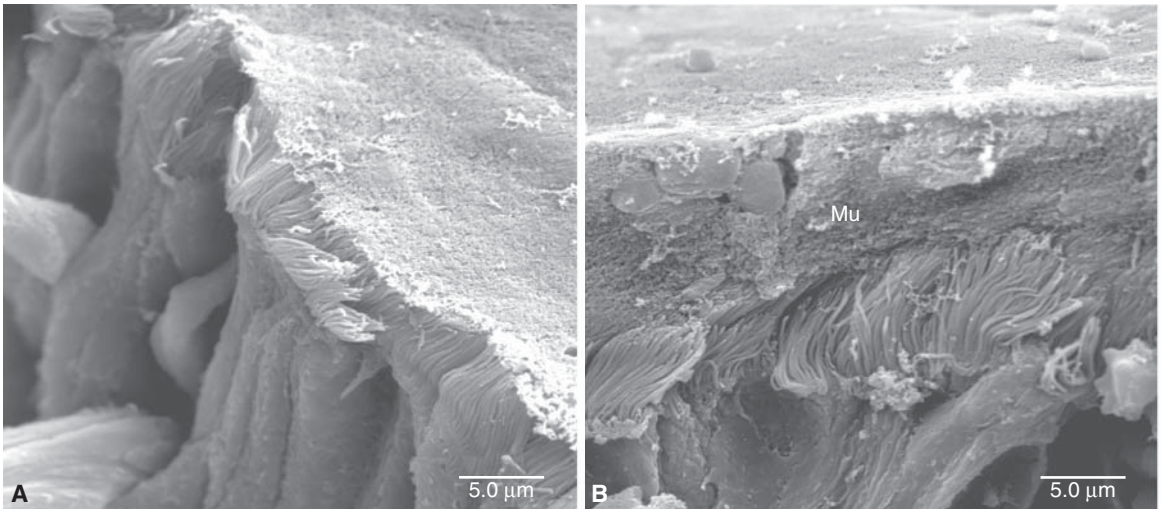

FIGURE 52-1 Microanatomy of the airway epithelium. The porcine airway epithelium was fixed with perfluorocarbon/osmium and imaged with a scanning electron microscope (A and B) and transmission electron microscope (C and D). **A.** The pseudostratified tracheal epithelium and the characteristic high density of cilia on the luminal surface are shown. Rare strings of mucus are evident above the cilia (magnification ×3000). **B.** A thin layer of mucus (approximately 5 µm) is demonstrated above the cilia (magnification ×3000).

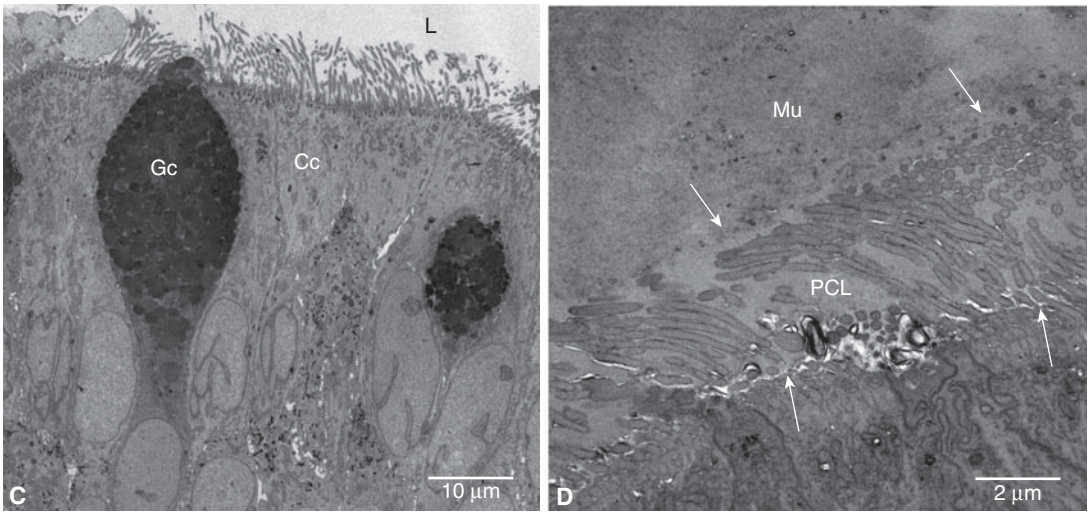

FIGURE 52-1 (*continued*) **C.** Higher magnification of the airway epithelium comprising goblet cells (*Gc*) and ciliated cells (*Cc*). Cilia are evident in the luminal (*L*) surface. Of note, electron-dense mucus granules of varying size are within the goblet cell (magnification ×3000). **D.** Microanatomy of the airway lining fluid. The *white arrows* delimitate the periciliary fluid. The electron-dense mucus layer (*Mu*) can be identified over the periciliary layer (magnification ×12,000). TABLE 52-2: MUC5AC EXPRESSION STIMULANTS

Inflammatory cytokines	TNF-α
	IL-1β
	IL-4
	IL-6
	IL-9
	IL-13
	IL-17
Bacterial products	LPS
	LTA
	Peptidoglycans
	Flagellin
Growth factors	EGF
	TGF-α
	Retinoic acids
	Thyroid hormones
Pollutants	Cigarette smoke
	Acrolein
Virus	Respiratory syncytial virus
	Rhinovirus

Abbreviations: EGF, epidermal growth factor; *IL*, interleukin; *LPS*, lipopolysaccharide; *LTA*, lipoteichoic acid; *TGF*, transforming growth factor; *TNF*, tumor necrosis factor.

See Thai et al[14] for a comprehensive review of regulation of mucins expression.

Several microbicidal products, that is, lysozyme, lactoferrin, collectins, defensins, and cathelicidins, have been identified in the airway lining fluid.[12,13]

Regulation of Mucus Production and Secretion

A small amount of mucus is continuously produced by goblet cells and submucosal glands so as to provide a barrier overlying the airway epithelium. Mucus production can be highly increased in response to stimuli. Several aspects of MUC5AC regulation have been elucidated in detail; conversely, regulation of MUC5B expression is still not entirely understood.[14] As depicted in Table 52-2, MUC5AC can be upregulated by several stimuli, among which interleukin-13 seems to play a primary role.[15,16]

Mucus secretion is regulated by three distinct neural pathways:[17,18] (a) the cholinergic, (b) the adrenergic, and (c) a nonadrenergic, noncholinergic (NANC) system. The cholinergic system is the most important motor control of secretion,[19] and cholinergic fibers can be identified in proximity to the submucosal glands. Parasympathetic nerve stimulation causes rapid mucus release through the muscarinic M3 receptors. Adrenergic stimulation of the airway epithelium causes only a small increase in mucus production. Finally, the NANC system is identified by the mucosecretory response following adrenoceptor and cholinoceptor blockade.[18,20] The main neurotransmitters of the NANC system are small-weight peptides, such as the vasoactive intestinal peptide, substance P, neurokinin A, and the gas nitric oxide.

Periciliary Liquid Layer and Mucociliary Clearance

The sol-phase, more properly termed *periciliary liquid layer*, is a thin low-viscosity fluid that extends to the height of the outstretched cilia[21] (see Fig. 52-1D). In humans, the periciliary liquid layer is approximately 7 μm thick and its volume is continuously regulated by the epithelial cells. Periciliary liquid layer water is driven by the luminal concentration of sodium chloride and resulting osmotic gradients. Hence, the epithelium controls the depth of the periciliary liquid layer through purinergic signaling[22,23] and activation of adenosine triphosphate $P2Y_2$ and adenosine A2b receptors. The purinergic signaling, in a paracrine–autocrine fashion, also regulates the cystic fibrosis transmembrane regulator chloride channel and the epithelial sodium channel.[24]

Each ciliated cell has approximately 200 cilia on its surface (see Fig. 52-1A), which move, within the periciliary liquid layer, at approximately 8 to 15 Hz.[25] Studies report mucociliary clearance rates between 4 and 20 mm/min, depending on the method of assessment.[26,27] Mucus clearance velocity decreases from central toward peripheral airways.[28,29] Interestingly, early studies have hypothesized that periciliary liquid layer is largely stationary.[30,31] More recent results[32,33] suggest that the outermost parts of the cilia (see Fig. 52-1B) initially move the mucus layer; as a result, because of the friction between mucus and the underlying fluid, the periciliary liquid layer is dragged along and travels at a similar rate.

Mucus Clearance via Two-Phase Gas–Liquid Transport

During breathing and cough, airflow interacts with the mucus lining the respiratory airways, which can be eventually propelled via a two-phase gas–liquid flow. Kim et al[34–36] first studied the critical conditions necessary to move mucus through such a mechanism. They demonstrated that the main factors consisted of (a) shear stress exerted by the airflow on the liquid layer; (b) the ratio between thickness of the mucus layer and the airway diameter; and (c) the rheologic properties of secretions. Importantly, during mechanical ventilation, inspiratory and expiratory airflows exert opposite shear forces on the mucus layer. Kim et al[36] assessed the in vitro effects of tidal airflow, tidal volume, and respiratory rate on movement of mucus simulants and found that mucus velocity can be predicted as follows:

$$Mucus\ Velocity \sim \rho v^{2*}(1\text{-}T_I/T_{TOT})^{*}\eta^{-1} \qquad (1)$$

where ρ is the gas density, v is the absolute value of the highest airflow velocity throughout the respiratory cycle, which is inversely related to the total cross-sectional area of the airways, T_I/T_{TOT} is the duty cycle, and η is the mucus

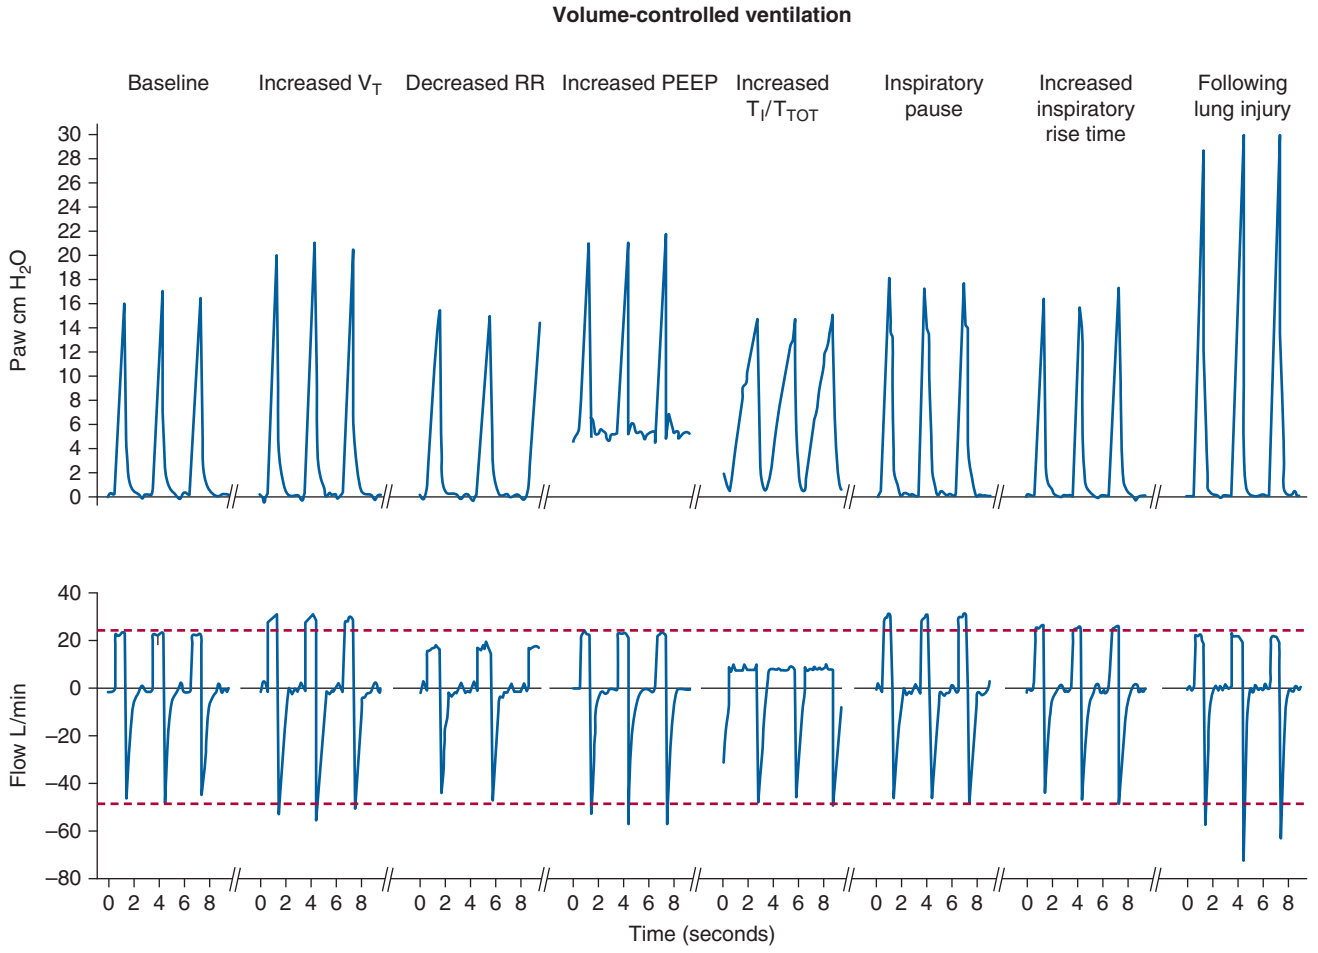

FIGURE 52-3 Pressure and flow waveforms during flow-controlled, volume-cycled ventilation in a healthy pig (36 kg) obtained with a SERVO-i mechanical ventilator (Maquet, Wayne, NJ). Inspiratory and expiratory flow rates generated with baseline ventilator settings (tidal volume [V_T] 290 mL, respiratory rate [*RR*] 20 breaths/min, duty cycle [T_I/T_{TOT}] 0.26) are compared against different adjustments of ventilator parameters. *Dotted red lines* indicate the highest inspiratory (21.6 L/min) and expiratory (–47.2 L/min) flow rates during baseline ventilation. An increase in tidal volume to 360 mL, an inspiratory pause of 6%, and an inspiratory rise time of 5% all increased inspiratory flow. Conversely, reducing the RR to 15 breaths/min and increasing T_I/T_{TOT} to 0.75, decreased the inspiratory flow. As expected, changes in lung volume, secondary to increased tidal volume or positive end-expiratory pressure (*PEEP*, 5 cm H_2O,) increased peak expiratory flow. Changes in elastic pulmonary conditions, induced by oleic-acid injury, caused an increase in peak expiratory flow. The effects of each individual ventilator setting on the net movement of mucus need to be thoroughly assessed by systematic in vivo studies.

viscosity. Tidal volume and respiratory rate were not associated with mucus movement; conversely, as reported in equation (1), the absolute value of the highest airflow influenced mucus movement. Indeed, the authors found that during volume-control mechanical ventilation mucus moved in waves, and the mucus speed was not influenced by the inspiratory flow until its rate reached 90% of the expiratory flow. A recent laboratory study by Volpe et al[37] confirmed previous results and also emphasized the role of lung impedance on mucus clearance. Intrinsic positive end-expiratory pressure (PEEP) caused by either elevated minute ventilation or expiratory resistance respectively improved and worsened mucus clearance.

Theoretically, during mechanical ventilation the difference between inspiratory and expiratory flow rate can be modulated by adjusting ventilator settings. As clearly described in Chapter 5, lung elastance, lung volume, and airway resistances are the major determinants of expiratory flow rate during passive expiration. In contrast, inspiratory flow can be easily modulated through the ventilator. For instance, Figures 52-3 and 52-4 imply that changes in (a) mode of ventilation, (b) tidal volume, (c) respiratory rate, (d) duty cycle (T_I /T_{TOT}), (e) inspiratory rise time, (f) inspiratory pause time, and (g) PEEP may all modify the inspiratory–expiratory flow rate difference. Despite consistent laboratory results, there is still great paucity of translational in vivo studies. To date, only one report in sheep has demonstrated the feasibility of mucus clearance via two-phase gas–liquid transport modulating the duty cycle.[38]

Mechanically ventilated patients are often positioned with the trachea oriented above the horizontal (i.e., the semirecumbent position). As a result, mucus transport via
