More recently, Claure et al performed a series of important investigations in closed-loop control of FI_{O_2} in neonates.[92–95] In their initial studies, the frequency of hypoxemia was not different between manual FI_{O_2} adjustment and automated FI_{O_2} adjustment. The nursing workload, however, was significantly less with the automated system.[96] In a second trial of sixteen mechanically ventilated infants, they found that, compared with manual adjustment, the percentage of time in the target SpO_2 range (88% to 95%) was greater during the automated control of FI_{O_2} (58% ± 10% vs. 42% ± 9%).[93] The percentage of time with SpO_2 less than 88%, however, increased during the automated period (33% ± 7% vs. 27% ± 9%) because of more frequent episodes of hypoxemia. The 4-hour median FI_{O_2} was lower during the automated period (29% ± 4% vs. 34% ± 5%).

The data suggest that by minimizing hyperoxemia (associated with retinal injury in premature infants), the incidence of hypoxemia may increase. The rapid response of the automated system to the hypoxemia, however, resulted in a similar durations of low SpO_2 between groups; that is, the number of hypoxemic events were more frequent, but the duration of each was shorter.

In their most recent trial of thirty-two premature infants, Claure et al demonstrated similar findings. The proportion of time that SpO_2 was in the target range (SpO_2 of 87% to 93%) was significantly greater during automated control of FI_{O_2} versus manual control (40% ± 14% vs. 32% ± 13%). Time with SpO_2 of less than 87%, however, increased significantly during the automated period (32% ± 12% vs. 23% ± 9%), with more frequent episodes with SpO_2 between 80% and 86%, whereas times with SpO_2 of less than 80% or less than 75% were not different. They also demonstrated significantly fewer manual FI_{O_2} changes (10 ± 9 vs. 112 ± 59 changes per 24 hours), compared with the manual period.[95] Figure 15-3 demonstrates the frequency of low SpO_2 events and required FI_{O_2} corrections in a single neonate on mechanical ventilation during a 4-hour period. This system remains under investigation and is not commercially available.

Johannigman et al investigated closed-loop FI_{O_2} in adult trauma patients with the goals of achieving normoxemia, preventing hypoxemia, and conserving oxygen.[97,98] These goals have significant importance during transport and in military operations. Closed-loop control of FI_{O_2} provides normoxemia regardless of the skill of the caregiver and prevents hypoxemia when patients are unattended.

Oxygen conservation is rarely an issue in the hospital, but is critical in resource-limited environments (e.g., mass casualty, far-forward deployments).

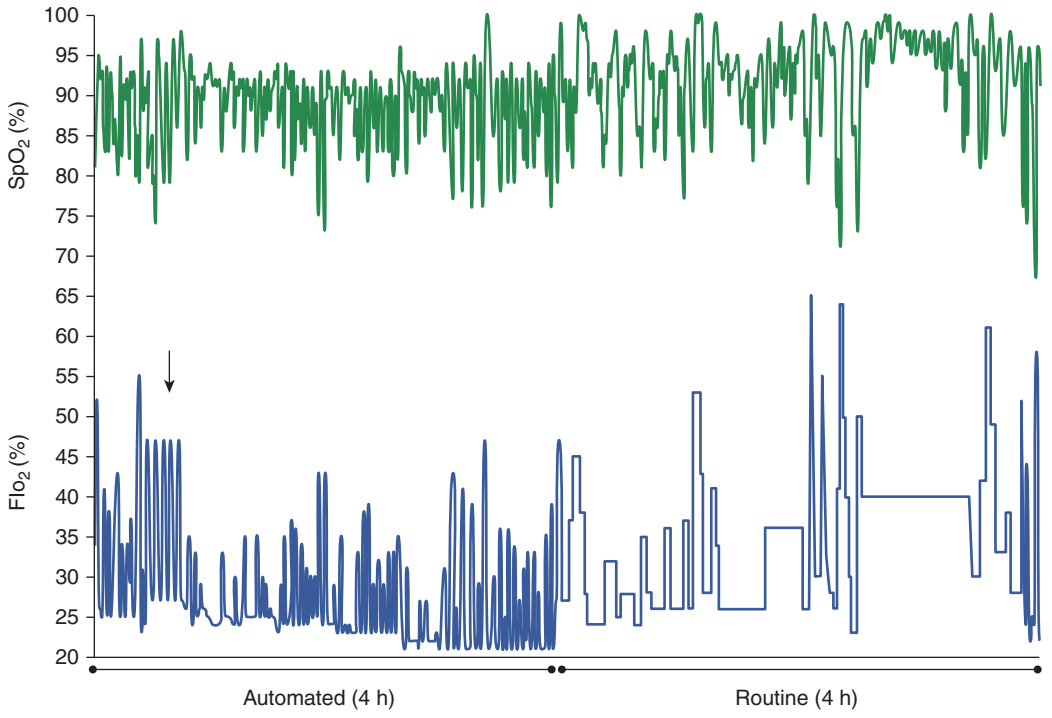

FIGURE 15-3 This recording of SpO_2 and FI_{O_2} illustrates the difficulty in maintaining SpO_2 within the intended range by manual FI_{O_2} adjustments during the routine period. These adjustments were not always consistent, and exposure to high FI_{O_2} was at times prolonged. Automated FI_{O_2} increases were brief in a gradually decreasing basal FI_{O_2}. The *arrow* points to manual FI_{O_2} adjustments during care procedures with the automated system on standby. (Used, with permission, from Claure, D'Ugard, and Bancalari.[93])

In an early pilot and follow-up study of forty-five trauma patients, Johannigman et al compared 4 hours of closed-loop control to 4 hours of manual FI_{O_2} control. They found that the target SpO_2 (92% to 96%) was achieved 82% of the time during closed-loop control versus only 37% of the time during manual control. The most common "out-of-target" condition in the manual control group was hyperoxemia (SpO_2 >97%), seen 61% of the time versus 17% during closed-loop control. The total time spent with SpO_2 less than 88% per patient was small (<1 minute) and was not different between groups. The authors also noted that many trauma patients never manifest hypoxemia, regardless of the study arm. Figure 15-4 is a graph of FI_{O_2} and SpO_2 during the 8-hour trial. This finding was recently supported by a Dutch study demonstrating hyperoxemia in trauma patients in spite of low inspired oxygen (<0.40).[99] These authors demonstrated that even in the face of significant hyperoxemia (Pa_{O_2} >120 mm Hg), if inspired oxygen was equal to or less than 0.40, clinicians rarely reduced FI_{O_2}. This was thought to be secondary to the commonly held belief that FI_{O_2} less than 0.50 is nontoxic to the lungs. This, however, does not account for potential negative consequences at the cellular level as a result of oxidative stress.[100] Oxygen usage was significantly less during closed-loop control (3 L/min) versus manual control (2.1 L/min). This 33% decrease in oxygen usage might be significant where oxygen stores are limited. Additionally, this level of oxygen requirement could be met with an oxygen concentrator.

Both these systems use a proportional-integral-derivative (PID) controller. In this case, a negative feedback PID system. A negative feedback system attempts to minimize the difference between the target value and the actual value. Ideally, the difference between target and measured is zero. In this instance, the FI_{O_2} is changed until the difference between the target SpO_2 and the measured SpO_2 is zero. A PID controller allows the FI_{O_2} to be changed in large steps based on the level of SpO_2 and the difference in set and actual SpO_2. When the target and measured values are close, the changes in FI_{O_2} are smaller. The FI_{O_2} can be adjusted both by changing the stepwise increase or decrease as well as the time between steps. At the time of this writing, no closed-loop FI_{O_2} system for mechanical ventilation is commercially available.

Concentration of Fractional Inspired Oxygen and Positive End-Expiratory Pressure Feedback Systems

Setting PEEP remains one of the most contentious issues in mechanical ventilation. Although automated control of FI_{O_2} is relatively simple, the effects of PEEP on hemodynamics, airway pressures, and lung protection create a much greater challenge. In preliminary findings, Lellouche et al found that in cardiac surgery patients, automated control of PEEP and FI_{O_2} resulted in similar outcomes compared to manual manipulations.[101] Interestingly, this group utilized

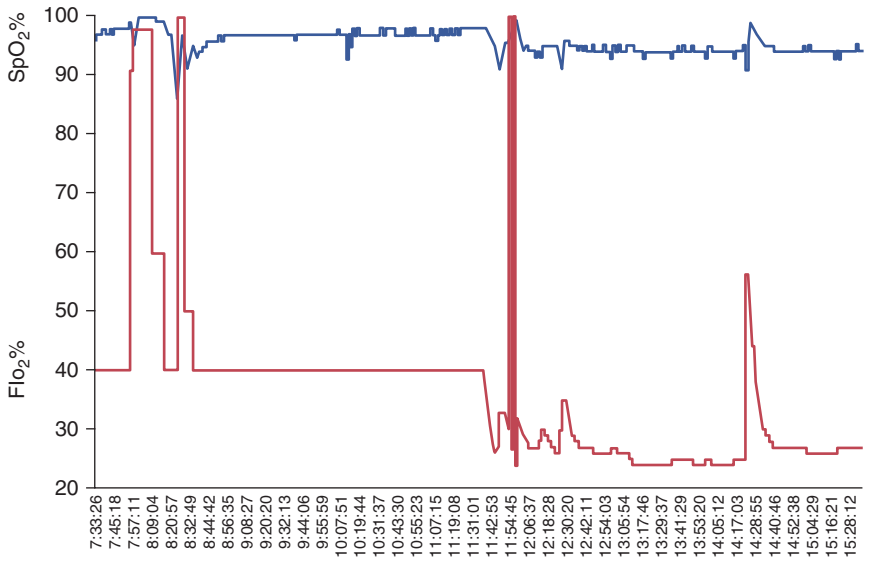

FIGURE 15-4 Example of closed-loop control of SpO_2 in an adult patient with traumatic respiratory failure. The first 4 hours represent the manual control period and the second 4 hours the automatic control period. Increases in FI_{O_2} to 100% are associated with hypoxemia (SpO_2 <88%).

the PEEP–FI_{O_2} table from the original ARDS Network trial to control the algorithm. We believe that a commercially available version of closed-loop control of PEEP would require some inference of hemodynamic performance or confirmation of hemodynamic stability by the caregiver. It may be that a decision-assist system for PEEP would be the first step.

FEEDBACK SYSTEMS DRIVEN BY NOVEL SENSORS OF PATIENT EFFORT

In the last decade, two novel feedback modes for delivering positive pressure in response to patient effort have been introduced.[50] The first is proportional-assist ventilation (PAV), which uses measured patient-generated inspiratory flow and then puts a clinician-set gain on both pressure and flow delivery.[102] PAV needs estimates of respiratory system compliance and resistance, which are determined from intermittent controlled "test" breaths or periodic pauses randomly applied during ventilation. The only clinician setting is then a proportion of the calculated work of breathing that the delivered flow and pressure are meant to overcome. The second is neurally adjusted ventilator assist (NAVA), which uses a diaphragmatic electromyogram signal on an esophageal catheter to determine patient effort during all three phases of breath delivery (i.e., trigger, flow delivery, and cycling).[103] Like PAV, NAVA applies a clinician-set gain to provide pressure and flow adjustments in proportion to the strength of the electromyogram signal. As these modes are not considered "conventional" modes of ventilation, they are not discussed further here. The reader is referred to more detailed accounts of these approaches in Chapters 12 and 13.

CONCLUSION

A positive-pressure breath ideally should provide a V_T that is adequate for gas exchange and appropriate muscle unloading while minimizing any risk for injury or discomfort. The latest generation of ventilators is now using sophisticated feedback systems to "sculpt" positive-pressure breaths according to patient effort and respiratory system mechanics. At the present time, however, these new control strategies are not totally "closed-loop" systems because the automatic input variables are still limited, some clinician settings are still required, and the specific features of the "perfect" breath design still are not entirely clear. Despite these limitations, there is at least some rationale for many of these newer feedback features, even though all of them await outcome studies to justify their widespread use.

NEGATIVE-PRESSURE VENTILATION

Antonio Corrado
Massimo Gorini

Conventional mechanical ventilation via endotracheal intubation or tracheostomy in the treatment of acute respiratory failure (ARF) is a lifesaving procedure. Yet it exposes patients to severe complications, including upper airway trauma and nosocomial pneumonia, and may prolong the length of stay in the intensive care unit (ICU) and hospital because additional time may be necessary for weaning.[1–4]

BASIC PRINCIPLES OF NEGATIVE-PRESSURE VENTILATION

Negative-pressure ventilation (NPV) works by exposing the surface of the thorax to subatmospheric pressure during inspiration. This pressure causes thoracic expansion and a decrease in pleural and alveolar pressures, creating a pressure gradient for air to move from the airway opening into the alveoli. When the pressure surrounding the thorax increases and becomes atmospheric or greater, expiration occurs passively owing to the elastic recoil of the respiratory system. The inspiratory changes with NPV, in pleural and alveolar pressures, replicate those during spontaneous breathing. On the contrary, positive-pressure ventilation (PPV) causes an increase in intrathoracic pressures during inspiration (Fig. 16-1).

All NPVs have two major components: an airtight, rigid chamber that encloses the rib cage and abdomen and a pump that generates pressure changes in the chamber.[5,6]

Negative-Pressure Ventilators

TANK VENTILATOR

Tank ventilators enclose the body up to the neck. The advantage is that chest wall expansion is not limited by contact with the sides of the chamber, and only one airtight

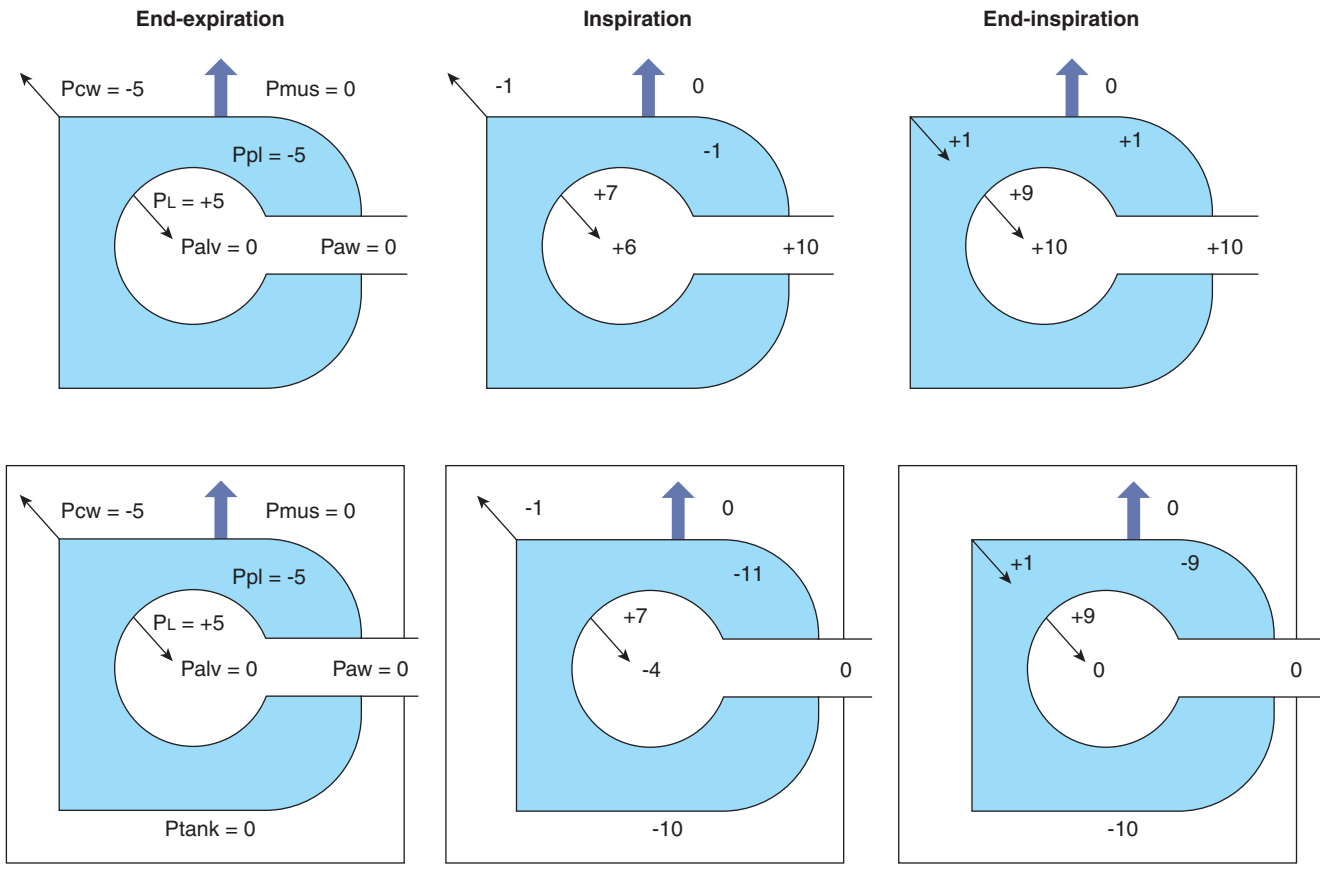

FIGURE 16-1 Airway and intrathoracic pressures during positive-pressure ventilation (*upper panel*) and during negative-pressure ventilation (*bottom panel*). *Palv,* Alveolar pressure; *PCW,* elastic recoil pressure of the chest wall; *PL,* elastic recoil pressure of the lung; *Paw,* airway pressure; *Pmus,* muscle pressure; *Ppl,* pleural pressure; *Ptank,* tank ventilator pressure.

seal is required around the neck. Most modern tank ventilators are constructed of aluminium and plastic and are lighter than previously. The patient's body rests on a thin mattress, and the head protrudes through a porthole at one end of the ventilator. A head and neck rest is provided in most designs to ensure comfort and to prevent upper airway collapse. Most tank ventilators have windows allowing patient observation and portholes for catheters and monitor leads and where procedures can be performed (Fig. 16-2).[7]

JACKET VENTILATOR (PULMO-WRAP, PONCHO-WRAP)

This ventilator is a windproof, water-permeable nylon parka suspended over a rigid grid that includes the rib cage and abdomen. It allows the application of negative pressure over the anterior portion of the chest wall.[8] Airtight seals around the neck, arms, and hips are required to prevent air leakage. The jackets do not restrain expansion of the rib cage and abdomen, but are awkward for many patients to put on and often cold to wear because of air leaks. They are preferable to tank ventilators for home use but less efficient for treating patients with ARF. The tidal volume they develop at any given level of negative pressure is less than that of a tank ventilator, and the peak pressure that patients can tolerate also usually is slightly less.[6]

CUIRASS

This consists of a rigid shell fitting firmly over the anterior portion of the chest. It applies negative pressure over a smaller surface area than either the iron lung or jacket and is the least efficient NPV.[8] Its efficiency improves if the anterior abdominal wall is enclosed in the device and movement of the lateral aspect of the upper rib cage is not restrained. Proper fitting can be difficult, and tailor-made fiberglass shells often are necessary, particularly in patients with kyphoscoliosis.

Negative-Pressure Ventilator Pumps

Negative pressure is generated by bellows or rotary pumps that are separate or incorporated into the structure of the ventilator. Modern rotary pumps perform pressure-preset

FIGURE 16-2 Microprocessor-based iron lung (Coppa CA 1001, Coppa, Biella, Italy).

ventilation.[9] After a breath is initiated, these pumps apply and maintain a targeted amount of subatmospheric pressure around the chest wall to meet a specified time-cycling criterion (Fig. 16-3). This mode is equivalent to pressure-controlled ventilation available with the latest PPVs. As with positive-pressure preset ventilation, tidal volume during NPV is a complex function of applied pressure and its rate of approach to target pressure, available inspiratory time, and the impedance to breathing (compliance of the respiratory system, airway resistance, and dynamic hyperinflation with intrinsic positive end-expiratory pressure [PEEP]).

Modes for Delivering Negative-Pressure Ventilation

Traditionally, NPV is controlled mechanical ventilation, and the device provides a fixed number of breaths per minute. If mechanical and spontaneous respiratory cycles do not match, the patient "fights" the ventilator, resulting in discomfort. Unlike PPV, during NPV, the airway opening is free; consequently, it is not possible to monitor airway pressure or flow continuously and to use these signals to trigger a mechanical breath. This patient-triggering inability may contribute to poor patient synchrony and induction of upper airway collapse secondary to the lack of coordinated activity between the upper airway and the inspiratory muscles.[10] To overcome this limitation, some NPVs have incorporated patient-triggered modes using pressure change sensed via nasal prongs. There are data indicating that this technology is slow and relatively insensitive to patient inspiratory efforts.[11] Recently, the performance of a prototype microprocessor-based iron lung capable of thermistor triggering was evaluated.[12] The device used to trigger the iron lung was thermally sensitive and similar to that used in sleep studies, and it was activated by temperature changes caused by the onset of inspiratory airflow (Fig. 16-4). In normal subjects and patients with chronic obstructive pulmonary disease (COPD) recovering from ARF, we measured (a) the time delay between airflow onset and start of an assisted breath, (b) pressure-time product for the diaphragm per minute (PTPdi) during triggered breaths, and (c) nontriggering inspiratory efforts (Fig. 16-5). At maximum trigger sensitivity, the time delay was about 0.21 second in both groups. PTPdi was reduced markedly. Nontriggering inspiratory efforts were 1.1% and 2.3% of total breaths, respectively. Although the time delay of the thermistor trigger is longer than most recent flow-triggering and pressure-triggering systems of PPVs,[13] the study suggests that this system permits the use of assisted NPV with an acceptable patient–ventilator interaction.

Presently, NPV can be delivered by five modes: (a) intermittent negative pressure, (b) negative/positive pressure, (c) continuous negative pressure (CNEP), (d) negative pressure/negative end-expiratory pressure (Fig. 16-6), and (e) external high-frequency oscillation.

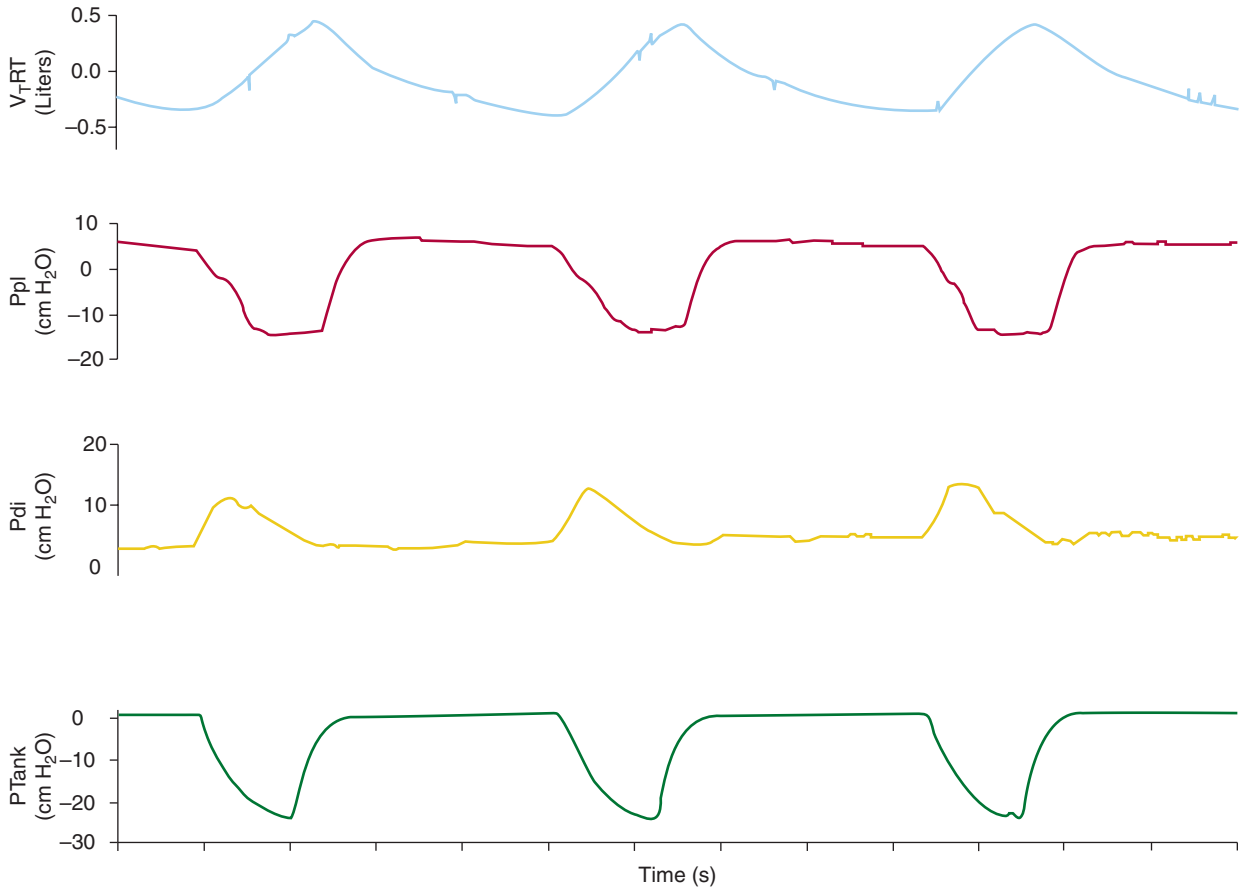

FIGURE 16-3 Recordings of tidal volume by Respitrace (V_T *RT*), pleural pressure (*Ppl*), transdiaphragmatic pressure (*Pdi*), and tank pressure (*Ptank*) in a patient with an acute exacerbation of chronic obstructive pulmonary disease during assist negative-pressure ventilation provided by iron lung.

INTERMITTENT NEGATIVE PRESSURE

The ventilator generates targeted subatmospheric pressure for the selected inspiratory time. Pressure around the chest wall becomes atmospheric during expiration, which occurs passively owing to the elastic recoil of the respiratory system.

NEGATIVE/POSITIVE PRESSURE

The ventilator generates the preset extrathoracic subatmospheric pressure during inspiration and preset extrathoracic positive pressure during expiration. In patients with chest wall disorders, this combination has been found to increase tidal volume more than intermittent negative pressure alone by reducing the end-expiratory volume of the respiratory system.[14] A useful application of this option is to assist cough and promote clearance of sputum in patients with copious secretions i.e., cystic fibrosis and bronchiectasis.[8]

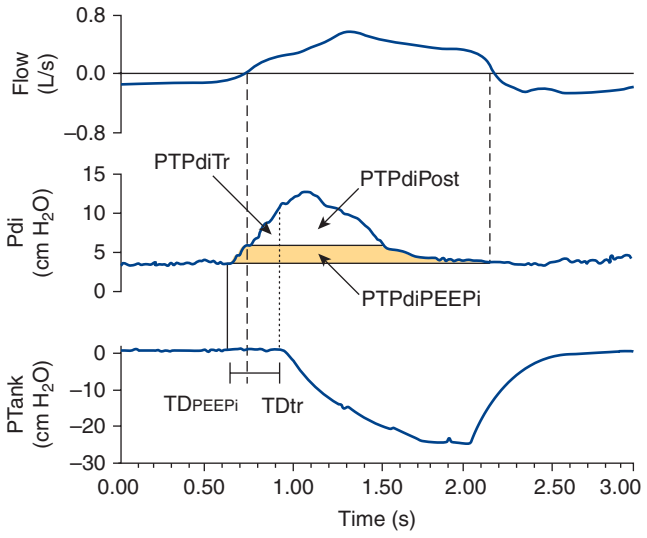

FIGURE 16-5 Recordings of flow, transdiaphragmatic pressure (*Pdi*), and tank pressure (*Ptank*) in a patient with chronic obstructive pulmonary disease receiving assist NPV. The *continuous vertical line* indicates the onset of inspiratory effort, the *dashed vertical line* indicates the start of inspiratory flow, and the *dotted vertical line* indicates the start of an assisted breath. The partitioning of the pressure-time product of the diaphragm is shown: effort required to overcome intrinsic positive end-expiratory pressure (*PTPdiPEEPi*), effort required to trigger the assisted breath (*PTPdiTr*), and effort exerted in the post-trigger phase (*PTPdiPost*). TDPEEPi and TDtr indicate the time delay between the onset of inspiratory effort and the start of inspiratory flow and the time delay between the onset of inspiratory flow and the start of assisted breath, respectively. (Used, with permission, from Gorini, et al. Effect of assist negative pressure ventilation by microprocessor based iron lung on breathing effort. *Thorax.* 2002;57:258–262.)

CONTINUOUS NEGATIVE EXTRATHORACIC PRESSURE

The ventilator provides a constant subatmospheric pressure throughout the respiratory cycle, and the patient breathes spontaneously.

NEGATIVE PRESSURE AND NEGATIVE EXTRATHORACIC END-EXPIRATORY PRESSURE

The ventilator generates the preset subatmospheric pressure during inspiration and maintains a preset level of negative pressure throughout the expiration.

EXTERNAL HIGH-FREQUENCY OSCILLATION

High-frequency ventilation using a jet system can be applied via a tracheal tube or a tracheotomy. Alternatively, a cuirass can be used to apply high-frequency oscillation externally.[15] The Hayek oscillator includes a cuirass, power unit, and control unit. The power unit has (a) a diaphragmatic pump, which can operate over a wide range of frequencies to generate an oscillating pressure wave, and (b) a vacuum pump, which enables the oscillation to be superimposed on a negative-pressure baseline. Peak inspiratory (up to −70 cm H_2O) and peak expiratory (up to 70 cm H_2O) pressures, frequency (8 to 999 cycles per minute), and inspiratory-to-expiratory timing (I:E) ratio (1:6 to 6:1) can be set on the control unit.

Two studies suggest that external high-frequency oscillation can provide effective ventilation in healthy subjects[15] and improve end-tidal carbon dioxide (CO_2) and oxygen (O_2) saturation (SaO_2) in patients with severe stable COPD.[16] In five patients with ARF, short-term application of external high-frequency oscillation improved oxygenation by 16% and reduced Pa_{CO_2} by 6%, compared with conventional PPV.[15] In a randomized, controlled study, a 4-hour period of external high-frequency oscillation improved cardiac index and tissue perfusion in adult patients after coronary artery bypass grafting compared with conventional PPV.[17]

PHYSIOLOGIC EFFECTS

Gas Exchange

Pioneering studies showed NPV, particularly that provided by tank ventilators, to be a highly effective form of mechanical ventilation, capable of maintaining normal arterial blood-gas tensions in patients with little or no spontaneous respiratory activity.[18–20] Recently, it has been shown[21] that CNEP, NPV, and NPV plus negative extrathoracic end-expiratory pressure provided by a microprocessor-based iron lung were able to improve ventilatory pattern, arterial blood gases, and pH significantly (Fig. 16-7).

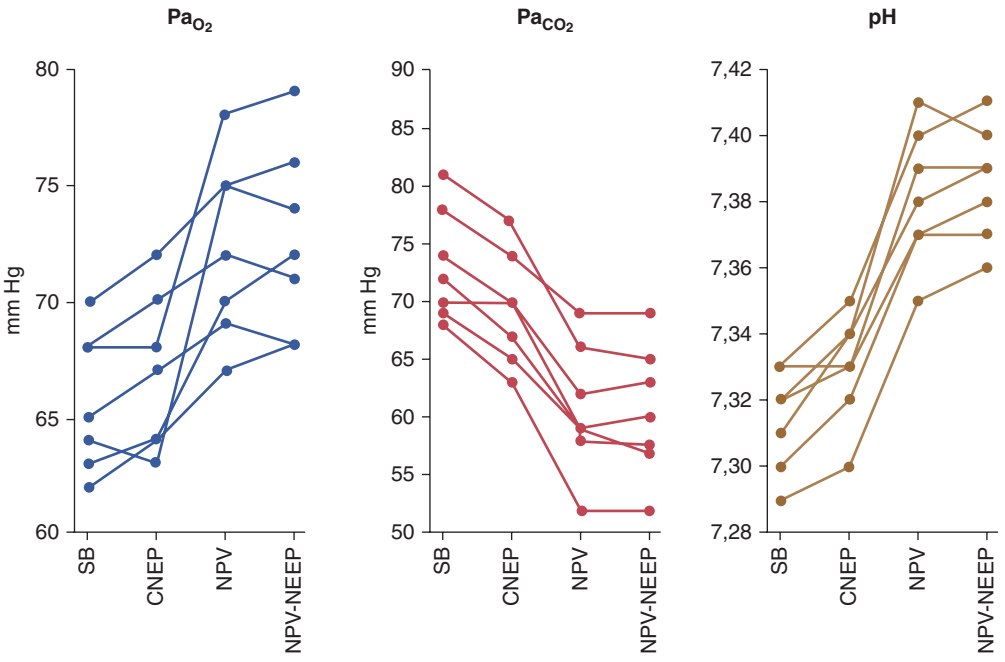

FIGURE 16-7 Values for Pa_{O_2}, Pa_{CO_2}, and pH in seven patients with acute exacerbation of chronic obstructive pulmonary disease during spontaneous breathing (*SB*), continuous negative extrathoracic pressure (*CNEP*), negative pressure ventilation (*NPV*), and negative extrathoracic end-expiratory pressure added to NPV (*NPV-NEEP*). Official Journal of the American Thoracic Society.)

Respiratory Muscles

Two studies[22,23] reported that in patients with acute exacerbation of COPD, NPV was effective in improving respiratory muscle strength and in decreasing Pa_{CO_2}. In patients with chronic respiratory failure secondary to COPD and restrictive diseases, NPV reduced electrical and mechanical activity of the inspiratory muscles.[24–28] Rodenstein et al[29] showed that controlled NPV provided by an old iron lung requires a short period of adaptation to obtain inspiratory muscle rest. Other studies show that when inspiratory and expiratory times are adjusted carefully to approximate the subject's spontaneous timing components, NPV results in a substantial suppression of electromyographic activity of inspiratory muscles.[25,26] Assist-control NPV provided by a cuirass is effective in relief of dyspnea induced experimentally in normal subjects by a combination of inspiratory resistive loading and hypercapnia, probably reducing inspiratory muscle workload.[30]

The effects of NPV provided by a microprocessor-based iron lung capable of providing CNEP and assist-control NPV on respiratory mechanics and inspiratory muscle effort in patients with COPD with ARF were evaluated by measuring the pressure-time product of the diaphragm and the electromyographic activity of parasternal muscles.[21] Compared with spontaneous breathing, CNEP (−5 cm H_2O) resulted in a significant decrease in dynamic intrinsic PEEP and pressure-time product of the diaphragm, whereas assist-control NPV caused a significant improvement in the pattern of breathing associated with a marked reduction in both pressure-time product of the diaphragm and electromyographic activity of the parasternal muscles. The application of −5 cm H_2O of negative extrathoracic end-expiratory pressure during NPV further decreased the pressure-time product of the diaphragm slightly and improved patient–ventilator interaction by reducing dynamic intrinsic PEEP and nontriggering inspiratory effort (Fig. 16-8). Reduction in diaphragmatic effort obtained during assist-control NPV[21] is similar to that measured in patients with an acute exacerbation of COPD with pressure-support ventilation.[31,32]

Upper Airway

The application of NPV during sleep in normal subjects,[33] and in patients with chronic respiratory failure secondary to COPD[10] and neuromuscular disorders,[34,35] may result in the development of recurrent episodes of apnea and hypopnea, as well as altered sleep quality.[10,34] However, a recent controlled study in patients with neuromuscular disorders showed that NPV resulted in a general improvement in sleep quality and oxygen saturation.[36] It has been reported that in normal subjects during voluntary respiratory muscle relaxation, NPV caused a decrease in the caliber of the upper airway at the glottic or supraglottic level.[37] In normal, awake subjects, the glottis width did not decrease with the increase in negative pressure applied to the chest wall.[38] Consequently, the increasing level of NPV resulted

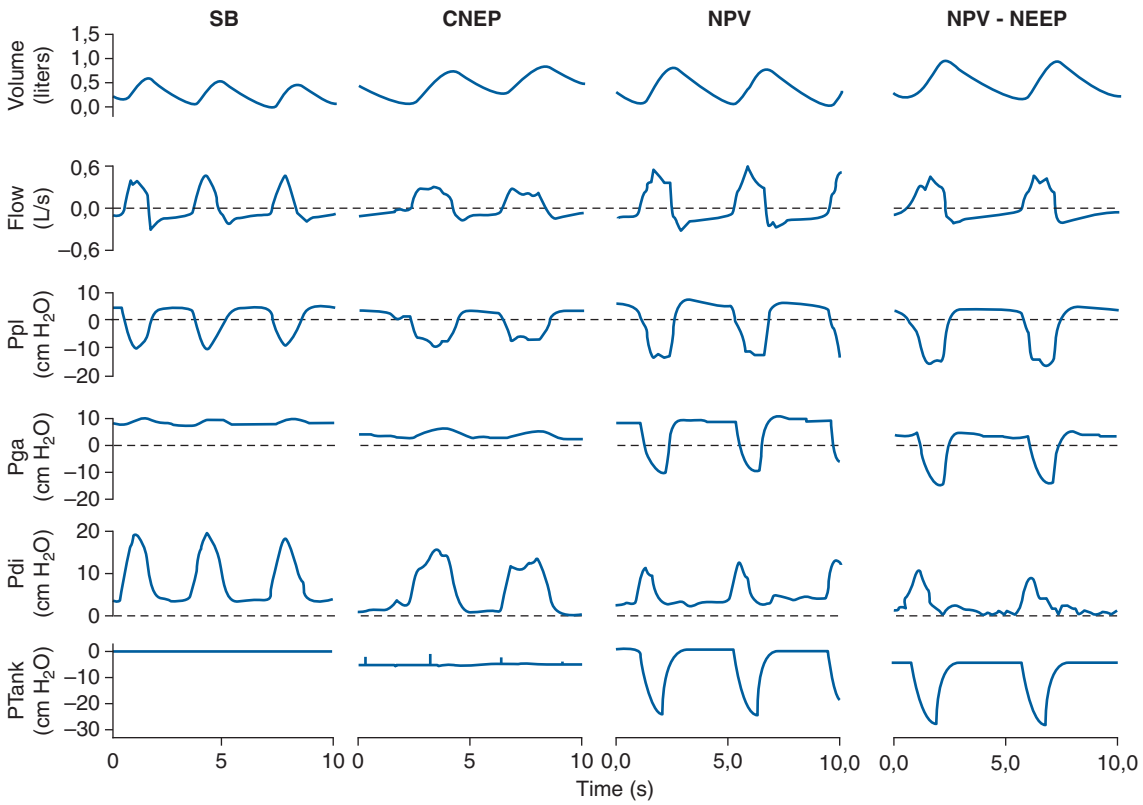

FIGURE 16-8 Recordings of volume, flow, pleural pressure (*Ppl*), gastric pressure (*Pga*), transdiaphragmatic pressure (*Pdi*), and tank pressure (*Ptank*) in a patient with an acute exacerbation of COPD during spontaneous breathing (*SB*), continuous negative extrathoracic pressure (*CNEP*), negative-pressure ventilation (*NPV*), and negative extrathoracic end-expiratory pressure added to NPV (*NPV-NEEP*). The *dashed lines* indicate the level of zero in flow, Ppl, Pga, and Pdi recordings. (Reprinted with permission of the American Thoracic Society. Copyright © 2012 American Thoracic Society. in progressive increases in tidal volume and minute ventilation. On the contrary, control positive-pressure ventilation provided by mask caused inspiratory adduction of the vocal cords, which reduced the tidal volume effectively reaching the lungs.[39,40]

The mechanisms of upper airway obstruction observed with NPV at supraglottic level have not been elucidated fully. During spontaneous breathing, activation of the pharyngeal and laryngeal muscles precedes activation of the inspiratory muscles, resulting in stiffening of the upper airway walls. When NPV is applied during sleep or in completely relaxed subjects, this coordinated respiratory muscle activity may be abolished. Consequently, the subatmospheric pressure developed in the upper airway during inspiration may result in their collapse.[5,10,34,37] Upper airway obstruction has been reported in two of ten patients with acute-on-chronic respiratory failure during treatment with NPV[41] and was the reason for NPV failure in 16% of patients in a large prospective cohort study.[42]

Lower Esophageal Sphincter

NPV may induce a lower esophageal sphincter dysfunction in healthy subjects[43] and in patients with COPD.[44] This dysfunction may cause regurgitation of stomach contents and expose patients to the risk of aspiration. It can be prevented completely with metoclopramide.[44]

Cardiovascular

The hemodynamic effects of mechanical ventilation are complex and are the result of changes in intrathoracic pressure and lung volume, which independently can affect the determinants of cardiovascular performance.[45–47] The increase in intrathoracic pressure caused by PPV decreases both venous return to the right ventricle and left-ventricular afterload. The net effect of this reduction depends on the cardiac function. When left-ventricular function is impaired, cardiac output increases in response to the rise in intrathoracic pressure because the decrease in left-ventricular afterload secondary to the reduction in transmural pressure has a greater effect than the decrease in venous return.[48] When left-ventricular function is normal, the increase in intrathoracic pressure reduces cardiac output because the decrease in venous return has more effect than the decrease in left-ventricular afterload.[49] In clinical situations such as hypovolemia, septic shock, and gas trapping associated with airflow obstruction, the reduction in cardiac output is more relevant.[50]

Although the hemodynamic effects of NPV have not been studied extensively,[51] the effects are assumed to be the opposite of those of PPV, that is, more physiologic and more likely to maintain a normal cardiac output. The exposure of the entire body (except for the airway opening) to NPV by tank ventilators, however, results in the same hemodynamic effects as occurs with PPV.[52] These effects occur because intrathoracic pressure actually is raised relative to body surface pressure, reducing the gradient for venous return. This consequence is not seen when NPV is confined to the thorax and upper abdomen using a cuirass or poncho-wrap.[53,54] Unlike tank ventilators, these machines selectively decrease intrathoracic pressure so that right-atrial pressure becomes more negative relative to the rest of body, potentially enhancing the gradient for venous return. In an animal model of acute lung injury, NPV plus negative extrathoracic end-expiratory pressure, provided by poncho-wrap, resulted in a similar improvement in gas exchange and in higher cardiac output compared with PPV plus PEEP.[53] In anaesthetized dogs, PPV plus PEEP and NPV plus negative extrathoracic end-expiratory pressure applied by iron lung had a similar effect on cardiac output, whereas the latter was higher with NPV plus negative extrathoracic end-expiratory pressure applied by poncho-wrap compared with the other two modes.[54]

NPV provided by cuirass does not induce adverse hemodynamic effects in stable patients with COPD,[55] whereas a significant reduction in cardiac output has been reported with mask ventilation with PEEP in patients with COPD, both when stable[56] and during acute exacerbations.[57] Short-term studies have compared the effects of CNEP provided by cuirass[58] or poncho-wrap[59,60] with those of PEEP in intubated patients with acute lung injury receiving volume-controlled ventilation. CNEP was adjusted to obtain the same change in transpulmonary pressure[60] or functional residual capacity[58] as with PEEP. The combination of volume-controlled ventilation with CNEP, compared with volume-controlled ventilation with PEEP, resulted in significant increases in oxygen delivery and cardiac index, whereas arterial oxygen content and Pa_{O_2}/FI_{O_2} ratio did not differ between the two modes of ventilation.[58–60] Further studies are required to define the feasibility of long-term clinical treatment with CNEP during controlled ventilation via endotracheal intubation and its effects on clinical outcomes. Children with congenital heart diseases, submitted to right-sided heart surgery with Fontan-type procedures, have unique cardiopulmonary physiology. In the absence of a right ventricle, pulmonary blood flow, the major determinant of cardiac output, is exquisitely sensitive to changes in intrathoracic pressure. In these patients, NPV, provided by cuirass, markedly increased pulmonary blood flow and cardiac output compared with volume-controlled PPV.[61,62]

Recently, the effects of CNEP applied to the chest through a cuirass during PPV in synchronized intermittent mandatory ventilation mode were evaluated in twenty patients with normal left-ventricular ejection fraction 2 hours after coronary artery bypass graft. With CNEP and synchronized intermittent mandatory ventilation, the stroke-volume index and cardiac index were significantly increased compared to ventilation with synchronized intermittent mandatory ventilation and PEEP. CNEP also reduced venous pressure and wedge pressure. Although the improvement in cardiac index and stroke volume was modest, the application of CNEP during PPV may have a greater benefit in patients with reduced ventricular function.[63]

RATIONALE, ADVANTAGES, AND LIMITATIONS

Rationale

NPV can be used to widen the field of application of noninvasive ventilator techniques. It is well known that compared with standard medical treatment, mask ventilation reduces the need for endotracheal intubation[64–66] and reduces hospital mortality[64–67] in selected patients with an acute exacerbation of COPD. A randomized study comparing mask with conventional mechanical ventilation in patients with exacerbations of COPD who failed medical treatment has shown that mask ventilation avoided endotracheal intubation in 48% of patients.[68] Mask ventilation, however, is not without its problems, and failure rates of 7% to 50% are reported.[69] Severe respiratory acidosis[70–72] and illness at presentation,[70,73] excessive airway secretions,[73] and inability to minimize the amount of air leakage[73] are major factors associated with failure of this technique.

In clinical studies, NPV has been used successfully in patients with severe respiratory acidosis or impaired level of consciousness.[74–76] During NPV, the airway opening is free, unlike in PPV, and consequently, performing bronchial aspiration or fiberoptic bronchoscopy to remove excessive airway secretions is easy. Finally, NPV can be used in patients who cannot tolerate a mask because of facial deformity, or as a rescue therapy to avoid endotracheal intubation in those in whom mask ventilation fails. Routine implementation of noninvasive PPV in critically ill patients with acute exacerbations of COPD or severe cardiogenic pulmonary edema was associated with improved survival and reduction of nosocomial infection.[77] For these reasons, mask ventilation is recommended as the standard method of ventilator support for exacerbations of COPD; invasive mechanical ventilation is regarded as second-line rescue therapy when mask ventilation fails.[78]

To verify the hypothesis that using both noninvasive mask and iron-lung ventilation should further reduce the need for endotracheal intubation in patients with acute on chronic respiratory failure, a prospective cohort study was carried out in 258 consecutive patients[42]: 77% of the patients were treated exclusively with noninvasive ventilation (40% with NPV, 23% with mask, and 14% with the sequential use of both) and 14% with invasive ventilation. In patients in whom NPV or mask ventilation failed, sequential use of the alternative technique allowed a significant reduction

in the failure of noninvasive mechanical ventilation (from 23.4% to 8.8%, p = .002, and from 25.3% to 5%, p = .0001, respectively). Overall hospital mortality (21%) was lower than that estimated by Acute Physiology and Chronic Health Evaluation (APACHE) II score (28%). This study shows that use of NPV and mask ventilation made it possible to avoid endotracheal intubation in the vast majority of unselected patients with acute-on-chronic respiratory disorders needing ventilator support.[42] Another recent study reported that using both modalities of noninvasive ventilation in patients with acute-on-chronic respiratory failure, the total rate of success in avoiding endotracheal intubation was 81.6%.[79]

Advantages

As with other modalities of noninvasive ventilation, the major advantage of NPV is the avoidance of endotracheal intubation and its related complications[1–4] while preserving physiologic functions such as speech, cough, swallowing, and feeding. Moreover, because the airway opening is free, airway suction and therapeutic and diagnostic maneuvers by fiberoptic bronchoscopy are performed more easily during NPV[41] than during mask ventilation.

Limitations

The following limitations should be considered when treating patients with NPV. First, the lack of upper airway protection, as with all modalities of noninvasive ventilation, may result in aspiration, especially in unconscious patients. Second, upper airway obstruction may occur or be enhanced in unconscious patients, patients with neurologic disorders that cause bulbar dysfunction, and patients with obstructive sleep apnea syndrome.[10,33–35] This effect compromises the effectiveness of ventilation with NPVs and requires shifting to PPV. In unconscious patients with normal bulbar function, the positioning of an oropharyngeal airway can minimize the risk of airway collapse. Third, tank and wrap ventilators restrict patients to the supine position, which may induce muscular back and shoulder pain. Fourth, severe obesity and kyphoscoliosis often compromise the possibility to put the patients in an iron lung or other NPV.

The incidence of complications and side effects of NPV delivered by iron lung was evaluated recently in 153 patients with acute-on-chronic respiratory failure[42] (Table 16-1). While NPV outcomes, such as complications and mortality rate, are within the ranges reported for noninvasive PPV,[80] it must be stressed that there are some difficulties in introducing this modality in the vast majority of ICUs, where mask ventilation is preferred as a noninvasive means of ventilation.[81,82] The main reasons are that the iron lung is cumbersome and needs a large amount of space, and most caregivers presently have little or no experience with NPV, rather than problems associated with NPV per se.

INDICATIONS AND CONTRAINDICATIONS

Acute Respiratory Failure

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Large studies with different experimental designs have reported the effectiveness of NPV in the treatment of patients with acute-on-chronic respiratory failure caused mainly by COPD (Table 16-2).[42,75,79,83–89] The effectiveness of NPV provided by iron lung in patients with hypercapnic encephalopathy was evaluated retrospectively in 150 consecutive patients (79% with COPD).[74] On admission, severe hypoxemia (Pa_{O_2} = 56 ± 22 mm Hg) and hypercapnia (Pa_{CO_2} = 112 ± 21 mm Hg) with respiratory acidosis (pH 7.13 ± 0.13) were present, Glasgow coma score ranged from 3 to 8, and the mean APACHE II score was 31.6 ± 5.3. The failure rate of NPV (death or need for endotracheal intubation) was forty-five of 150 (30%); the observed mortality rate was 24% versus 67.5% predicted mortality based on APACHE II. Nine patients (6%) required intubation because of a lack of control of the airway. In recent years, the effectiveness of NPV for the treatment of acute-on-chronic respiratory failure in patients with COPD has been confirmed in two case-control studies[75,87] and in two randomized, prospective control studies[88,89] (Table 16-2).

NEUROMUSCULAR DISORDERS

Few uncontrolled studies have investigated the effect of NPV in the treatment of neuromuscular patients with ARF. NPV, provided by iron lung[90–92] or pneumowrap,[93] was successful in avoiding endotracheal intubation and

in facilitating weaning from invasive ventilation in small groups of patients. In a retrospective study, we reported the effects of NPV provided by iron lung in the treatment of fifteen neuromuscular patients with ARF.[94] On admission, all patients exhibited severe hypoxemia ($Pa_{O_2} = 37.6 \pm 12.4$ mm Hg) and hypercapnia ($Pa_{CO_2} = 88.2 \pm 20.4$ mm Hg) with uncompensated respiratory acidosis (pH 7.25 ± 0.08). The treatment was successful in twelve of fifteen patients (80%). Although these reports suggest that NPV can be effective in the treatment of ARF in patients with neuromuscular diseases, prospective, controlled studies are needed to clarify the impact of noninvasive ventilation on clinical outcome in these patients.

PEDIATRIC DISEASES

During the 1970s and 1980s, several uncontrolled[95–98] and controlled[99,100] studies showed that NPV was effective in the management of the neonatal respiratory distress syndrome. More recently, Samuels et al[101] performed a prospective, randomized, controlled trial over a period of 4 years in 244 neonates comparing CNEP (−4 to −6 cm H_2O) with standard therapy that included continuous positive airway pressure of 4 cm H_2O. They found that need for intubation was slightly less with CNEP than with standard therapy (86% vs. 91%).

Infants with ARF who fail to respond to conventional ventilation are considered elective candidates for extracorporeal membrane oxygenation. In 1989, an uncontrolled study reported that the use of CNEP administered by a tank ventilator in conjunction with invasive ventilation was successful in five neonates suffering from respiratory failure and persistent pulmonary hypertension, thus avoiding the use of extracorporeal membrane oxygenation.[102] The benefit of combining invasive ventilation and CNEP in these patients has been confirmed by the same group in a crossover prospective, randomized study.[103] Patients treated with CNEP showed a greater increase in Pa_{O_2} than did those treated with PEEP without any increase in morbidity.

Chronic Respiratory Failure

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

There is no evidence that long-term NPV treatment can improve respiratory muscle function, exercise endurance, quality of life, and survival in patients with severe COPD.[28,104–108] It is important to stress that until now, no other ventilator technique has been shown to be effective in the long-term treatment of stable patients with COPD.

RESTRICTIVE DISORDERS

Many studies, although uncontrolled, have shown that NPV can be used successfully for long-term home ventilation in patients with restrictive ventilatory impairment secondary to neuromuscular and chest wall diseases.[109–114] NPV devices, however, are more cumbersome and difficult to use than recent home PPVs. In patients who need discontinuation of mask ventilation secondary to intolerable nasal irritation or upper airway congestion,[115] and in those

with other clinical condition, such as facial deformity or lack of teeth, NPV should be used as an alternative to mask ventilation.

Other Applications

NEGATIVE PRESSURE VENTILATION DURING RIGID BRONCHOSCOPY

Some studies report that in patients submitted to interventional rigid bronchoscopy under general anesthesia, NPV,[116–118] compared with spontaneous assisted ventilation, was able to prevent apnea and significant intraoperative derangement of acid–base balance, and was associated with a reduction in administration of opioids and shortened recovery time.

COMPARISON WITH OTHER MODES

Negative-Pressure Ventilation versus Invasive Mechanical Ventilation

Two studies have compared the effects of NPV and conventional invasive mechanical ventilation (IMV) in patients with COPD and severe ARF.[75,88] A retrospective case-control study, carried out in sixty-six patients,[75] showed that NPV was associated with a similar mortality rate to that of IMV (23.1% and 26.9%, respectively) and a reduction in duration of ventilation in survivors. These findings were recently confirmed in a prospective, randomized, controlled study.[88] Forty-four patients with an exacerbation of COPD and severe respiratory acidosis (mean pH 7.20 ± 0.04) were assigned either to iron-lung ventilation (twenty-two patients) or IMV (twenty-two patients). Primary end points were improvement in gas exchange and complications related to mechanical ventilation. Compared with baseline, NPV and IMV induced a similar and significant improvement in Pa_{O_2}/FI_{O_2}, Pa_{CO_2}, and pH after 1 hour and at discontinuation of treatments. Among patients treated with NPV, four (18.2%) needed endotracheal intubation. Major complications tended to be more frequent in patients treated with IMV than in those treated with NPV (27.3% vs. 4.5%), whereas mortality rate was similar (27.3% vs. 18.2%). Ventilator-free days and length of hospital stay were significantly lower in the iron-lung group than in the IMV group.

Negative-Pressure Ventilation versus Noninvasive Positive-Pressure Ventilation

A direct comparison between the two noninvasive ventilator techniques in the treatment of patients with COPD in ARF was reported in a retrospective case-control study involving fifty-three pairs of patients, well matched for age, sex, causes of ARF, APACHE II score, and pH, who were treated with iron-lung and mask ventilation.[87] Treatment failure (death and/or need for endotracheal intubation) was 20.7% in the NPV group and 24.5% in the mask ventilation group. Duration of mechanical ventilation (29.6 ± 28.6 vs. 62.3 ± 35.7 hours) and length of hospital stay (10.4 ± 4.3 vs. 15 ± 5.2 days) were significantly lower in patients treated with NPV than in those treated with mask ventilation.

This finding was recently confirmed by a multicenter prospective randomized crossover study[89] carried out in 141 patients (seventy assigned to NPV and seventy-one to mask ventilation). To establish the failure of the technique employed as first-line therapy, major and minor criteria for endotracheal intubation were used. When a major criterion was fulfilled, endotracheal intubation was promptly performed. When at least two minor criteria were met, patients were shifted from one technique to the other. When used as first-line therapy, the success of NPV (87%) was significantly greater (P = 0.01) than mask ventilation (68%) because of the number of patients who met minor criteria for endotracheal intubation (Fig. 16-9). After the shift between the techniques, however, the need of endotracheal intubation and hospital mortality was similar in the two groups. The total rate of success using both techniques increased from 77.3% to 87.9% (P = 0.028) (Fig. 16-9). These data show that when the two techniques are combined, endotracheal intubation can be avoided in a high percentage of cases.

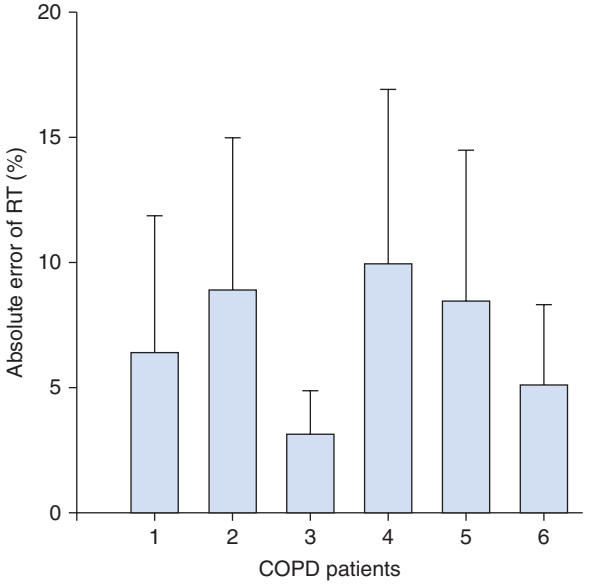

FIGURE 16-9 Error of inductance plethysmography (Respitrace, *RT*) in estimating tidal volume during NPV in patients with an acute exacerbation of COPD. The error of the Respitrace was assessed as $(VT,_{Respitrace} - VT,_{pneumotachograph})/VT,_{pneumotachograph} \times 100$. Individual values are shown.

§Rate 6 to 1200 cycles/min, I:E ratio: 1:6 to 6:1.

VARIATIONS IN DELIVERY AMONG VENTILATOR BRANDS

Table 16-3 reports the characteristics of modern negative-pressure pumps. A study by Smith et al[9] on five NPV pumps, using a lung model, showed that tidal volume during NPV is related both to target pressure and the pressure waveform generated by the pump. For the same target, pumps generating a square wave and produce a tidal volume up to 30% greater than pumps that generate a half sine wave.[9] Most modern NPV pumps respond rapidly to changing leaks to maintain the preset pressure[9] and allow independent setting of the pressure to be delivered during inspiration and expiration, as well as inspiratory and expiratory duration.

ADJUSTMENTS AT THE BEDSIDE

Guidelines concerning the bedside management of patients ventilated with NPV are scarce.[6,8] The effectiveness of NPV depends on strict supervision by well-trained nurses and physiotherapists with considerable expertise in this technique. Proper fit of the airtight seal around the neck and correct position of the head and neck rest are very important in optimizing comfort and preventing kinking and upper airway obstruction.[6]

Values ranging from −30 to −40 cm H_2O have been recommended for the setting of negative pressure during inspiration.[6] In our experience, the setting of pressures and timing depends on the clinical condition and chest wall impedance of patients. In patients with severe respiratory acidosis and hypercapnic encephalopathy, we used control NPV with a frequency of 12 to 15 cycles per minute and an I:E ratio of 1:3 to 1:4, whereas assist-control NPV is used preferentially in patients with tachypnea and respiratory distress to facilitate patient–ventilator synchrony. Inspiratory negative pressure is set initially at values ranging from −30 to −40 cm H_2O and then adjusted in each patient to obtain a tidal volume of about 6 mL/kg.[87]

Positive expiratory pressures of 10 to 15 cm H_2O are set to assist cough in patients with excessive secretions[8] or to increase tidal volume in restrictive disorders;[14] negative extrathoracic expiratory pressure is set to counterbalance intrinsic PEEP in patients with COPD (usually ranging from −4 to −6 cm H_2O)[12] or to improve oxygenation in patients with severe hypoxemia (ranging from −5 to −10 cm H_2O). Arterial blood gases are checked approximately 30 minutes after mechanical ventilation starts and after any setting changes. During NPV, oxygen is supplemented by nasal cannula, venturi mask, or mask with reservoir. The flow is adjusted to keep O_2 saturation usually between 92% and 94%. Bronchodilators also can be administered by metered-dose inhaler or by aerosol.

TROUBLESHOOTING

Many problems must be considered when treating acute patients with NPVs.

TABLE 16-4: TYPICAL SETTING OF IRON LUNG USED IN CONTROL MODE FOR THE TREATMENT OF PATIENTS WITH ACUTE-ON-CHRONIC RESPIRATORY FAILURE

- Negative inspiratory pressure: Usually from −30 to −40 cm H_2O at first, and then adjusted so as to obtain a tidal volume of approximately 6 mL/kg.
- Expiratory positive pressure: From +10 to +15 cm H_2O in patients with excessive secretions to assist cough or to improve patient–ventilator synchrony.
- The timing must be adjusted some breaths below patient's spontaneous rate.
- Typical setting for a ventilatory rate of 15 cycles/min: $T_I = 1.2$ s; $T_E = 2.8$ s; ($T_I/T_{TOT} = 30\%$).
- Typical setting for a ventilatory rate of 27 cycles/min: $T_I = 0.8$ s; $T_E = 1.4$ s; ($T_I/T_{TOT} = 36\%$); when patient is "captured," respiratory rate is reduced progressively.

Setting in Control Mode

The old iron-lung models have only this mode of ventilation, which may cause patients to "fight the ventilator," resulting in discomfort and ineffective ventilation. In order to "capture" the patient to the superimposed frequency of the machine, we can operate mainly on the timing. Table 16-4 reports some examples of iron-lung settings in the control mode to overcome this concern.

Monitoring of Tidal Volume

During NPV, the patient airway opening is free, which is a disadvantage for continuous monitoring of tidal volume. Currently, tidal volume is monitored intermittently using a Wright spirometer connected to a face mask. Continuous monitoring can be achieved with the use of inductance plethysmography (Respitrace), which permits an indirect evaluation of tidal volume. Recently, we compared tidal volume measured by a pneumotachograph and by Respitrace in patients with COPD in acute exacerbation treated by iron lung. The error of the Respitrace, assessed as ($VT,_{Respitrace} - VT,_{pneumotachograph}$)/$VT,_{pneumotacograph} \times 100$, ranged from 3% to 10% (Fig. 16-10). These observations suggest that inductance plethysmography may be a useful tool, allowing continuous estimate of tidal volume during NPV.

Nursing Care

The major problems related to the assistance of patients with NPV by iron lung are transfer from the bed to inside the chamber of the tank ventilator and access to patients for nursing procedures during ventilation. Well-trained nurses, however, can manage both transfer, by using aids (e.g., a roll mattress and a mechanical elevator), and nursing procedures (e.g., insertion of a urinary catheter and venous lines, placement of electrocardiograph electrodes and SaO_2 probe for monitoring the level of oxygenation) easily using the portholes in the tank ventilator. We have measured the time spent by nurses in the second day after admission in patients with COPD in ARF treated with the iron lung.[76] The following procedures were considered: transfer of patients from the bed to inside the tank ventilator, measurement of tidal volume and minute ventilation by a Wright spirometer, tracheobronchial suction, arterial blood-gas sampling, drug administration, and other procedures. The total time spent by nurses for these procedures was 250 minutes. Even though there are no studies comparing nursing workload in patients submitted to NPV and IMV, Nava et al[119] have reported that nursing workload in patients treated with IMV was 527.5 ± 51.1 minutes in the first 48 hours after admission.

IMPORTANT UNKNOWNS

It is completely unknown if NPV may play a role in the treatment of patients with acute lung injury. Physiologic studies[58–60] have shown the advantageous hemodynamic effects of NPV applied to the chest wall in patients with acute lung injury, although studies on clinical outcomes are completely lacking. The absence of this information is

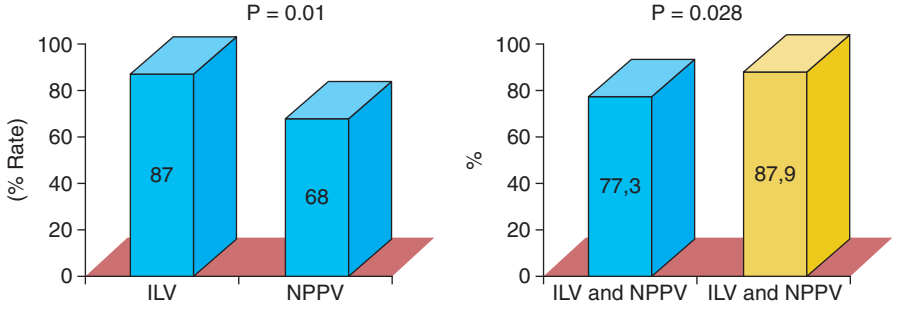

FIGURE 16-10 The rate of success of iron-lung ventilation (ILV) and noninvasive positive pressure ventilation (NPPV) as first-line therapy in 141 patients presenting with an acute exacerbation of COPD. *Left panel:* The success of ILV (87%) was significantly greater than that of NPPV (68%) (P = 0.01). *Right panel:* Mean rate of success of ILV and NPPV used as first line of treatment and total rate of success of both techniques used sequentially.

particularly relevant because some physiologic studies suggest that NPV may result in reduced lung biotrauma compared with PPV.[115,121,122] Physiologic studies[52,54] show that NPV by iron lung has the same hemodynamic effects as PPV. Recently the effects of NPV, applied with a custom-made whole-body chamber, were compared to those of PPV in a model of acute lung injury in anesthetized, surfactant-depleted rabbits. NPV resulted in a superior oxygenation unrelated to lung perfusion and was associated with more effective inflation of lung volume during both inspiration and expiration.[123] The same group using dynamic computed tomography in six anesthetized rabbits with acute respiratory distress syndrome induced by repeated saline lavage, reported that NPV was associated with increased percentage of ventilated lung at mid-inspiration and midexpiration compared to PPV.[124]

Future studies should determine whether iron-lung ventilation may be applied successfully to patients with cardiogenic pulmonary edema.

THE FUTURE

Inspiratory Trigger System

Sinderby et al[125] used diaphragmatic electrical activity, recorded by electrodes attached to a nasogastric tube, to trigger ventilatory support. This signal is directly related to phrenic nerve activity and probably to the output of the respiratory center; unlike airway pressure or flow, it is not affected by mechanical dysfunction (dynamic hyperinflation and intrinsic PEEP). By overcoming the problem associated with the current technology for triggering, this "neural trigger" has the potential to improve patient–ventilator interaction during both positive-pressure and negative-pressure mechanical ventilation.

Design of Tank Ventilator

Most iron lungs, although improved in design, remain cumbersome and need a large amount of space. A lighter and completely transparent chamber incorporated into the ICU bed would enable the posture of patients to be changed from supine to semirecumbent. This step should permit a major implementation of NPV in the ICU.

Potential Clinical Application

The clinical relevance of intra-abdominal pressure, which may cause organ dysfunction, is being recognized increasingly in the ICU settings.[126,127] It has been suggested that NPV applied around the abdomen by a cuirass might be a potential tool to treat intra-abdominal hypertension.[128] This hypothesis has been investigated in a physiologic study of thirty patients admitted to an ICU.[129] Continuous NPV decreased intra-abdominal pressure from 8.7 ± 4.3 to 6 ± 4.2 mm Hg (p <.001). There was a further decrease in intra-abdominal pressure when more negative pressure was applied. Future studies with clinical outcome are necessary to assess the effectiveness of this technique for the treatment of increased abdominal pressure.

SUMMARY AND CONCLUSIONS

Evidence now exists that (a) NPV unloads respiratory muscles and improves gas exchange in patients with COPD and ARF; (b) volume-controlled ventilation with CNEP, compared with volume-controlled ventilation with PEEP, increases oxygen delivery and cardiac index in patients with acute lung injury and children submitted to right-sided heart surgery; (c) iron-lung ventilation, in expert hands, is as effective as mask ventilation and invasive ventilation in the treatment of acute-on-chronic respiratory failure; and (d) NPV can been used successfully for home mechanical ventilation in patients with chronic respiratory failure who are unable to tolerate mask ventilation. Furthermore, the use of both NPV and mask ventilation may avoid endotracheal intubation and its complications in most of these patients, widening the field of application of noninvasive ventilator techniques.

NONINVASIVE RESPIRATORY AIDS: ROCKING BED, PNEUMOBELT, AND GLOSSOPHARYNGEAL BREATHING

Nicholas S. Hill

ROCKING BED AND PNEUMOBELT

The rocking bed and pneumobelt are noninvasive ventilators that were developed and saw their greatest use during the latter years of the polio epidemics but are used rarely today. They both rely on the effect of gravity to assist diaphragmatic motion and are particularly well suited to patients with severe diaphragmatic weakness or paralysis. Neither one should be used in the management of acute respiratory failure, and both have limited present-day applicability. Despite the similarities, there are also important differences, such as portability and suitability for nocturnal versus daytime use. This chapter reviews the historical development, mechanisms of action, and present-day uses of the rocking bed and pneumobelt. Glossopharyngeal breathing, another noninvasive approach to ventilator assistance, is discussed briefly at the end of the chapter.

Historical Development

The conceptual groundwork for development of the rocking bed was laid during the early 1930s by Eve,[1] who described the use of manual rocking to assist ventilation in two patients with acute respiratory paralysis. The technique consisted of placing the patient supine on a stretcher that was pivoted on a fulcrum placed at waist level. The patient then was rocked up and down approximately 45 degrees in either direction. Eve noted that the "weight of the viscera pushed the flaccid diaphragm alternatively up and down," achieving artificial respiration.[1] The technique was adopted subsequently by the British Navy as the recommended means of resuscitation for drowning victims.[2] Later studies demonstrated that this tilting method compared quite favorably with other resuscitation methods of the day, and it remained an acceptable means of resuscitation until mouth-to-mouth resuscitation gained acceptance during the 1960s.[3,4]

Automatic rocking beds were first introduced as ventilatory aids during the late 1940s. Wright[5] was the first to describe the management of respiratory insufficiency using an oscillating bed that had been designed originally to assist circulation. This experience led to the development of the McKesson Respiraid rocking bed, which was accepted by the Council on Physical Medicine and Rehabilitation in 1950.[6] Intended mainly as an aid to weaning patients with poliomyelitis from dependence on the tank respirator,[7] it facilitated nursing care and enhanced patient freedom but was quite noisy, bulky, and heavy (455 kg).[6,7] The Emerson rocking bed (J. H. Emerson Co., Cambridge, MA), also introduced during the late 1940s, was quieter and lighter than the McKesson bed and became the dominant model during the 1950s. Hundreds of rocking beds were manufactured between 1950 and 1960 (Emerson JH, personal communication), but after introduction of the Salk and Sabin vaccines and control of the polio epidemics, demand fell drastically. Many survivors of the polio epidemics continued to use rocking beds for ventilator support, sometimes for decades,[8] but most have since died or switched to other ventilators, and present-day use is rare.

The intermittent abdominal pressure respirator or insufflator (pneumobelt) was introduced at the end of the polio epidemics in an attempt to address the limitations of existing ventilators.[9] The pneumobelt was designed to allow complete freedom of the upper extremities and mouth during use in the sitting position and was intended mainly as a daytime ventilatory aid during meals or wheelchair use. Several modifications of the pneumobelt have been reported since the original description, but these never gained wide acceptance. These modifications include a piston-like device that compresses the abdomen while the patient sits in a wheelchair[10] and a combination of the pneumobelt and intermittent positive-pressure breathing.[11] Like the rocking bed, the pneumobelt has seen only limited use since control of the polio epidemics.

Mechanism of Action

Eve compared the rocking-induced motion of the abdominal viscera within the thorax with that of a piston within a cylinder.[1] As the head moves down, the viscera and diaphragm slide cephalad, assisting exhalation (Fig. 17-1). In the foot-down position, the abdominal contents and diaphragm slide caudad, assisting inhalation (Fig. 17-2).

A number of early studies on the efficacy of rocking compared it as a method of resuscitation with others then used commonly.[3,4] These studies used fresh corpses or live subjects with pharmacologically induced paralysis or voluntarily suspended respirations to show that rocking produced tidal volumes ranging from a few hundred milliliters to a liter, and success in the resuscitation of near-drowning victims was reported.[2] Later, Plum and Whedon[12] found that the automatic rocking bed was not as effective as the tank respirator but produced adequate alveolar ventilation in eleven convalescent patients with respiratory paralysis secondary to poliomyelitis. The bed, however, was unable to sustain adequate ventilation in five patients during the acute stages of respiratory paralysis. Plum and Whedon recommended that use of the rocking bed be reserved for stable patients who are capable of at least some spontaneous breathing, a recommendation that holds true today.

FIGURE 17-1 Rocking bed in 10-degree head-down position. Sliding of the viscera and diaphragm cephalad assists exhalation.

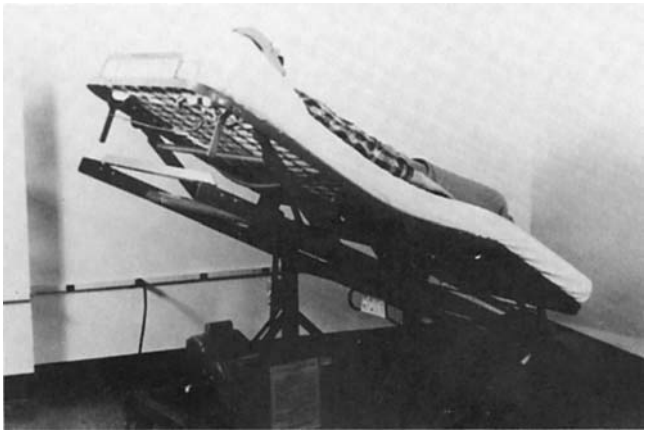

FIGURE 17-2 Rocking bed in 27-degree foot-down position. Sliding of the abdominal viscera and diaphragm caudad assists inhalation. (Used, with permission, from Hill.[17])

Colville et al[13] subsequently examined the physiologic effects of rocking on respiratory mechanics and identified factors responsible for the wide individual variations in tidal volumes generated during rocking. They found that the greatest displacement of the diaphragm occurred during rocking from horizontal to the 40-degree foot-down position (Fig. 17-3). Beyond this angle, relatively little further displacement of the diaphragm occurred. Likewise,

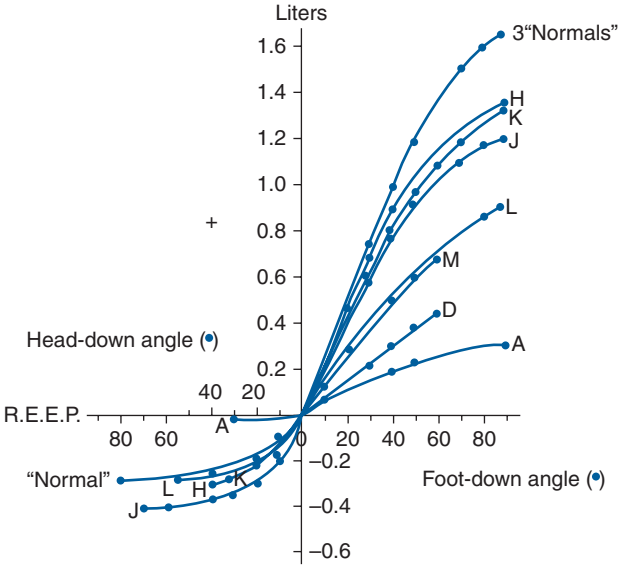

FIGURE 17-3 Relationship between angle of rocking bed and static lung volume in three normal individuals and in patients with poliomyelitis, as indicated by letters. Note that the greatest volume shift occurs between 0 degrees and the 40-degree foot-down angle. Note also the marked variability between individuals. *REEP*, resting end-expiratory position. (Used, with permission, from Colville P, et al. Effects of body tilting on respiratory mechanics. *J Appl Physiol.* 1956;9:19–24.)

relatively little displacement of the diaphragm occurred during rocking from the horizontal to the head-down position. This indicated that in the horizontal position, the resting diaphragm was fairly close to its uppermost position, so the greatest passive motion could be achieved by applying gravitational force in the caudad direction.

Along these lines, Joos et al[14] found that tidal volumes were greater in some patients when rocking was achieved entirely in the head-up position (5 to 42 degrees above the horizontal plane) rather than between the head-down and head-up positions (10 degrees below to 27 degrees above the horizontal plane). In addition, others found that relatively little increase in minute volume could be achieved by increasing the rate of rocking beyond 15 to 16 rocks per minute.[3] At higher rocking frequencies, the tidal volume tended to diminish, negating the effects of the increased rocking rate.

With regard to the large individual variation (see Fig. 17-3), Colville et al[13] found that as the compliance of the abdominal wall increased, the greater was the tidal volume during rocking. Thus, rocking was relatively ineffective in patients with severe kyphoscoliosis, who have low abdominal and diaphragmatic compliance and short abdominal lengths. Taken together, these findings indicate that the efficacy of the rocking bed is highly dependent on patient body characteristics and that function is likely to be optimal when rocking is between the near-horizontal and the 40-degree foot-down positions at rocking rates between 12 and 16 rocks per minute. Wider manipulations of rocking rate and arc, however, may be useful in optimizing alveolar ventilation in some patients.

The pneumobelt[9] operates by a mechanism similar to that of the rocking bed in that it assists diaphragmatic motion by causing piston-like motions of the abdominal viscera within the thoracic "cylinder." The major difference is that the pneumobelt assists exhalation by applying positive pressure to the abdominal surface rather than using gravitational force. It consists of an inflatable rubber bladder held firmly over the abdomen by an adjustable corset (Fig. 17-4). Inflation of the bladder squeezes the viscera, forcing the diaphragm cephalad and actively assisting exhalation. On deflation of the bladder, gravity pulls the viscera and diaphragm back to their original positions, assisting inhalation (Fig. 17-5). Because of this dependence on gravitational force, the pneumobelt must be used in a sitting position, optimally at angles of 45 degrees or greater. Below 30 degrees, the ability to assist ventilation is diminished markedly. Thus, nocturnal use of the pneumobelt is limited to patients who can sleep in a sitting position.[15]

Despite this limitation, the pneumobelt can be a very useful device in appropriately selected patients. The ability of the pneumobelt to augment tidal volume is linearly related to the inflation pressure of the bladder between pressures of approximately 15 and 50 cm H_2O. Pressures exceeding 50 cm H_2O are rarely tolerated because of abdominal discomfort. As with the rocking bed, the ability of the device to augment tidal volume varies considerably among individuals. Important factors that contribute to the variability among individuals include abdominal and chest wall compliances. High abdominal compliance favors efficient functioning of the device, but high chest wall compliance may allow expansion of the chest wall during bladder inflation, reducing efficiency.[9] Thus, like the rocking bed, body habitus is also an important determinant of ventilator efficiency for the pneumobelt. Although thin patients can be ventilated effectively,[16] both devices work less efficiently in extremely thin or obese patients and in those with severe kyphoscoliosis. The sitting position in patients with severe kyphoscoliosis often brings the lower rib cage in contact with the thighs, rendering proper positioning of the pneumobelt impossible.

FIGURE 17-4 Pneumobelt is shown attached via a connecting hose to a Bantam positive-pressure ventilator (Puritan-Bennett Corp, Lenexa, KS). (Used, with permission, from Rondinelli et al. In: Delisa JA, ed. *Rehabilitation Medicine: Principles and Practice*. Philadelphia, PA: Lippincott; 1988.)

Application

Rocking beds are no longer available commercially. Pneumobelts (small, medium, or large) can be obtained via home medical equipment vendors via Philips Respironics, Inc. (Murrysville, PA). Positive-pressure volume-limited

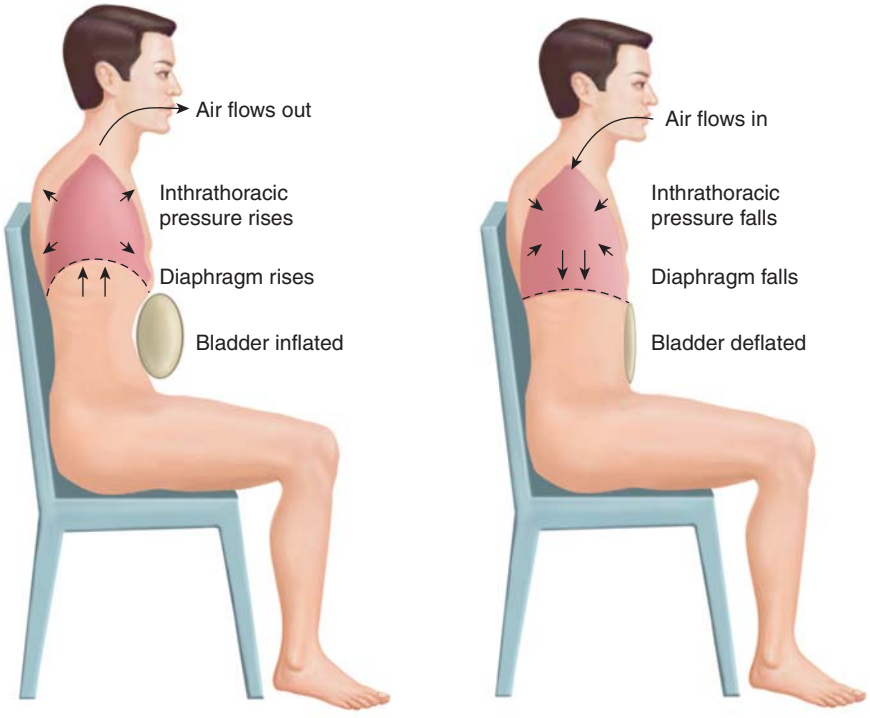

FIGURE 17-5 The pneumobelt functions by exerting positive pressure on the abdominal viscera, forcing the diaphragm up and assisting exhalation (*left*). When the bladder deflates, gravity returns the diaphragm to its original position, assisting inhalation (*right*). (Reproduced with the permission from the American College of Chest Physicians. Hill NS. Clinical applications of body ventilators. *Chest.* 1986;90:897–905.)

ventilators with sufficient pressure-generating and volume-generating capabilities can be used. Most portable "bilevel" positive-pressure devices, however, are insufficient.

Consisting of a bed frame that is suspended on an axis 100 cm above the ground, rocking beds are bulky (193 cm long by 84 cm wide) and heavy (approximately 136 kg). Although the axis of rotation can be adjusted, they usually are set to rotate 10 degrees in the head-down direction and 27 degrees foot-down. As noted previously, maintaining the rocking arc in the head-up range may improve efficacy in some patients.[14] Adjustable cranks allow raising of the head and knees to minimize slippage. Excessive flexion of the hips, however, may impair functioning.[14] A foot rest also may be attached to prevent downward sliding, but with proper positioning of the head and knees, this is usually unnecessary.

The most attractive feature of the rocking bed is its ease of application. With use of a foot stool, most patients can position themselves on it with minimal assistance. Paralyzed patients require help from one or two attendants depending on body weight. The patient lies supine with the head and knees raised slightly to maximize comfort. A baseline minute volume is measured using a portable spirometer. Rocking then is commenced at rates between 12 and 16 rocks per minute, again adjusted to optimize patient comfort. The patient is coached to exhale during head-down rocking and to inhale while the head moves up. When synchronization has been achieved, further adjustments in rocking rate may be made to optimize minute volume. An arterial blood-gas determination may be helpful after an hour or two during the initial trial to assess adequacy of alveolar ventilation.

Patients then are encouraged to initiate rocking at bedtime and to extend the hours of use gradually until they are able to sleep through the night. Most patients find the rocking bed quite comfortable and encounter little difficulty in learning to sleep while rocking. Motion sickness is unusual, presumably because the bed rocks in one plane only, but it may disturb some patients. The bed limits daytime mobility, so most patients use it only nocturnally. If daytime ventilatory assistance is necessary, another technique, such as noninvasive positive pressure ventilation or the pneumobelt, is recommended for daytime supplementation.

Application of the pneumobelt is slightly more difficult than that of the rocking bed, usually requiring at least one attendant unless the patient has full upper extremity strength. The corset is positioned while the patient is sitting comfortably. The rubber bladder is positioned over the abdomen with the curved lower border of the corset over the pubis and the horizontal upper border over the xiphoid. Some coverage of the lower rib cage may serve to minimize paradoxical motion of the ribs during assisted exhalation, although some authors have found more efficient functioning if the corset is placed below the xiphoid.[16] If the corset extends too far below or above the lower rib margin, another of the three available sizes should be tried. The corset then is tightened using the three straps that surround the abdomen until the rubber bladder is held firmly but not uncomfortably

against the abdomen. After baseline spontaneous respiratory rate and tidal volume are measured, the rubber bladder is attached to a positive-pressure ventilator using a connecting hose. Volume-limited positive-pressure ventilators that generate adequate pressures and volumes will operate the pneumobelt successfully, but portable "bilevel-type" pressure-limited devices that are popular to provide noninvasive positive-pressure ventilation are not adequate because their pressure-generating capabilities are too limited.

The ventilator is set at a rate that approximates spontaneous respiratory frequency and an inspiratory-to-expiratory (I:E) ratio of approximately 1:1.5. Some authors have found that function is optimal at rates of 12 to 14 breaths/min,[16] but this may depend on the underlying respiratory disorder. Some patients prefer rates as high as the low 20s per minute (see "Case 2: Use of the Pneumobelt" below). Ventilator assistance is initiated by intermittently inflating the rubber bladder with peak inflation pressures of 20 to 25 cm H_2O. Inflation pressure then is raised gradually until the patient's assisted tidal volume increases to the desired range, usually 30% to 50% over spontaneous breathing or the patient reaches the limit of tolerance. Peak pressures of 30 to 50 cm H_2O are usually sufficient, but pressures up to 60 cm H_2O may be necessary in some patients.[16] Pressures exceeding 60 cm H_2O rarely are tolerated because of discomfort. Considerable coaching usually is necessary during initial adaptation to encourage synchronization of patient breathing with ventilator cycling. Patients who will be successful usually learn to synchronize their breathing with the ventilator after a few sessions.

In addition to measurement of minute volume, efficacy is assessed using arterial blood-gas determinations that are done as soon as the patient is comfortable and synchronizing well. The desired amount of ventilator assistance will vary depending on the patient, but a decrease in arterial carbon dioxide tension (Pa_{CO_2}) of approximately 5 to 10 mm Hg below spontaneous breathing levels is acceptable during the initial sessions. Subsequent use of the device also depends on the patient. Most often, because the pneumobelt must be used in the sitting position, it is used as a daytime ventilator aid to supplement another device used nocturnally. As illustrated by Case 2 (see below) and another case report,[15] however, occasional patients may adapt to nocturnal use. The monthly rental for the belt itself is less than $100, but ventilator costs and associated respiratory therapy services raise monthly charges to the $500 to $1000 range.

Long-term follow-up of patients using either the rocking bed or pneumobelt should include assessment for symptoms or signs of chronic hypoventilation such as morning headache, hypersomnolence, and ankle swelling. Daytime spontaneous arterial blood-gas determinations are particularly useful for assessing the adequacy of ventilatory assistance,[17,18] and attempts should be made to increase assisted minute volume if Pa_{CO_2} remains substantially above 50 mm Hg. Nocturnal oximetry or polysomnography are useful not only to assess adequacy of nocturnal oxygenation but also to detect obstructive apneas that may be induced by negative-pressure ventilators[19] and also may occur during use of the rocking bed or pneumobelt.

Complications of rocking bed or pneumobelt use are relatively few. Some patients using the pneumobelt for many consecutive hours develop skin abrasions, and others have trouble coordinating their breathing with either of the ventilators so that efficacy may be inadequate. If appropriate patients are selected, the risk of worsened respiratory failure or arrest during use is low because such patients should be capable of some spontaneous breathing. As deterioration occurs with progressive neuromuscular syndromes or acute respiratory infections, however, patients may have to switch to other, more effective ventilators.

Indications

Considering that the rocking bed and pneumobelt share similar mechanisms of action, it is not surprising that they also share indications for use (Table 17-1). Because both assist ventilation essentially by augmenting diaphragmatic motion, they are particularly useful in patients with bilateral diaphragmatic weakness or paralysis. Abd et al[20] demonstrated the utility of this application in patients with bilateral diaphragmatic paralysis following open-heart surgery. In this study, ten patients were weaned from conventional positive-pressure ventilation to the rocking bed and continued to use it nocturnally until phrenic nerve function recovered after 4 to 27 months.

The rocking bed and pneumobelt also may be used in the management of chronic respiratory failure caused by a

TABLE 17-1: INDICATIONS AND CONTRAINDICATIONS FOR THE ROCKING BED AND PNEUMOBELT

Indications
Chronic respiratory failure[a] caused by:
Bilateral diaphragmatic paralysis
Muscular dystrophies
Duchenne
Limb-Girdle
Myotonic
Postpolio syndrome
Amyotrophic lateral sclerosis
Multiple sclerosis
Traumatic quadriplegia[b]
Contraindications
Acute respiratory failure or rapidly progressive neuromuscular disease
Excessive secretions
Upper airway dysfunction
Excessive obesity or thinness
Severe kyphoscoliosis

[a]With intact upper airway and appropriate body habitus.

[b]Pneumobelt only.

variety of slowly progressive neuromuscular syndromes that weaken the diaphragm and leave upper airway function intact. Chalmers et al[21] described their experience with fifty-three neuromuscular patients, thirty with postpolio syndrome, twelve with various muscular dystrophies, four with adult-onset acid maltase deficiency, and four with motoneuron disease (amyotrophic lateral sclerosis). Forty-three of the patients used the rocking bed for an average of 16 years with good control of symptoms and stabilization of gas exchange in most patients. Seventeen patients discontinued use: nine because of discomfort and eight because progression of respiratory insufficiency necessitated more efficacious therapy. The pneumobelt has been used in patients with high spinal cord lesions, mainly as a daytime supplement, often in combination with positive pressure ventilation administered noninvasively or via a tracheostomy.[16] In this setting, the pneumobelt frees the face of encumbrances and improves speech and mobility. It also may be used for total ventilator support.[22] Surprisingly, those with the least ability to sustain spontaneous breathing adapt best to pneumobelt use.[22]

Because both ventilators have limitations that are influenced heavily by the patient's body habitus, however, a number of caveats should be borne in mind (see Table 17-1). Neither device is suitable for use in acute respiratory failure mainly because a period of adaptation is necessary for optimal efficiency and also because excessive secretions interfere with function.[12] In addition, care should be exercised to select patients who have an appropriate body habitus, adequate upper airway function, and a condition that is sufficiently stable or slowly progressive so that the anticipated duration of use will justify the effort and time required for adaptation.

Because the rocking bed is suited for nocturnal use and the pneumobelt for daytime use, the two may be used in complementary fashion. A patient might use the rocking bed during sleep and the pneumobelt for daytime desk work or wheelchair use.

Many choices are available currently for noninvasive ventilation of patients with chronic respiratory failure secondary to idiopathic diaphragmatic paralysis or slowly progressive neuromuscular conditions. Noninvasive positive-pressure ventilation administered via a nasal mask is unquestionably the mode of first choice because of its convenience, ease of application, portability, and avoidance of the intermittent upper airway obstructions and oxygen desaturations associated with the use of negative-pressure ventilators.[19,23] Nevertheless, other noninvasive ventilators still should be considered in patients with chronic respiratory failure who are unable to use noninvasive positive-pressure ventilation, as illustrated in a recent report of a woman with scapuloperoneal muscular dystrophy who used a rocking bed successfully when loss of upper extremity strength rendered her incapable of applying her nasal ventilator.[24]

Efficacy comparisons between the rocking bed and pneumobelt and other noninvasive ventilators are limited because few relevant studies are available. In acutely anesthetized intubated subjects, Bryce-Smith and Davis[25] showed that the rocking bed produced barely adequate tidal volumes when rocking through an arc of 40 degrees and was much less effective than negative-pressure ventilators, including the tank ventilator and chest cuirass. Goldstein et al[26] demonstrated that cuirass-type negative-pressure ventilators augment tidal volumes and suppress diaphragmatic electromyographic activity more effectively than did the rocking bed in patients with neuromuscular disease. Both types of ventilators, however, were deemed effective, and considering that this was an acute daytime study, the rocking bed may have been more effective at reducing diaphragmatic electrical activity had patients been monitored overnight after a suitable adaptation period. Even so, the conclusion that the rocking bed is less effective than negative-pressure ventilators seems justified. In one case, the rocking bed was combined with noninvasive positive-pressure ventilation via a nasal mask to enhance efficacy and achieve "necessary ventilatory support."[27]

In summary, both the pneumobelt and rocking bed currently have limited indications (see Table 17-1). They are unsuitable for use in acute respiratory failure, must be used in patients with a relatively "normal" body habitus, and have marginal efficacy even under optimal circumstances. Noninvasive positive-pressure ventilation has convenience and efficacy advantages over these devices. Nonetheless, there are occasional patients who are unable to tolerate a nasal mask or negative-pressure ventilator who may prefer the relatively greater comfort of the rocking bed or the daytime freedom that the pneumobelt affords. The following cases illustrate such applications.

CASE 1: USE OF THE ROCKING BED

J.F., a 47-year-old man with myotonic dystrophy, first presented with symptoms of chronic hypoventilation, including morning headache and daytime hypersomnolence. He was found to have global muscular weakness, although he was still able to walk with a cane. Pulmonary function studies demonstrated a severe restrictive defect with a forced vital capacity (FVC) of 1.5 L (31% of predicted) and a forced expiratory volume in 1 second (FEV_1) of 1.3 L. Room-air arterial blood-gas determinations revealed a pH of 7.36, a Pa_{CO_2} of 53 mm Hg, and a Pa_{O_2} of 69 mm Hg. Nocturnal polysomnography showed mild obstructive sleep apnea and sustained mild oxygen desaturations consistent with hypoventilation. A trial of noninvasive positive-pressure ventilation via a nasal mask was initiated. Despite much coaching and trials with different masks, the patient declined further use after 2 months because of intolerable mask discomfort. Megestrol, 40 mg PO TID, then was begun, followed within a month by normalization of blood gases and resolution of symptoms.

Two years later, the patient again developed symptoms of morning headache and daytime hypersomnolence. A daytime arterial blood-gas determination showed a pH of 7.36, a Pa_{CO_2} of 65 mm Hg, and a Pa_{O_2} of 42 mm Hg. Nocturnal polysomnography was repeated (see Fig. 17-6), showing periodic breathing and sustained severe oxygen desaturations. Oxygen supplementation was begun, but the Pa_{CO_2}

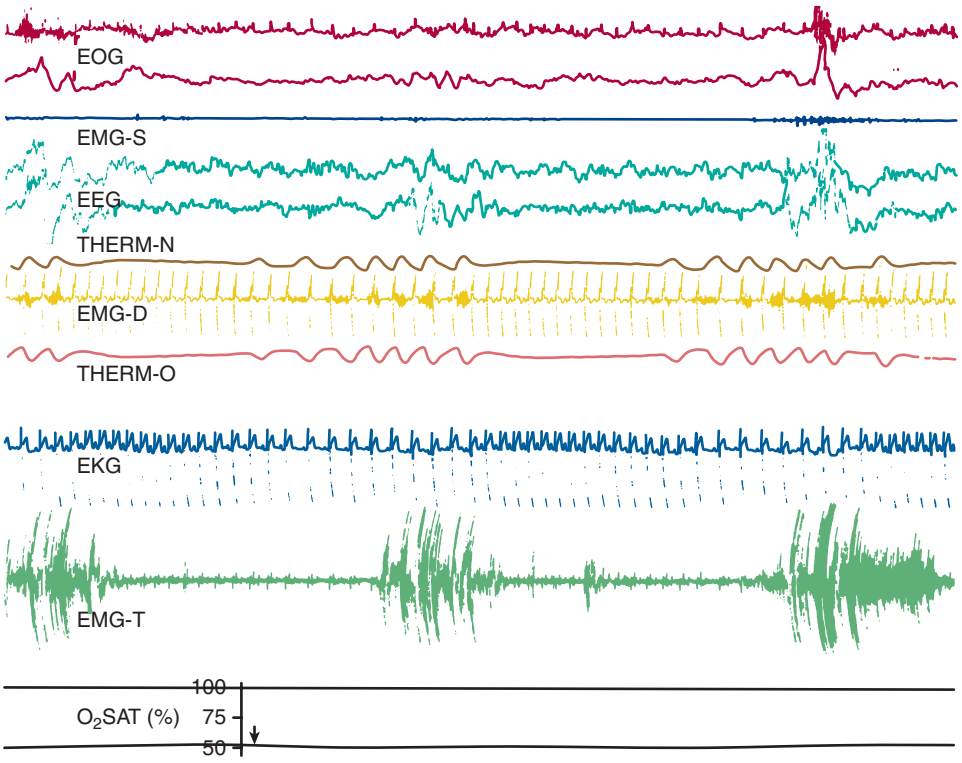

FIGURE 17-6 Nocturnal polysomnogram in patient 1, obtained in August 1991 during spontaneous room-air breathing, shows periodic breathing with sustained severe oxygen desaturation. *EEG*, electroencephalogram; *EKG*, electrocardiogram; *EMG*, electromyelogram; *EMG-D,* diaphragmatic EMG; *EMG-S*, submental electromyogram; *EMG-T*, temporal EMG; *EOG*, electrooculogram; *l*, left; *O_2SAT*, oxygen saturation; *r*, right; *THERM-N*, nasal thermistor; *THERM-O*, oral thermistor.

rose to 76 mm Hg. Nasal ventilation was tried once more and was rejected rapidly by the patient. Initiation of negative-pressure ventilation using a pneumowrap brought about a rapid improvement in symptoms and daytime gas exchange, with a room-air arterial blood-gas determination showing a pH of 7.42, a Pa_{CO_2} of 55 mm Hg, and a Pa_{O_2} of 65 mm Hg. The patient's wife, however, refused to consider use of the pneumowrap at home because placing the patient in it each night seemed too difficult.

Nocturnal ventilation using the rocking bed then was begun at a rocking rate of 16 rocks per minute. Tidal volume during the initial rocking trial ranged from 300 to 350 mL. The patient's wife found the rocking bed more acceptable because of simpler application. After a several-day adaptation period, the patient was able to sleep for 4 to 5 hours using the device, and he was discharged home. Nocturnal polysomnography obtained after several months of use showed good synchronization of chest wall motion with the rocking bed, but some obstructive hypopneas and apneas continued to occur (Fig. 17-7). The oxygen desaturations associated with the obstructive events were ameliorated by 2 liters/min of nasal oxygen used nocturnally (Fig. 17-8). The patient slept 7 to 8 hours nightly using the rocking bed with supplemental oxygen, and a daytime unassisted room-air arterial blood-gas determination after 15 months showed a pH of 7.42, a Pa_{CO_2} of 52 mm Hg, and a Pa_{O_2} of 78 mm Hg. After 3 years of clinical stability with nocturnal rocking bed use, the patient was hospitalized with pneumonia and progressive respiratory failure; he declined intubation and died.

This case illustrates that trials of a variety of noninvasive ventilators may be necessary before an acceptable one is identified. It also shows that many considerations, including pragmatic limitations in the home, help to determine the final selection. Here the rocking bed was selected not because of greater efficacy or patient preference but because of greater ease of application as perceived by the patient's wife.

CASE 2: USE OF THE PNEUMOBELT

M.C., a 24-year-old man with Duchenne muscular dystrophy, presented with a weakening voice, morning headaches, and hypersomnolence. Pulmonary function studies showed severe restriction with reductions of both FVC and FEV_1 to 0.5 L (14% of predicted). Arterial blood-gas determinations on room air showed a pH of 7.36, a Pa_{CO_2} of 68 mm Hg, and a Pa_{O_2} of 55 mm Hg. The patient was admitted to the hospital for a trial of noninvasive ventilation.

Noninvasive positive-pressure ventilation was tried initially, but the patient could not tolerate a face mask or lip seal. (Comfortable nasal masks were not available commercially at that time.) Negative-pressure ventilators were tried,

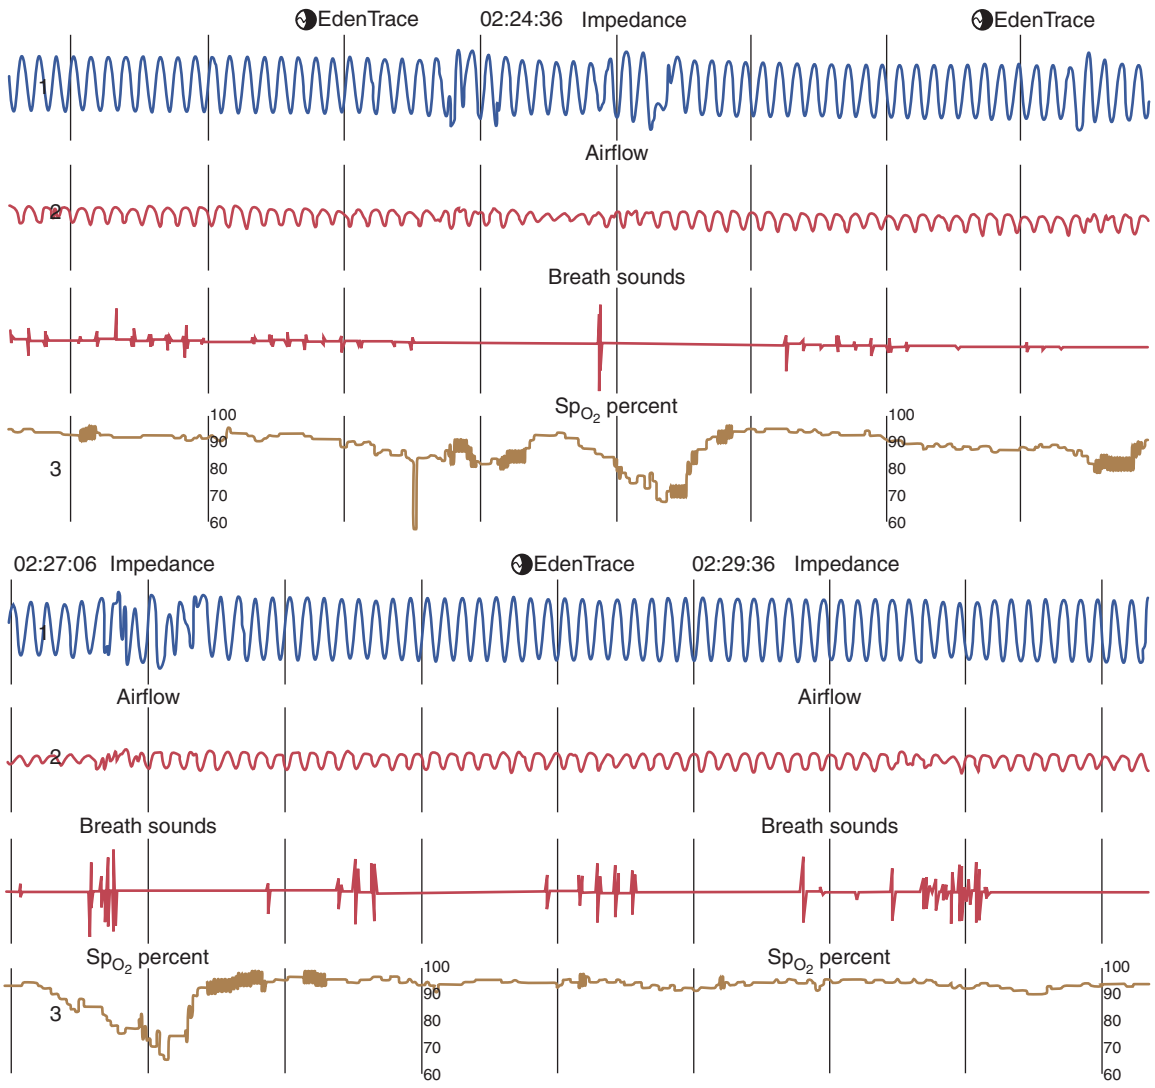

FIGURE 17-7 Continuous nocturnal recording of case 1 during rocking bed use without oxygen supplementation. Tracing shows consistent regular chest wall motions at a rate of 16 breaths/min, indicating good synchronization with the rocking bed. However, periodic obstructive hypopneas are signified by decreases in airflow followed by oxygen desaturations and arousals, as evidenced by disruption of chest wall synchrony. *Channel 1* is chest wall impedance, *channel 2* is combined nasal and oral thermistor, and *channel 3* is finger pulse oximetry. *Vertical lines* indicate 30-second intervals. Monitoring was performed using Edentec monitor (Edentec, Inc., Eden Prairie, MN).

but the patient found the iron lung too bulky and the pneumowrap too restricting and uncomfortable. Standard chest shells fit poorly because of his mild scoliosis. Only the pneumobelt, which was quite effective in augmenting his minute volume, was acceptable to the patient. His spontaneous respiratory rate was 28 breaths/min, tidal volume was 90 mL, and minute volume was 2.5 L/min. The pneumobelt was set at a rate of 22 breaths/min and a positive pressure of 35 cm H_2O, producing a tidal volume of 200 mL and a minute volume of 4.4 L/min. Arterial blood-gas determination after 2 hours during the initial trial showed a pH of 7.41, a Pa_{CO_2} of 59 mm Hg, and a Pa_{O_2} of 78 mm Hg.

The patient was discharged with instructions to use the pneumobelt at night and as needed during the daytime. Arrangements were made to attach a ventilator platform to his wheelchair to facilitate daytime use. The patient rapidly adapted to nocturnal use and encountered little difficulty in sleeping while sitting upright. In addition to nocturnal use, he used the ventilator for 2 to 3 hours during the daytime. A daytime room-air arterial blood-gas determination during spontaneous breathing after full adaptation 7 months after initiation showed a pH of 7.37, a Pa_{CO_2} of 49 mm Hg, and a Pa_{O_2} of 84 mm Hg. A nocturnal polysomnogram showed excellent synchrony of chest wall movement with the ventilator and no evidence of obstructive apneas (Fig. 17-9). Oxygen saturations remained between 95% and 98% throughout the night while the patient was breathing room air.

The patient continued to use the pneumobelt both nocturnally and during the daytime for the next 2 years and

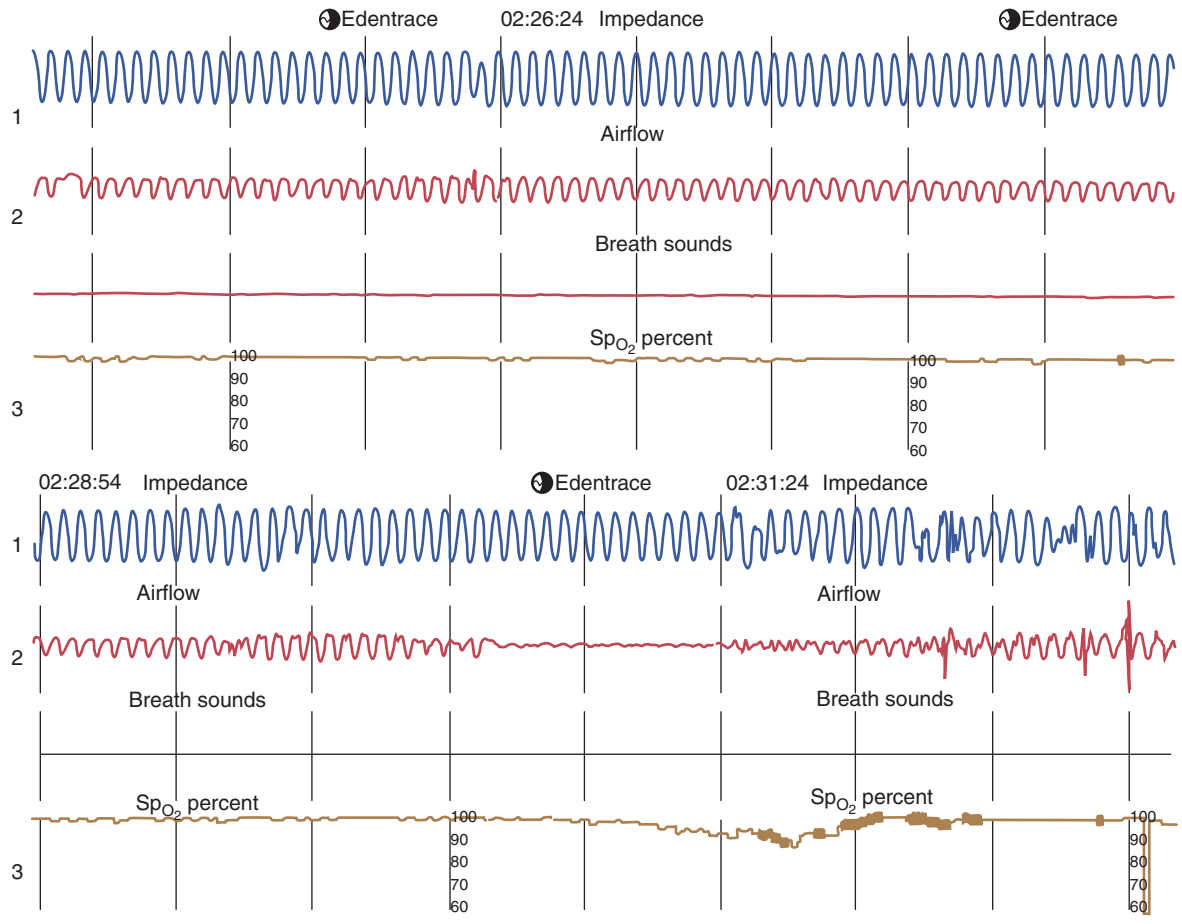

FIGURE 17-8 Nocturnal recording of case 1 using rocking bed and 2 L/min O_2 via nasal cannula. Tracing again shows excellent synchrony of chest wall motion with rocking. A 50-second obstructive apnea is apparent in the lower tracing, but is associated with only a mild oxygen desaturation to 90%. *Channel 1* is chest wall impedance, *channel 2* is combined nasal and oral thermistor, and *channel 3* is finger pulse oximetry.

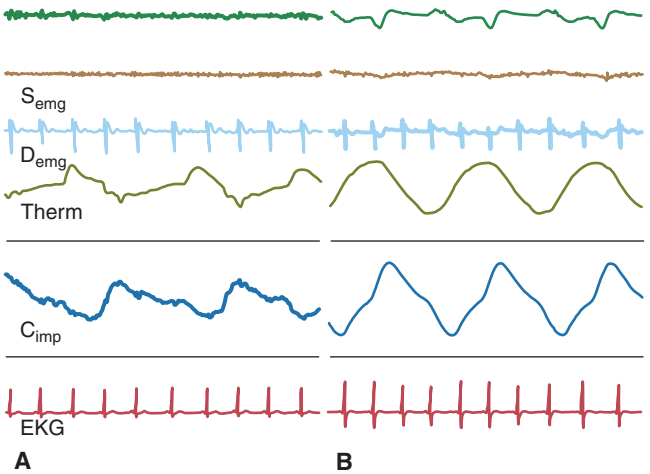

FIGURE 17-9 Nocturnal recording of case 2. **A.** Spontaneous breathing at a rate of 20 breaths/min. As expected, airflow increases, whereas chest wall dimensions decrease. **B.** During use of pneumobelt at a rate of 22 breaths/min, chest wall and ventilator are synchronized. However, chest wall motion is paradoxical, expanding during expiration. Diaphragmatic electromyogram (D_{emg}) failed to detect electrical muscular discharge during either spontaneous breathing or ventilator use. C_{imp}, chest wall impedance; *ECG*, electrocardiogram; *EMG*, electromyelogram; *Semg*, submental EMG; *THERM*, nasal thermistor.

found it particularly useful for reducing dyspnea associated with eating. During this time, his pulmonary function deteriorated gradually, necessitating increasing daytime use of the pneumobelt. Eventually, he had very little free time from the ventilator, amounting to 1 to 2 hours/day. Shortly, in September 1985, the patient developed pneumonia and required endotracheal intubation because of airway secretions that were unmanageable with either the pneumobelt or an iron lung, despite manual cough assistance (mechanical assistance was not tried). He was unable to resume pneumobelt use, and a tracheostomy was performed. He lived at home for an additional 3 years following tracheostomy placement but died unexpectedly when his ventilator inadvertently became detached from his tracheostomy tube.

This case shows that the pneumobelt may be used as the main mode of ventilator support in exceptional patients who prefer it to other forms of noninvasive ventilation. This patient was able to adapt quickly to nocturnal use while sleeping in the sitting position. The pneumobelt was an appropriate choice for him not only because he preferred it but also because he had a favorable body habitus and slowly progressive respiratory failure that allowed a

several-week adaptation period. The pneumobelt proved to be temporizing in this patient, although it provided adequate ventilator assistance even when he was almost entirely dependent on ventilator support. It was inadequate, however, when he developed a pulmonary infection, illustrating the limitations of the device in the face of acute respiratory failure.

GLOSSOPHARYNGEAL BREATHING

Glossopharyngeal, or "frog," breathing was first described by Dail et al[28] after they observed a polio patient who had begun using it spontaneously. The technique consists of repetitive gulping motions in which the tongue thrusts small boluses of air into the lungs (Fig. 17-10). The 40-mL to 80-mL boluses take roughly 0.5 second and are repeated eight to twelve times in succession to achieve a tidal volume of 500 to 600 mL, followed by passive exhalation. Roughly ten of these tidal volume maneuvers are performed each minute so that a minute volume of 4 to 8 L/min can be attained. In this way, persons with severely weakened respiratory muscles can use the technique to sustain ventilation and free themselves from the need for continuous ventilator assistance. Patients who become adept at the technique typically use it for periods ranging from a few minutes to several hours, but some ventilator-dependent patients can use it for up to 14 consecutive hours without other aids to ventilation (Sternburg L, personal communication).

Glossopharyngeal breathing also may be used to aid spontaneous breathing in patients with marginal pulmonary reserve by supplementing each tidal breath with 1 to 2 boluses of air or to assist coughing. Coughing is assisted by repeating boluses until tidal volumes of 2 to 2.5 L/min are achieved, allowing greater expiratory flows.[28,29] Complications are infrequent, with occasional patients complaining of aerophagia or chest tightness when fully inflating their lungs to assist cough.

Glossopharyngeal breathing requires intact function of upper airway structures, including the glottis, and therefore is of little value in patients with severe global weakness or bulbar dysfunction. Efficiency is also impaired by reduced chest wall or lung compliance or increased airway resistance, limiting use in patients with chest wall deformities or chronic obstructive pulmonary disease. In addition, because the upper airway contractions are voluntary, it cannot be used during sleep. Use of the technique complements any of the noninvasive aids to ventilation to extend "free time" from the ventilator.[30]

Glossopharyngeal breathing was used widely during the 1950s when it was taught to many patients with respiratory paralysis secondary to poliomyelitis. It is used less often today, however, partly because skilled teachers are few and also because most conditions leading to chronic respiratory insufficiency are associated with global muscle weakness or alterations in respiratory system compliance or airway resistance. Nonetheless, occasional glossopharyngeal breathers are found among survivors of the polio epidemics,[29] and some patients with muscular dystrophy or cervical spinal cord lesions learn to use the technique, sometimes spontaneously. Illustrative is a recent case study of a 6-year-old boy with a high cervical lesion secondary to tumor resection who

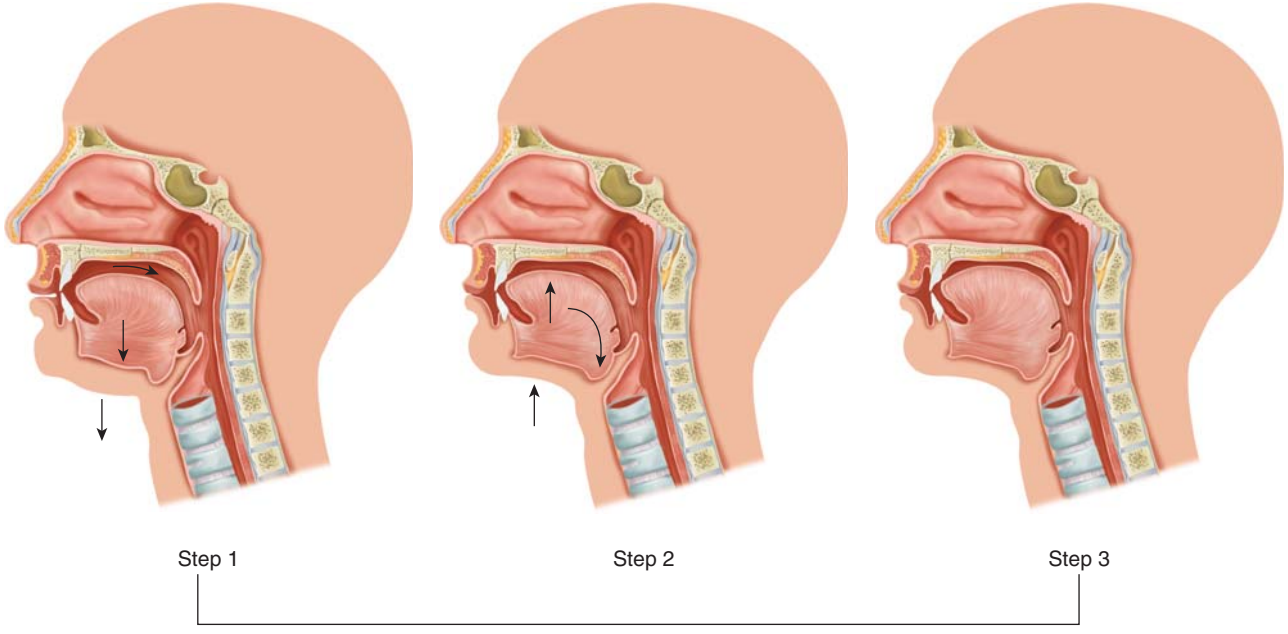

FIGURE 17-10 Illustration of steps taken by patient using glossopharyngeal breathing. In *step 1*, the mouth fills with air as the tongue is retracted. In *step 2*, the lips are closed and the tongue is raised to the roof of the mouth forcing air through the open glottis. In *step 3*, the larynx is closed, trapping air in the lungs, and the cycle is then repeated. (Used, with permission, from Maltais F. Glossopharyngeal breathing. *Am J Respir Crit Care Med.* 2011;184:381).

learned glossopharyngeal breathing on his own and was able to use it for ventilator-free breathing for up to 12 hours a day during a 16-year period. Despite having a tracheostomy, he was able to achieve a vital capacity of 3.3 L to augment cough.[30]

NONINVASIVE POSITIVE-PRESSURE VENTILATION

Nicholas S. Hill

Noninvasive ventilation (NIV) refers to the provision of mechanical ventilation without the need for an invasive artificial airway. Many different approaches to assisting ventilation noninvasively have been used in the past, including negative-pressure ventilators, pneumobelts, and rocking beds (see Chapters 16 and 17).[1] By virtue of its effectiveness and convenience compared with other noninvasive approaches, however, noninvasive positive-pressure ventilation (NIPPV) using a mask (or *interface*) that conducts gas from a positive-pressure ventilator into the nose or mouth has become the predominant means of administering NIV throughout the world. NIPPV has long been used to treat chronic respiratory failure caused by chest wall deformities, slowly progressive neuromuscular disorders, or central hypoventilation.[2] In more recent years, NIPPV has been increasingly used to treat patients with various forms of acute respiratory failure.[3] For the purposes of this discussion, NIPPV refers to active ventilator assistance achieved by the noninvasive provision of a mechanical positive-pressure breath during inhalation, and *continuous positive airway pressure* (CPAP) refers to the provision of a nonfluctuating positive-pressure. This chapter discusses the rationale for use, evidence for efficacy of noninvasive positive-pressure techniques in both acute and chronic settings, selection of appropriate patients, techniques for administration, and pitfalls and complications.

WHY USE NONINVASIVE VENTILATION AND HOW DOES IT WORK?

Rationale

NIV has become an integral component of ventilator support in both acute and chronic settings because it avoids the complications of invasive ventilation. Invasive mechanical ventilation is highly effective and reliable in supporting alveolar ventilation, but endotracheal intubation carries well-known risks of complications that have been described elsewhere in detail (see Chapter 39).[4,5] These complications have been lumped into three main categories: complications related to insertion of the tube and mechanical ventilation, those caused by loss of airway defense mechanisms, and those that occur after removal of the endotracheal tube.[4]

In the first category, aspiration of gastric contents; trauma to the teeth, hypopharynx, esophagus, larynx, and trachea; arrhythmias; hypotension; and barotrauma may occur during placement of a translaryngeal tube.[6,7] Tracheostomy tube placement incurs risks of hemorrhage, stomal infection, intubation of a false lumen, mediastinitis, and acute injury to the trachea and surrounding structures, including tracheal rupture,[8] and esophageal and vascular injury.[6] In the second category, endotracheal tubes serve as a source of continual irritation, interfere with airway ciliary function, and require frequent suctioning that contributes to airway injury, patient discomfort, and mucus hypersecretion. They also provide a direct channel to the lower airways for microorganisms and other foreign materials, leading to biofilm formation, chronic bacterial colonization, and ongoing inflammation. As a consequence, health care–acquired pneumonias are seen in up to 20% of mechanically ventilated intensive care unit (ICU) patients (see Chapter 46),[9] and sinusitis is seen in 5% to 25% of nasally intubated patients, related to blockade of the sinus ostia and accumulation of infected secretions in the paranasal sinuses (see Chapter 47).[10] In the third category, hoarseness, sore throat, cough, sputum production, hemoptysis, upper airway obstruction secondary to vocal cord dysfunction or laryngeal swelling, and tracheal stenosis all may follow extubation.[11]

In addition, from the point of view of the patient, translaryngeal intubation is uncomfortable and compromises the ability to eat and communicate, contributing to feelings of powerlessness, isolation, and anxiety.[12] This increases the need for sedation, delaying weaning, prolonging the duration of invasive mechanical ventilation, and potentiating the risks of further complications. If tracheostomy placement becomes necessary, sophisticated equipment including suctioning paraphernalia and a high level of technical expertise among caregivers are required. Tracheostomies promote upper airway colonization with gram-negative bacteria, increasing the risk of pneumonias.[7] Furthermore, long-term tracheostomies are complicated by tracheomalacia, granulation tissue formation, and tracheal stenoses that sometimes obstruct the airway, chronic pain, and tracheoesophageal or even tracheoarterial fistulas.[11] These considerations and potential complications may limit the options for chronic care placement, add substantially to the costs of care,[13] and even preclude home discharge in patients with limited caregiver and financial resources.

NIV can avoid many of these complications if candidates are selected properly using guidelines that are discussed in detail later. NIV leaves the upper airway intact, preserves airway defense mechanisms, and allows patients to eat, drink, verbalize, and expectorate secretions. NIPPV reduces the infectious complications of mechanical ventilation, including nosocomial pneumonia and sinusitis.[14,15] It also enhances patient comfort, convenience, and mobility at no greater[16] or even less[13] cost than endotracheal intubation. NIV can be administered outside the ICU setting as long as adequate nursing and respiratory therapy support can be provided, allowing for more rational use of acute care beds, and it greatly simplifies care for patients with chronic respiratory failure in the home.

Mechanisms of Noninvasive Positive-Pressure Ventilation Action

ACUTE RESPIRATORY FAILURE

NIPPV improves the respiratory status of failing patients via a number of mechanisms. Most important, NIPPV reduces the work of breathing by the same mechanism as invasive positive-pressure ventilation: By applying supra-atmospheric

pressure intermittently to the airways, it increases transpulmonary pressure, inflates the lungs, augments tidal volume, and unloads the inspiratory muscles. Exhalation is achieved by passive lung recoil. Studies in patients with severe stable chronic obstructive pulmonary disease (COPD) or restrictive thoracic disorders show that NIPPV reduces or, if inflation pressure is sufficient, even eliminates diaphragmatic work.[17,18] In patients with severe COPD exacerbations, the addition of positive end-expiratory pressure (PEEP) to inspiratory pressure support further reduces the work of breathing by counteracting the effects of auto-PEEP. This combination (pressure support plus PEEP) lowers diaphragmatic pressure swings even more than with either pressure support or PEEP alone.[19] These actions lead to a prompt reduction in respiratory rate, sternocleidomastoid muscle activity, dyspnea, and carbon dioxide (CO_2) retention.

Other beneficial actions include an increase in functional residual capacity that opens collapsed alveoli, reducing shunt and enhancing ventilation–perfusion ratios in certain forms of respiratory failure, such as acute cardiogenic pulmonary edema. These effects improve oxygenation and may further reduce the work of breathing because the respiratory system is shifted to a more compliant position on its pressure-volume curve. In addition, CPAP alone (and with NIPPV) may improve left-ventricular function by virtue of an afterload-reducing effect of increased intrathoracic pressure.[20] This effect occurs mainly in patients with dilated, hypocontractile left ventricles whose heart function is more dependent on afterload than on preload. The increased intrathoracic pressure reduces both preload and afterload, but the latter effect predominates, lowering transmyocardial pressure and enhancing cardiac output.[21]

A major effect of NIPPV that appears to be responsible for benefits reported in many studies, including reduced complication rates, mortality, and hospital lengths of stay, is a reduction in health care–acquired infections. Two prospective surveys[14,15] observed roughly a fourfold reduction in the risk of health care–acquired pneumonia compared with physiologically matched endotracheally intubated patients, even after controlling for severity of illness. Patients treated with NIPPV also tend to receive fewer other invasive interventions, such as urinary bladder catheters or central intravenous lines,[15] and this also likely contributes to a lower rate of health care–acquired infections and episodes of sepsis.

Despite the advantages of NIPPV related to the avoidance of airway invasion, the lack of a direct connection to the lower airway also poses a number of challenges. The patient must be able to protect his or her airway and clear secretions adequately, or failure is inevitable. The patient's upper airway must permit airflow into the lungs, so NIPPV cannot be used in patients with high-grade, fixed, upper-airway obstructions. In addition, air leaks around the interface seal or via other routes are nearly ubiquitous with NIPPV and may interfere with the efficacy of ventilation. Furthermore, the patient must be able to cooperate and synchronize breathing with the ventilator, or no reduction in the work of breathing can be achieved, but the patient cannot be heavily sedated or paralyzed to achieve synchrony. Thus, patients who are to receive NIPPV must be selected carefully and managed with an eye to these limitations in ways that differ from the approach used for invasive mechanical ventilation.

CHRONIC RESPIRATORY FAILURE

Long-term NIPPV is used mainly nocturnally during sleep, when intermittent air leaking through the mouth or under the mask seal is universal, but sufficient air usually enters the lungs to assist ventilation.[22] The adaptations that permit air entry into the lungs while NIPPV is administered during sleep are poorly understood, but resistance to airflow in the upper airway is undoubtedly an important factor. In one study, large amounts of air leaking through the mouth during nasal CPAP increased nasal resistance,[23] an effect that was countered by provision of heated, humidified air, consistent with the idea that nasal mucosal cooling was responsible. Increases in nasal resistance secondary to this mechanism, upper airway infection, or allergy is likely to reduce delivered tidal volumes during nasal NIPPV. Passive positioning of the soft palate is also important in maintaining patency of the upper airway,[24] as underlined by the observation that patients treated with nasal CPAP experience increased air leaking through the mouth after uvulopharyngoplasty.[25]

Glottic aperture is also important in determining the flow of gas into the lower airways during NIPPV. Compared with the awake state, the glottic aperture narrows and delivered tidal volume falls when NIPPV is administered during stage 1 or 2 sleep.[26,27] In deeper sleep (stage 3 or 4), the glottic aperture widens, permitting more ventilation; if minute volume is increased excessively, however, the glottic aperture narrows once again, partly related to the reduction in the partial pressure of arterial carbon dioxide (Pa_{CO_2}). These findings indicate that both sleep stage and the amount of ventilator assistance influence glottic aperture, which is a potentially important determinant of the efficacy of NIV. They also apply mainly to controlled modes of ventilation;[28] glottic aperture is not as important when NIPPV is administered via a pressure-limited "bilevel" ventilator in the spontaneous mode.[29]

Three theories have been proposed to explain the mechanism by which stabilization of daytime gas exchange is achieved in patients with chronic respiratory failure who are receiving ventilator assistance for as little as 4 to 6 hours nightly. One postulates that NIV rests chronically fatigued respiratory muscles, thereby improving daytime respiratory muscle function.[30,31] Supporting this theory are studies demonstrating that respiratory muscles do indeed rest during NIV;[32–34] also, indices of respiratory muscle strength and endurance may improve in patients with chronic respiratory failure after varying periods of noninvasive ventilatory assistance.[32–35] Conversely, chronic respiratory muscle fatigue has never been defined adequately or demonstrated convincingly; other studies have failed to demonstrate improvement

in respiratory muscle function after initiation of NIV,[36] and some studies have demonstrated that patients with neuromuscular disease have stable Pa_{CO_2} values for years despite a progressive decline in pulmonary function.[37]

A second theory proposes that NIV improves respiratory system compliance by reversing microatelectasis of the lung, thereby diminishing daytime work of breathing.[38] This theory derives from studies showing improvements in forced vital capacity (FVC) without changes in indices of respiratory muscle strength after periods of positive-pressure ventilation. Once again, however, data are conflicting, with a number of studies showing no changes in vital capacity after periods of NIV.[35,36] In addition, computed tomographic scanning of the chest indicates that microatelectasis is not an important contributor to chest wall restriction in patients with respiratory muscle weakness.

A third theory proposes that NIV lowers the respiratory center "set point" for CO_2 by reversing chronic hypoventilation.[30,39] During deeper stages of sleep, particularly rapid eye movement sleep, upper airway muscle tone and the activity of nondiaphragmatic inspiratory muscles diminish.[40] This response may be exaggerated in patients with ventilatory impairment, leading to progressive nocturnal hypoventilation. Repeated episodes of nocturnal hypoventilation are thought to lead to a gradual accumulation of bicarbonate, desensitization of the respiratory center to CO_2, and worsening of daytime hypoventilation.[39] Nocturnal ventilator assistance reverses nocturnal hypoventilation and allows excretion of bicarbonate and a gradual downward resetting of the respiratory center set point for CO_2, thereby reducing daytime hypercarbia. In addition, NIPPV may improve the quantity and quality of sleep by preventing hypoventilation-related arousals that lead to sleep fragmentation,[41] reducing fatigue, and improving daytime function. Evidence for this theory derives from studies showing that when ventilator assistance is discontinued for a night in patients with chronic respiratory failure who have been using nightly NIV, the degree of nocturnal hypoventilation is less than before initiation, suggesting a resetting of respiratory center sensitivity for CO_2.[42] Also, nocturnal ventilation, oxygen (O_2) saturation, sleep quality, and daytime symptoms deteriorate without reductions in respiratory muscle strength or vital capacity when nocturnal NIPPV is discontinued temporarily in patients with restrictive thoracic disease and improve promptly when NIPPV is resumed.[35,41] Moreover, in sixteen patients with chronic respiratory failure secondary to restrictive thoracic disorders followed prospectively for 3 years after starting NIPPV, Pa_{CO_2} improved in association with an increase in the slope of the ventilatory response curve, whereas the maximal inspiratory pressure remained unchanged.[43] These studies suggest that amelioration of nocturnal hypoventilation with resetting of respiratory center CO_2 sensitivity and improved sleep quality may be the most important mechanisms contributing to the efficacy of long-term NIPPV. The three theories, however, are not mutually exclusive, and all could contribute more or less, depending on the patient.

Clearly, much remains to be learned regarding specific mechanisms of action of NIV. Understanding of these mechanisms is complicated by the application of NIV in both acute and chronic settings using many different techniques for patients with varying etiologies of respiratory failure. The ability to unload respiratory muscles appears to be key, particularly in the acute setting. Mechanisms controlling upper airway responses and respiratory center adaptations are less well understood but appear to be critical to success in the long-term setting.

EPIDEMIOLOGY OF NONINVASIVE POSITIVE-PRESSURE VENTILATION

Acute care applications of NIPPV are increasing in Europe and North America.[44,45] An observational study of NIV utilization for COPD and cardiogenic pulmonary edema patients in acute respiratory failure in a single twenty-six-bed French ICU revealed an increase from 20% of ventilator initiations in 1994 to nearly 90% in 2001.[45] In association with this increase, the occurrence of health care–acquired pneumonias and ICU mortality fell from 20% and 21% to 8% and 7%, respectively. In an Italian study examining outcomes of NIPPV in two different time periods during the 1990s, success rates remained steady despite an increase in acuity of illness scores, suggesting that sicker patients in the later time period were being managed as successfully as less ill patients in the earlier period. Both groups of authors speculated that increased experience and skill of the caregivers was responsible for the increased use and improved outcomes.[44,45]

Sequential surveys of European (mainly French) ICUs demonstrated an increase in the use of NIV as a percentage of total initiations of ventilations from 16% in 1997 to 23% in 2002, with utilization in patients with COPD and cardiogenic pulmonary edema increasing from 50% to 66% and from 38% to 47%, respectively.[46] Esteban et al conducted a worldwide survey in more than twenty countries that compared the trends of mechanical ventilation use and demographics between 1998 and 2004, enrolling more than 1600 patients and showing an increase in NIPPV use from 4.4% to 11.1%[47] The differences in rates between the French ICU survey and the worldwide survey may reflect lower utilization rates in some countries as well as the differing methodologies between the two surveys. The French survey examined use in terms of incidents whereas the worldwide survey focused on prevalence of use. Considering that NIPPV is used for shorter periods of time on average than invasive ventilation, prevalence will accordingly be lower.

Some hospital units lend themselves well to NIPPV applications and have very high utilizations rates. In Italy, Confalonieri et al[48] reported high utilization rates of NIV in specialized respiratory intensive care units, which are similar to "intermediate" or "step-down" units in the United States, where a large proportion of patients have COPD either as an etiology of acute respiratory failure or as a comorbidity. In that setting, 425 of 586 (72.5%) patients requiring

mechanical ventilation were treated initially with NIV (374 using NIPPV and fifty-one using an "iron lung").[48]

In a 2003 national audit of COPD exacerbations in the United Kingdom, however, NIV was unavailable in nineteen of 233 hospitals and 39% of ICUs, 36% of "high-dependency units," and 34% of hospital wards.[49] Similar results were seen in a North American survey of use of NIV in seventy-one hospitals in Massachusetts and Rhode Island.[50] Overall use of NIPPV was estimated to be 20% of total ventilator initiations, but 30% of hospitals had estimated rates of less than 15%. Reasons for low utilization were mostly attributed to lack of physician knowledge of NIPPV, inadequate equipment, and lack of staff training. Most disturbingly, estimated use of NIV for COPD exacerbations and cardiogenic pulmonary edema was only 29% and 39% of ventilator initiations, respectively.[50] A follow-up study in Massachusetts using data collected prospectively from 2005 to 2007 revealed an overall 38.7% NIV utilization rate, with 80% and 69% of COPD and cardiogenic pulmonary edema patients, respectively, receiving NIV as the initial mode.[51] More recently, clear evidence for the dramatic increase in NIPPV use derived from a Nationwide Inpatient Survey constituting more than 7 million hospital admissions from 1998 to 2008. NIPPV use increased from 1% to 4.5% of total admissions while there was a concomitant fall in invasive mechanical ventilation from 6% to 3.5%. Mortality rates improved in most groups, but the authors raised concerns about a small subgroup of patients who were transitioned from initial NIPPV to invasive ventilation and had a 29% mortality, higher than in patients who were treated with invasive ventilation from the start.[52]

A national survey of U.S. Veterans Affairs hospitals showed that despite wide availability of NIV, its perceived use was low.[53] Almost two-thirds of respiratory therapists responding to the survey thought that NIV was used less than half of the time when its use was indicated. The survey also revealed that wide variations in the perception of NIV use was dependant partly on the size of the ICUs, with larger ones reporting more frequent use.[53] Along these lines, a Canadian study reported that between 1998 and 2003, only 66% of patients meeting criteria for NIPPV actually received it.[54]

Suboptimal utilization has been reported in non-Western countries as well. A Korean survey reported that NIV was used in just two of twenty-four university hospitals and comprised only 4% of ventilator initiations. A majority of the physician staff (62%) and 42% of the nurses expressed a desire for additional educational programs on NIV.[55] In an Indian survey of 648 physicians, perceived NIV use was mostly limited to the ICU (68.4%), and COPD was the most common indication for its use.[56] Findings of this survey were similar to those of the Korean, European, and North American surveys in that rates of NIV use varied widely between centers, with a substantial portion reporting low rates. Thus, although overall use of NIV is clearly increasing, these findings underline the need for NIV educational programs at individual hospitals that permit caregivers to develop the requisite expertise in administering NIV.

NONINVASIVE POSITIVE-PRESSURE VENTILATION IN THE ACUTE CARE SETTING

Evidence for Efficacy

Numerous acute applications of NIPPV have been described, but only a few are supported by strong evidence (Table 18-1). The following sections discuss important applications according to the type of respiratory failure.

Obstructive Diseases

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Patients with exacerbations of COPD usually are good candidates for NIPPV because they respond to partial ventilator support, hypoxemia is usually mild to moderate, and the condition is most often reversible within a few days. Thus numerous earlier uncontrolled studies have reported that NIPPV avoids intubation in patients with COPD, with success rates ranging from 58% to 93%. Some studies have reported the use of CPAP alone to treat acute exacerbations of COPD,[57,58] based on the rationale that by counterbalancing auto-PEEP, it will reduce the work of breathing.[59] In these studies, relatively low levels of nasal CPAP (5 to 9.3 cm H_2O) were associated with improvements in Pa_{CO_2} and arterial oxygen tension (PA_{O_2}), and few patients required intubation. The lack of controls, however, renders these studies inconclusive.

Kramer et al[60] randomized thirty-one patients with various etiologies for respiratory failure, twenty-one of whom had COPD, to receive NIPPV or conventional therapy. Among COPD patients who received NIPPV in their study, respiratory rate and Pa_{CO_2} fell more rapidly during the first hour of therapy than among controls, and intubation rates were reduced to 9% compared with 67% in controls. In a multicenter European trial[17] of eighty-five patients with COPD randomized to receive face-mask pressure-support ventilation (PSV) or conventional therapy, respiratory rate but not Pa_{CO_2} fell significantly in the NIPPV group during the first hour; intubation (26% vs. 74%), complication (16% vs. 48%), and mortality (9% vs. 29%) rates and hospital lengths of stay (35 vs. 23 days) all were significantly lower in the NIPPV than in the control group.

Another randomized, controlled trial compared the efficacy of standard medical therapy with NIPPV in thirty patients with acute hypercapnic respiratory failure caused by exacerbations, pneumonia, or congestive heart failure.[61] Those randomized to NIPPV had greater improvements in pH and respiratory rate within 6 hours, higher success rate (93%), and shorter hospital lengths of stay (11.7 vs. 14.6 days, $p < 0.05$) than controls. The largest study to date on NIPPV for exacerbations of COPD randomized 236 patients to receive NIPPV or standard therapy at fourteen British centers.[62] NIPPV was administered in general respiratory wards by nurses who had a few hours of in-service training with

Level of evidence: **A**, multiple randomized, controlled trials and meta-analyses; **B**, single controlled trial and cohort series or multiple randomized studies with conflicting findings; **C**, anecdotal reports and case series; **D**, not recommended based on contrary evidence or expert opinion.

the technique. Patients treated with NIPPV had lower intubation (15% vs. 27%) and mortality (10% vs. 20%) rates than controls, but the benefit was seen only in patients with pH values of 7.3 or greater. The authors concluded that although NIPPV proved to be effective in their study, these sicker patients probably should have been treated in an ICU.

In addition to the favorable findings regarding the use of NIPPV for acute exacerbations of COPD, some studies have found that 1-year survival rates are better and the need for rehospitalization and consumption of ICU beds over the next year are less for patients treated with NIPPV as opposed to conventional therapy.[63,64] Although these latter studies were not randomized, so the results could have reflected a selection bias favoring less ill patients in the NIPPV group, it is also possible that NIPPV avoids late complications of invasive ventilation, such as sustained muscle weakness or swallowing dysfunction.[10]

Among the many controlled and uncontrolled studies examining the efficacy of NIPPV in exacerbations of COPD, only two have obtained unfavorable results. In one,[65] twenty-five of forty-nine consecutive COPD patients with acute exacerbations were treated with nasal NIPPV, and twenty-four were intolerant and served as the "control" group. Blood gases in both groups improved at similar rates, and no differences in outcome were apparent between the two groups. In the second, Barbe et al[66] randomized twenty-four patients with acute exacerbations of COPD to receive nasal NIPPV or standard therapy. Four of fourteen patients randomized to NIPPV were intolerant; among the remaining patients, blood-gas improvements and hospital lengths of stay were similar, and no differences in intubation or mortality rates were apparent, leading the authors to conclude that NIPPV is ineffective in COPD. Both studies, however, enrolled consecutive patients who, on average, had less-severe blood-gas abnormalities than patients enrolled in favorable studies; none of the patients in the study of Barbe et al[66] required intubation, as did almost three-quarters of the controls in the studies of Kramer et al[60] and Brochard et al.[17] These observations support the contention that the patients in the two unfavorable studies were less ill than those in the favorable studies, and argue that NIPPV should be reserved for sicker patients with COPD who are at risk of requiring intubation.

Multiple randomized, controlled trials lend themselves to meta-analysis. An earlier meta-analysis by Keenan et al[67] concluded that NIPPV significantly reduces mortality and reduces the cost of hospitalization by an average of $3244 (Canadian) compared with conventional therapy. Peter et al[68] examined both COPD and non-COPD causes of acute respiratory failure in their meta-analysis, and concluded that NIPPV significantly reduces the need for intubation as well as mortality. Meta-analyses by Keenan et al[69] and Lightowler et al[70] (Cochrane analysis) observed absolute and relative risk reductions of 28% and 0.42 for intubation, 10% and 0.41 for mortality, and 4.57 and 3.21 hospital days, respectively (all $p < 0.05$) (Fig. 18-1). The analysis of Keenan et al also concluded that there is little evidence to support NIPPV use in milder COPD, although they analyzed only two studies of mild patients. The analysis of Lightowler et al also found that Pa_{CO_2}, heart rate, and dyspnea scores improved more rapidly than in conventionally treated patients. A more recent meta-analysis by Quon et al[71] derived similar findings, observing reductions of 65% in intubations, 55% in mortality, and 1.9 days in hospital length of stay among COPD patients

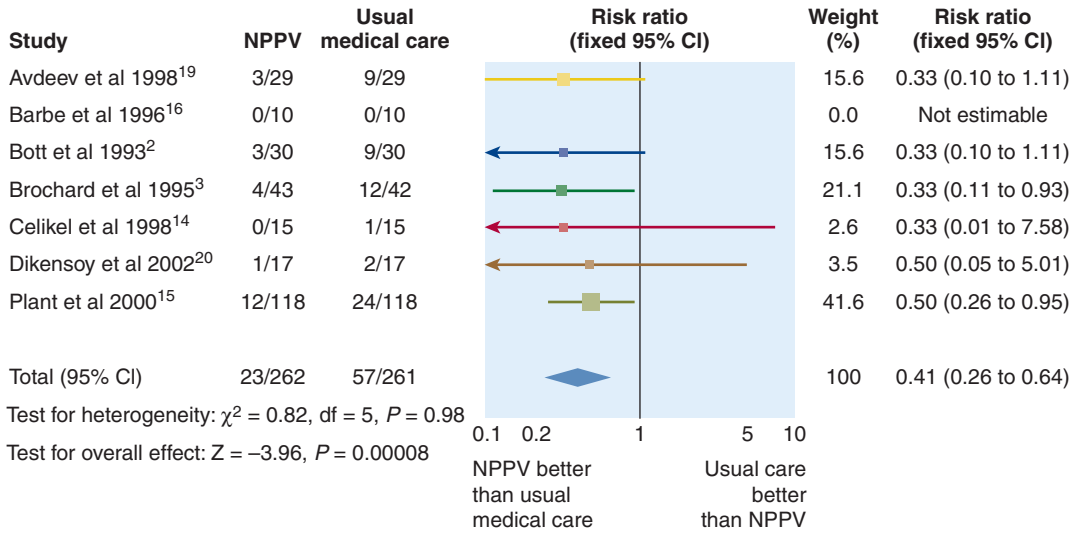

FIGURE 18-1 Forest plot of eight randomized, controlled studies on NPPV in patients with acute respiratory failure secondary to COPD. The reduction in mortality rate was consistent among studies. Noninvasive positive pressure ventilation to treat respiratory failure resulting from exacerbations of chronic obstructive pulmonary disease: Cochrane systematic review and meta-analysis. *Br Med J.* 185–189, 2003.)

admitted with exacerbations and treated with NIPPV. These studies lend strong support to the use of NIPPV for patients with COPD in the acute care setting, leading consensus groups to recommend that the modality "be considered" in selected patients,[72] and the Canadian Thoracic Society Guideline committee to recommend that NIV be considered the ventilatory modality of first choice for patients with acute respiratory failure secondary to exacerbations of COPD.[73] The need for careful patient selection cannot be overemphasized (see "Selection Guidelines" below). NIPPV is best used to avoid intubation, not to replace it. Although NIPPV should be viewed as the ventilator therapy of first choice for appropriate COPD patients, those with contraindications to NIPPV should be intubated and ventilated without delay.

In view of the idea that NIPPV is best used to avoid intubation, Squadrone et al[74] asked whether it can serve as an alternative to intubation in patients with COPD and advanced acute hypercapnic respiratory failure (pH ≤ 7.25, Pa_{CO_2} ≥ 70 mm Hg, respiratory rate ≥ 35 breaths/min). Sixty-four such patients had similar mortality rates and hospital lengths of stay but fewer serious complications (mainly infectious) and a trend toward a higher weaning rate at 30 days compared with a historically matched control group of invasively ventilated patients. The authors concluded that NIPPV can be used as an alternative to invasive mechanical ventilation in severely ill patients with COPD, but considering that the failure rate approached two-thirds in the NIPPV group and that the more recent report by Chandra et al[52] raised concerns about this approach, NIPPV should be applied with great caution in such patients. As pointed out previously, the use of historical controls is a serious design limitation that may favor the treatment group.

Few data provide guidance on selecting patients who might benefit from continued use of NIPPV after hospital discharge. In an uncontrolled retrospective study, Tuggey et al[75] found that patients treated with NIV during their acute admissions and sent home with it had many fewer hospital days per year (25 vs. 78 days; $p = 0.004$) and incurred much lower costs per year ($7407 vs. $23,065) after starting domiciliary NIV than before. Despite the small number of patients and uncontrolled design, these results support the idea that domiciliary NIV should be considered in "revolving-door patients" who require repeated hospital admissions and highlight the need for more definitive studies addressing this question.

ASTHMA

Although acute asthma would be anticipated to respond favorably to NIPPV because it shares pathophysiologic features with COPD, much less evidence supports this application. One early report described seventeen patients with asthma who had an average initial pH of 7.25, a Pa_{CO_2} of 65 mm Hg, and were treated with face-mask PSV.[76] Only two required intubation (for increasing Pa_{CO_2}), average duration of ventilation was 16 hours, and no complications occurred.

More recently, Fernandez et al[77] reported on fifty-eight patients with status asthmaticus, thirty-three of whom were retrospectively deemed candidates for NIPPV because of persisting CO_2 retention (Pa_{CO_2} > 50 mm Hg) and because they met other clinical criteria.[77] Of these, eleven were intubated according to clinician preference, and twenty-two were managed noninvasively. The noninvasively and invasively treated groups had similar initial Pa_{CO_2} values, which improved less rapidly in the noninvasive group. Only 14% of the NIPPV-treated patients eventually required intubation, and they had shorter ICU and hospital lengths of stay than the intubated group. Thus far, four randomized, controlled trials have been reported. Holley et al[78] were able to enroll only one-tenth of the roughly 350 patients their power analysis had projected.

Not surprisingly, their major outcome variable—intubation rate—was not reduced significantly in their NIPPV group (one of nineteen versus two of sixteen in controls), and they observed no deaths. Their major finding was that physicians who a priori believed that NIPPV was effective were less likely to enroll patients in the trial because of concern that the patients might require intubation if randomized to the control group. Soroksky et al[79] randomized thirty-three patients with severe acute asthma (average initial forced expiratory volume in 1 second [FEV_1] roughly 33%) to receive NIPPV or sham therapy via a face mask. The NIPPV group had a significantly greater increase in FEV_1 within the first hour (53.5% vs. 28.5%) and fewer hospitalizations (three of seventeen versus ten of sixteen) compared with the sham group. Both groups received aerosolized bronchodilators via a nebulizer, not the ventilator. The authors speculated that the greater improvement in airflow in the NIPPV group might be related to a bronchodilator effect of positive-pressure.

The third randomized trial[80] supports the notion that NIPPV may have an initial bronchodilator effect in acute asthma. In this study, forty-four patients with status asthmaticus (mean FEV_1 33% predicted) received "low" NIPPV (inspiratory and expiratory pressure 6 and 4 cm H_2O, respectively), "high" NIPPV (inspiratory and expiratory pressure 8 and 6 cm H_2O, respectively), or oxygen supplementation in controls. For the first hour, they received hydrocortisone but no bronchodilators. After the initial hour, the "high" NIPPV group had an improvement in FEV_1 over baseline of 20%, compared to no improvement in controls ($P < 0.05$).

In the fourth trial,[81] undoubtedly underpowered, fifty-three patients with severe asthma were randomized to NIPPV (inspiratory pressure 12 cm H_2O, expiratory pressure 5 cm H_2O) plus standard therapy or standard therapy alone. The NIPPV group spent less time in the ICU and used less bronchodilation, but no other significant differences were observed, including rate of improvement in FEV_1 or gas exchange, or rate of intubation.

These studies suggest that NIPPV may be effective at improving airflow, correcting gas-exchange abnormalities, avoiding intubation, and reducing the need for hospitalization in patients with acute severe asthma. Published studies, however, are either uncontrolled or underpowered or the findings have not been replicated. A Cochrane analysis concluded that evidence for use of NIPPV for acute asthma was "very promising" but "controversial" and that more controlled studies are needed.[82] Furthermore, medical therapy alone may be quite effective.[83] Lacking more evidence, no firm conclusions can be drawn regarding the relative effectiveness of NIPPV versus conventional therapy in exacerbations of asthma. The British Thoracic Society Standards of Care Committee opined that NIPPV should not be used routinely for acute asthma.[84] Nonetheless, an empiric trial of NIPPV might be considered in patients not responding promptly to standard medical therapy if selected according to commonly used criteria (see "Selection Guidelines" below). Also, more research into the role of positive-pressure in enhancing acute bronchodilation seems warranted.

CYSTIC FIBROSIS

NIPPV has been used to treat acutely deteriorating patients with end-stage cystic fibrosis. In one study, six patients with FEV_1 ranging from 350 to 800 mL and severe acute-on-chronic CO_2 retention (initial Pa_{CO_2} ranging from 63 to 112 mm Hg) were treated with NIPPV for periods of 3 to 36 days; four survived until a heart-lung transplantation could be performed.[84] The same investigators reported more recently on 113 patients with cystic fibrosis treated with NIPPV for acute deteriorations.[85] Ninety of these patients (median FEV_1/FVC ratio of 0.5) were listed for lung transplantation, twenty-eight survived to transplantation, ten remained on the list at the time of reporting, and the remainder expired. NIPPV improved hypoxia but not hypercapnia. These case series suggest that NIPPV may serve as a rescue therapy to provide a "bridge to transplantation" for patients with acutely deteriorating cystic fibrosis, but control of airway secretions is still a big challenge and mortality is high if the wait for an organ is prolonged beyond a few months.[86]

UPPER AIRWAY OBSTRUCTION

The inappropriate use of NIPPV in patients with tight, fixed upper airway obstruction should be avoided so as not to delay the institution of definitive therapy. In my experience, however, NIPPV can be used to treat patients with reversible upper airway obstruction, such as that caused by glottic edema following extubation, sometimes in combination with aerosolized medication and/or helium–oxygen gas mixture. Although no controlled trials demonstrate the efficacy of this approach in adults, a controlled trial in ten infants with respiratory failure showed that NIPPV[87] and CPAP were equally efficacious in lowering respiratory rate, but NIPPV contributed to patient–ventilator asynchrony. If used, NIPPV should be administered cautiously and monitored closely because these patients are at risk for precipitous deteriorations.

DECOMPENSATED OBSTRUCTIVE SLEEP APNEA OR OBESITY HYPOVENTILATION SYNDROME

Patients with acute-on-chronic respiratory failure caused by sleep apnea syndrome, often in combination with obesity hypoventilation, have been treated successfully with NIPPV and transitioned to CPAP once stabilized,[88] but no controlled trials have evaluated this application. Sturani et al[89] described the successful use of nasal NIPPV administered with the biphasic intermittent positive airway pressure (BiPAP) device (18 cm H_2O inspiratory and 6 cm H_2O expiratory pressures) in five morbidly obese patients (mean body mass index of 50 kg/m^2) with severe sleep apnea. Anecdotally, high inflation pressures, sometimes necessitating use of volume-limited ventilators that have greater pressure-generating capabilities than portable pressure-limited ventilators, may be needed because of high respiratory system impedance.

Restrictive Diseases

Although NIPPV to treat patients with chronic respiratory failure secondary to restrictive thoracic diseases is well accepted (see "Chronic Respiratory Failure" above), it is used for only a small portion of patients admitted to acute care hospitals with respiratory failure. Accordingly, few studies on the management of acute respiratory failure in these patients have been reported. Small uncontrolled series have reported success using NIPPV to alleviate gas-exchange abnormalities and to avoid intubation in patients with acute respiratory failure secondary to neuromuscular disease[90] and kyphoscoliosis.[91] Despite the lack of evidence, the British Thoracic Society Standards of Care Committee considers that NIPPV "is indicated" in patients with acute or acute-on-chronic respiratory failure secondary to restrictive thoracic diseases.[92]

A regimen for managing acute deteriorations in patients with chronic respiratory failure secondary to neuromuscular disease, reported by Bach et al,[93] requires that patients receive NIV at home 24 hours a day during the exacerbation. When O_2 saturation falls below 90% as determined by continuous pulse oximetry, airway secretions are removed aggressively using manually assisted coughing and mechanical aids such as the cough insufflator–exsufflator until O_2 saturation returns to the 90% range. In this small series of patients, the need for hospitalization was reduced dramatically after institution of the regimen.[79]

Limited information is available on NIPPV therapy for patients with acutely deteriorating restrictive lung diseases such as idiopathic pulmonary fibrosis. Such patients usually fare poorly with mechanical ventilation.[94] On the other hand, in a recent retrospective cohort of eleven patients with idiopathic pulmonary fibrosis and acute respiratory failure treated with NIPPV,[95] five survived the hospitalization and lived for more than 3 months. Thus, some such patients could be considered for NIPPV if they have a possible reversible superimposed condition and are otherwise good NIPPV candidates.

Hypoxemic Respiratory Failure

Hypoxemic respiratory failure is defined as a P_{CO_2}/FI_{O_2} ratio of less than 200 and a respiratory rate greater than 35 breaths/min; contributing diagnoses include acute pneumonia, acute pulmonary edema, acute respiratory distress syndrome (ARDS), and trauma.[96] It is an extremely broad category of acute respiratory failure. Hence, perhaps not surprisingly, studies of NIPPV to treat it have yielded conflicting results. Meduri et al[97] were the first to report the successful application of NIPPV in such patients. In a randomized trial,[98] the same authors found no benefit of NIPPV over conventional therapy among all entered patients. Initial hypercapnia predicted a favorable outcome: Patients with an initial Pa_{CO_2} of greater than 45 mm Hg had significantly lower intubation and ICU mortality rates and shorter ICU lengths of stay than normocapnic patients. The authors concluded that hypoxemic respiratory failure without CO_2 retention responds poorly to NIPPV.

Conversely, Antonelli et al[96] randomized sixty-four patients with hypoxemic respiratory failure to NIPPV or immediate intubation. Improvements in oxygenation were similar in the two groups, and only 31% of the NIPPV-treated patients required intubation. NIPPV-treated patients had significantly fewer septic complications such as pneumonia or sinusitis (3% vs. 31%), and there were trends toward decreased mortality and ICU length of stay (27% vs. 45% and 9 vs. 15 days, respectively) compared with intubated controls. Another randomized, controlled trial of sixty-one patients with various forms of acute respiratory failure found a significantly reduced intubation rate when patients with acute hypoxemic respiratory failure were treated with NIPPV as opposed to conventional therapy (7.5 vs. 22.6 intubations per 100 ICU days); mortality rates, however, were not significantly different.[99]

More recently, Ferrer et al[100] randomized patients with severe hypoxemia (defined as a P_{CO_2} of less than 60 mm Hg or an arterial oxygen saturation [SaO_2] of less than 90% on 50% FI_{O_2} for at least 6 to 8 hours) to receive NIPPV or conventional therapy. Intubation rate was decreased from 52% to 25%, the incidence of septic shock was reduced, and both ICU (39% vs. 18%) and 90-day mortality were lower in the NIPPV group than in controls. In contrast to some previous studies, substantial benefit was observed in patients with severe pneumonia, whereas patients with cardiogenic pulmonary edema had no reduction in intubation rate.

The favorable results of these latter studies might be interpreted to show broad support for the use of NIPPV in patients with hypoxemic respiratory failure. In fact, a recent survey of European pulmonologists and anesthesiologists showed that 48% (more pulmonologists than anesthesiologists) considered acute hypoxemic respiratory failure as a preferred indication for NIPPV.[101] A systematic review, however, noted that although intubations in patients with acute hypoxemic respiratory failure seem to be reduced by NIPPV, the heterogeneity between studies precluded any firm conclusions and recommended against the routine use of NIPPV in these patients.[102] Also, when overall results are favorable in a heterogeneous group of patients, it cannot be assumed that each subgroup benefits equally. It is possible that harm to a particular subgroup could be obscured by benefit in other subgroups. The following subsections examine evidence regarding the use of NIPPV in specific subgroups of patients with acute hypoxemic respiratory failure that may be more appropriate to apply to individual patients.

ACUTE CARDIOGENIC PULMONARY EDEMA

CPAP, although not a form of mechanical ventilatory assistance per se, was described as a treatment for acute pulmonary edema dating back to the 1930s.[103] Over the past 15 years, a number of studies have demonstrated that CPAP (10 to 12.5 cm H_2O) is effective in treating acute pulmonary

edema. Rasanen et al[194] randomized forty patients with cardiogenic pulmonary edema to either face-mask CPAP or standard medical therapy, and demonstrated that CPAP more rapidly improves oxygenation and respiratory rate. In a study of fifty-five patients with pulmonary edema, Lin and Chang[105] found that those randomized to face-mask CPAP (adjusted to maintain a PA_{O_2} of 80 mm Hg or greater) had a lower intubation rate (17.5% vs. 42.5%, $p < 0.05$) than conventionally treated controls. Bersten et al[106] and Lin et al[92] subsequently performed randomized studies on thirty-nine and 100 patients, respectively, demonstrating more rapid improvements in respiratory rates and oxygenation and a reduced need for intubation in patients treated with CPAP. The study of Bersten et al[106] also showed a significant reduction in the length of ICU stay among CPAP-treated patients, and the study of Lin et al[107] showed a trend for a lower hospital mortality rate. The average absolute reduction in intubation rate among these studies was 28% (from 47% in controls to 19% for CPAP). These studies provide strong evidence to support the use of CPAP to treat acute cardiogenic edema.

As discussed earlier, the combination of increased inspiratory pressure and positive expiratory pressure (i.e., pressure support plus PEEP or NIPPV) might be expected to reduce work of breathing more effectively than CPAP alone, bringing about more rapid relief of dyspnea and improvement in gas exchange. Thus, more recent studies have focused on the use of NIPPV to treat acute cardiogenic pulmonary edema. One prospective, uncontrolled study found that face-mask PSV improved pulse oximetry, pH, and Pa_{CO_2} within 30 minutes in twenty-nine patients with acute pulmonary edema, only one of whom required intubation.[108] A second prospective, uncontrolled study[109] reported similar effects on gas exchange, but five of twenty-six patients required intubation, and successfully treated patients had higher Pa_{CO_2} (54 vs. 32 mm Hg) and lower creatine phosphokinase levels (176 vs. 1282 IU) (both $p < 0.05$) than failure. Furthermore, four patients died in the first study and five in the second, three and four, respectively, with myocardial infarctions. The authors concluded that NIPPV is a "highly effective technique." The accompanying editorialist, however, cautioned about applying NIPPV to patients with acute myocardial infarctions.[110]

Several randomized, controlled trials have been performed subsequently comparing NIPPV with conventional O_2 therapy to treat patients with acute cardiogenic pulmonary edema. Masip et al[111] found that inspiratory and expiratory pressures of 15 and 5 cm H_2O, respectively, lowered the intubation rate from 33% in eighteen controls to 5% among twenty-two patients randomized to NIPPV ($p = 0.037$). NIPPV also improved oxygenation more rapidly, but hospital lengths of stay and mortality rates were similar in the two groups. Sharon et al[112] randomized forty patients to receive NIPPV plus low- or high-dose nitroglycerin. The NIPPV group had higher rates of intubation (80% vs. 20%), myocardial infarction (55% vs. 10%), and death (10% vs. none) compared with the nitroglycerin controls (all $p < 0.05$), leading the authors to conclude that NIPPV was less effective and potentially harmful compared with high-dose nitroglycerin. This inference, however, is suspect because the treatments were not comparable, and the inordinately high intubation rate in the NIPPV group (80%) is difficult to explain. In a larger study, Nava et al[113] randomized 130 patients with acute pulmonary edema to receive NIPPV (average: 14.5 cm H_2O of pressure support and 6.1 cm H_2O of PEEP) or O_2 therapy; hypercapnic and normocapnic patients were prospectively distributed equally between groups. As in the earlier studies, NIPPV improved oxygenation, respiratory rate, and dyspnea more rapidly than conventional therapy, but mortality and hospital lengths of stay did not differ between the groups. Overall, the rates of intubation were not significantly different (25% in controls vs. 20% for NIPPV); in the hypercapnic subgroup, however, the intubation rate was lower in the NIPPV group than in controls (6% vs. 29%, $p = 0.015$). These studies suggest that NIPPV is effective therapy for acute pulmonary edema, but whether this is true only for hypercapnic patients awaits further evaluation.

The question of whether NIPPV (the combination of pressure support and PEEP) is superior to CPAP alone is important because CPAP can be delivered more simply and less expensively. An earlier randomized trial comparing the two to treat acute pulmonary edema showed significantly more rapid reductions in respiratory rate, dyspnea scores, and hypercapnia in the NIPPV group compared with the CPAP-treated group.[114] The study was stopped prematurely after enrollment of twenty-seven patients, however, because of a greater myocardial infarction rate in the NIPPV group (71% vs. 31% in controls). This difference may have been attributable to unequal randomization because more patients in the NIPPV group presented with chest pain. The results nonetheless raise concerns about the safety of ventilator techniques used to treat acute pulmonary edema.

More recent randomized, controlled trials comparing NIPPV with CPAP have not detected differences in the myocardial infarction rate. Crane et al[115] randomized sixty patients with cardiogenic pulmonary edema to three different therapies: conventional, CPAP (10 cm H_2O), or bilevel ventilation (15 cm H_2O inspiratory and 5 cm H_2O expiratory pressures). Treatment success was 15% in the control group, 35% in the CPAP group, and 45% in the bilevel group ($p = 116$). Although myocardial infarction rate did not differ among the groups, hospital mortality was 30% in the control group, 0% in the CPAP group, and 25% in the bilevel group ($p = 0.029$). The difference in mortality was not statistically significant until after the first week of hospitalization, after patients had stopped using the devices.

Several additional studies have randomized patients with acute cardiogenic pulmonary edema to CPAP or noninvasive PSV plus PEEP and have found no differences in myocardial infarction rates.[116,119] Physiologic variables improved equally in both groups, intubation and mortality rates were similar, and troponin I levels and the speed of clinical resolution were nearly identical. In addition to finding no increase in the myocardial infarction rate in NIV-treated patients, these

latter studies also found no clear advantage of NIPPV over CPAP alone. These findings must be interpreted with caution, however, because patients with myocardial infarction or acute ischemia were excluded.

In the largest study reported to date, Gray et al[120] randomized 1069 patients with cardiogenic edema to receive CPAP (5 cm H_2O) alone, NIPPV (inspiratory and expiratory pressures 8 and 4 cm H_2O, respectively) or oxygen plus routine therapy in controls. No differences were noted between the CPAP and NIPPV groups, so they were combined in the analysis. Although dyspnea and pH improved more rapidly in the positive-pressure groups than in controls, no differences were apparent in intubation or mortality rates. The authors concluded that noninvasive positive-pressure treatment of cardiogenic pulmonary edema was useful to alleviate symptoms, but not to improve other outcomes. The very low intubation rate in this study (roughly 3% in all groups), however, was much lower than in most previous studies despite the use of low positive-pressures, suggesting that the patients had relatively mild respiratory compromise. Thus, the study may not be comparable to the earlier studies showing significant avoidance of intubations or even mortality.

A number of meta-analyses[121–126] have concluded that CPAP alone is effective in reducing dyspnea, improving vital signs and gas exchange, and reducing intubation and mortality rates, without any significant effect on myocardial infarction rates. Similar benefits have been attributed to NIPPV, except that improved mortality has been found in only a few,[124–126] probably because there have been fewer studies of NIPPV than on CPAP. These meta-analyses have also compared NIPPV and CPAP, finding no differences between the two modalities with respect to intubation and mortality rates as well as occurrence of myocardial infarction. These findings have held up, even when meta-analyses were performed after publication of the Gray study.[125,126]

Deciding which patients with acute cardiogenic pulmonary edema should receive NIPPV can be challenging because they may respond rapidly to conventional therapy. Using their single-center registry, Masip et al[127] obtained data on eighty conventionally treated patients with cardiogenic pulmonary edema to identify those at risk for intubation. Patients with a pH of less than 7.25 or hypercapnia and a systolic blood pressure of less than 180 mm Hg were found to be at high risk. The authors recommended that such patients should be "promptly considered" for NIV. Because studies have not shown definitively that NIV is more effective than CPAP, however, the most sensible current recommendation is to use CPAP (10 cm H_2O) initially, and consider switching to NIPPV if the patient has unrelenting dyspnea or persisting tachypnea or hypercapnia. Furthermore, either CPAP or NIPPV should be used with great caution, if at all, in patients with acute myocardial infarction or active ischemia. These recommendations are in line with those of a Cochrane analysis that deemed NIV, especially CPAP, as "safe and effective" for the treatment of cardiogenic pulmonary edema in adults.[128]

Prehospital Use of CPAP for Cardiogenic Pulmonary Edema. An important trend in the application of CPAP for acute cardiogenic pulmonary edema has been the use in the field by ambulance crews to treat patients before hospitalization. The experience with this practice has been favorable thus far. Plaisance et al[129] observed a strong trend for reduced intubation and mortality rates among 124 patients with cardiogenic pulmonary edema randomized to "early" (started immediately on site) versus "late" (delayed by 15 minutes) CPAP (7.5 cm H_2O). In another randomized, controlled trial, Thompson et al[130] observed an absolute reduction of 30% in intubation rate (seventeen of thirty-four patients [50%] vs. seven of thirty-five [20%]) and absolute mortality fell by 21% among patients with cardiogenic pulmonary edema treated with CPAP compared to usual therapy with oxygen, including intubation and bag-valve-mask-ventilation if needed.

A pilot study by Duchateau et al[131] reported an improved respiratory status in twelve "do not intubate" patients when offered NIPPV out-of-hospital by emergency medical services. Respiratory rate decreased from 34 to 27 breaths/min ($p = 0.009$) and pulse oximetry improved from 86% to 94% ($p < 0.01$) with only one intolerant patient. These studies suggest that outcomes of patients with cardiogenic pulmonary edema can be improved by very early initiation of noninvasive positive-pressure therapy in the field and adoption of this as a routine practice for emergency medical services seems likely. A recent Cochrane analysis concluded that prehospital NIV "appears to be a safe and feasible therapy" that may lower the need for intubation compared to initiation in the emergency department.[132] The authors of the Cochrane analysis cautioned, however, that the evidence is preliminary and that cost-effectiveness analyses have not been performed.

PNEUMONIA

An earlier retrospective study found that acute severe pneumonia is a predictor of NIV failure, perhaps because NIPPV does little to facilitate the clearance of secretions.[133] Confalonieri et al[134] randomized fifty-six patients with severe community-acquired pneumonia to receive NIPPV or standard O_2 therapy. The NIPPV group had fewer intubations (21% vs. 50%) and shorter ICU lengths of stay (1.8 vs. 6 days) than controls (both $p < 0.05$). In addition, NIPPV-treated patients with COPD had significantly better survival at 2 months, thought to be related to fewer late complications of intubation. The most important observation, though, was that all the benefit was attributable to the subgroup with COPD, and no clear benefit of NIPPV was seen in patients without COPD patients. More recently, a prospective study on NIPPV to treat patients with severe community-acquired pneumonia but without COPD found that oxygenation and respiratory rates improved initially in twenty-two of twenty-four patients after starting NIPPV, but 66% eventually required intubation.[135] Based on the preceding evidence, initiation of NIPPV is justifiable in appropriate patients with pneumonia and

COPD. The benefit of NIPPV in patients with pneumonia but without COPD has not been established. As such, NIPPV should be used selectively and with caution in such patients.

The severe acute respiratory syndrome epidemic was characterized by a high rate of respiratory failure among afflicted individuals, many of whom were otherwise healthy health care workers. Initially, use of NIPPV was discouraged because of concerns about aerosolization and transmission of the highly contagious coronavirus to other health care workers. Two retrospective studies, however, one from Beijing on twenty-eight patients treated with NIPPV[139] and the other from Hong Kong on twenty patients,[140] suggest that NIPPV is effective in avoiding intubation in some patients. Intubation was required in only 33% and 30% of NIPPV-treated patients in the two studies, respectively. Stringent infection-control measures, including the use of a face mask, an inline viral/bacterial filter in the bilevel ventilator tubing, and a high-efficiency particulate accumulator mask by all health care workers having contact with the patients, prevented transmission of severe acute respiratory syndrome to any caregivers. Both studies reported high rates of barotraumas, 22% and 20%, respectively; it was unclear that this was related to NIPPV. Given the lack of controls, these studies cannot be used to assess the efficacy of NIPPV in severe acute respiratory syndrome, although the lack of transmission to health care workers should allay fears about NIPPV spreading the virus so long as stringent isolation and prevention measures are employed.

More recently, the use of NIPPV to treat influenza pneumonia during the H1N1 epidemic was controversial.[138] Based on the 1 m dispersion of aerosol beyond the mask demonstrated during NIPPV applied to a human-like mannequin,[139] some advised against use of NIPPV for influenza pneumonia, although actual transmission by this route was never demonstrated, nor was it compared to dispersion occurring during invasive mechanical ventilation or even spontaneous breathing.

IMMUNOCOMPROMISED PATIENTS

The use of NIPPV to avoid endotracheal intubation in immunocompromised patients is appealing because, by assisting ventilation without having to invade the airway, it reduces infectious and hemorrhagic complications. Encouraging results derived from an uncontrolled series that reported NIPPV success rates as high as 67% (in forty-eight patients with AIDS and *Pneumocystis carinii* pneumonia).[140] Conti et al[141] avoided intubation in fifteen of sixteen patients treated with NIPPV with acute respiratory failure complicating hematologic malignancies, although patients were excluded if they had more than two organ-system failures or were responding poorly to antineoplastic therapy. More recently, Antonelli et al[142] randomized forty patients with acute respiratory failure of various etiologies following solid-organ transplantation to receive NIPPV or standard therapy. NIPPV reduced the need for intubation and lowered ICU mortality rate (both 20% vs. 50% in controls, $p < 0.05$), but total hospital mortality was similar. Trends for fewer health care–associated pneumonias and episodes of severe sepsis also were apparent among NIPPV-treated patients. In a subsequent study of fifty-two immunocompromised patients with respiratory failure, 58% with hematologic malignancies, randomized to receive NIPPV for at least 2 hours three times daily or standard O_2 therapy, those treated with NIPPV had fewer intubations (46% vs. 77%) and mortalities (50% vs. 81%, both $p < 0.05$).[143]

The sizable reductions in mortality among these high-risk patients strongly supports the use of NIV as the ventilatory modality of first choice in selected immunocompromised patients with acute respiratory failure. Patients developing respiratory insufficiency should be started on NIPPV relatively early,[133] before progression to severe respiratory failure, watched closely, and intubated without delay if needed. The need to perform invasive diagnostic procedures sometimes requires intubation in these patients although NIPPV can be used to support patients during fiber-optic bronchoscopy (see below).

ACUTE RESPIRATORY DISTRESS SYNDROME

The use of NIPPV to treat ARDS has been controversial, some considering it the "last frontier." One early cohort series reported that NIPPV maintained adequate oxygenation and averted intubation in six of twelve episodes of ARDS in ten patients.[144] In an observational cohort of seventy-nine patients with acute lung injury, Rana et al[145] found that shock, metabolic acidosis, and profound hypoxemia were predictors of NIV failure and cautioned against use in such patients. A more recent study used NIPPV as a "first-line" therapy of ARDS.[146] Of 479 patients presenting with ARDS, 147 had not been intubated upon admission to the ICU. These were begun on NIPPV and 54% avoided intubation. Not unexpectedly, outcomes were much better in those who avoided intubation than in those who failed NIPPV and required intubation: 2% versus 20% rate of ventilator-associated pneumonia and 6% versus 53% mortality rate, respectively. A simplified acute physiology score of equal to or less than 34 at baseline and a Pa_{O_2}/FI_{O_2} greater than 175 after the first hour of NIPPV predicted success. Although not controlled, the trial suggests that a small minority (15% in this trial) of patients with ARDS can be managed successfully with NIPPV, but they must be chosen carefully and monitored very closely in an ICU. If their oxygenation fails to improve substantially within the first hour, urgent intubation should be considered.

Recently, a randomized controlled trial of NIPPV in patients with acute lung injury ($200 > Pa_{O_2}/FI_{O_2} < 300$ showed reductions in the need for intubation one of twenty on NIPPV pts and seven of 19 control patients) and actual intubations (one of twenty-one versus four of nineteen) as well as occurrence of organ failure (three of twenty-one versus fourteen of nineteen) (all $p < 0.05$), with a trend toward reduced mortality.[147] These studies suggest that NIPPV may have a role in

the management of some patients with acute lung injury and ARDS, but it should be avoided in those with multiorgan system failure and very severe oxygenation defects who are likely to require prolonged ventilator support using sophisticated modes. If a trial of NIPPV is initiated, patients should be intubated without undue delay if they deteriorate or even fail to improve sufficiently.

TRAUMA

Traumatic chest wall injuries such as flail chest or mild acute lung injury might respond favorably to NIPPV, but other etiologies might not. In a retrospective survey on forty-six trauma patients with respiratory insufficiency treated with NIPPV, Beltrame et al[148] found rapid improvements in gas exchange and a 72% success rate, but burn patients responded poorly. More recently, a controlled trial that randomized thoracic trauma patients with $Pa_{O_2}/FI_{O_2} < 200$ to NIPPV or high-flow oxygen was stopped early after enrollment of fifty patients because of significant reductions in intubation rate (12% vs. 40%) and hospital length of stay (14 vs. 21 days) in the NIPPV group.[149] These results support the use of NIPPV for hypoxemic respiratory failure in postthoracic trauma cases, but it is well to remember that these were carefully selected patients.

NONINVASIVE POSITIVE-PRESSURE VENTILATION FOR CATEGORIES OF PATIENTS WITH ACUTE RESPIRATORY FAILURE

Do-Not-Intubate Patients

Some argue that there is little to lose by using NIPPV in almost any terminal patient. NIPPV could be used to lessen dyspnea, preserve patient autonomy, and permit verbal communication with loved ones during a terminal patient's final hours.[150] Some patients might be salvaged in the near term who otherwise would die without ventilatory assistance. This application is controversial, however, with some arguing that it could merely prolong the dying process, diminish patients' comfort in their waning hours, and promote excessive resource utilization.[151]

Among reports on NIPPV to treat patients who have declined or are reluctant to undergo intubation, Benhamou et al[152] retrospectively studied thirty such patients, mostly elderly men (mean age: 76 years) with COPD. Despite severe respiratory failure (mean PA_{O_2} of 43 mm Hg and Pa_{CO_2} of 75 mm Hg), NIPPV was successful initially in 60% of patients. The authors considered NIPPV to be preferable to endotracheal intubation because short-term prognosis was better, and the modality appeared to be more comfortable with fewer complications. In another uncontrolled series, Meduri et al[153] observed a similar response to NIPPV among twenty-six patients with acute hypercapnic and hypoxemic respiratory failure who refused intubation.

In a prospective survey of 113 do-not-intubate patients treated with NIV,[154] amounting to 10% of all patients treated with NIPPV, survival to hospital discharge was 72% and 52% for patients with acute pulmonary edema and COPD, respectively, whereas it was less than 25% for patients with pneumonia or cancer. In addition, the absence of an effective cough and the inability to be awakened were significantly associated with hospital mortality. Similar findings were reported by Schettino et al.[15] Thus, the use of NIV may be justifiable in do-not-intubate patients who have a high likelihood of surviving the hospitalization. Longer-term survival of these hospital survivors, however, is poor; Chu et al[156] found a 30% 1-year survival for do-not-intubate patients with COPD as compared with 65% for patients desiring intubation. Also, no studies have yet assessed effects on patient comfort or family satisfaction.

NIV can also be used for palliation in patients whose prognosis is poor for surviving an admission to hospital, with the possible aims of alleviating dyspnea or prolonging survival long enough to enable a patient time to settle affairs or say goodbye to loved ones. As recommended by a consensus statement by a task force of the Society of Critical Care Medicine on NIV,[157] it is necessary for the patient, family, and caregivers to agree on these goals and to cease NIPPV promptly if it seems to be adding to suffering (via mask discomfort, for example) rather than alleviating it.

Postoperative Patients

Several early case series on the use of NIPPV to treat respiratory insufficiency in postoperative patients with Pa_{CO_2} values of greater than 50 mm Hg, PA_{O_2} values of less than 60 mm Hg, or evidence of respiratory muscle fatigue reported prompt reductions in respiratory rate and dyspnea scores, improvement in gas exchange, and high success rates (roughly 75%) in avoiding the need for reintubation.[158,159] Subsequent studies found that NIPPV was more effective than CPAP or chest physiotherapy in improving lung mechanics and oxygenation after coronary artery bypass surgery,[160] and better than O_2 therapy alone in improving oxygenation after lung-resection surgery.[161] NIPPV also ameliorated postgastroplasty pulmonary dysfunction in morbidly obese patients.[162]

These earlier studies heightened interest in the prophylactic use of CPAP or NIPPV after high-risk surgeries such as major abdominal surgery[162–165] or thoracoabdominal aneurysm repair.[166] These studies, using CPAP (10 cm H_2O) for 24 hours postoperation, observed reductions in the incidence of hypoxemia, pneumonia, atelectasis, and intubations compared with standard treatment.

Few studies have examined the postoperative role of NIPPV in patients with frank respiratory failure, but a randomized trial of NIPPV in forty-eight post–lung-resection patients with acute respiratory insufficiency, most with COPD, showed significant improvements in oxygenation and reductions in the need for intubation (21% vs. 50%) and

mortality rate (13% vs. 38%) compared with conventionally treated controls (both $p < 0.05$).[167]

These studies strongly support the idea that both CPAP and NIPPV should be considered to prevent and treat postoperative respiratory complications and failure, especially in high-risk surgeries, but only a few studies have examined each of the various surgeries and positive-pressure techniques possible, so more specific recommendations cannot currently be made.

Facilitation of Weaning

Nava et al[168] tested the hypothesis that NIPPV could be used to shorten the duration of invasive ventilation and reduce the occurrence of associated complications in a randomized, controlled trial of fifty patients intubated for acute respiratory failure secondary to COPD. If they failed a T-piece weaning trial performed 48 hours after intubation, patients were randomized to extubation followed by facemask PSV or continued intubation and routine weaning. The NIPPV patients had higher overall weaning rates (88% vs. 68%), shorter durations of mechanical ventilation (10.2 vs. 16.6 days), briefer stays in the ICU (15.1 vs. 24 days), and improved 60-day survival rates (92% vs. 72%) (NIPPV-treated versus controls, all $p < 0.05$). In addition, no NIPPV-treated patients had nosocomial pneumonia compared with seven pneumonias among the controls. In a similar trial, Girault et al[169] randomized thirty-three patients with acute-on-chronic respiratory failure to remain intubated or to be extubated to NIPPV after failure of a 2-hour T-piece trial. The NIPPV group had a shorter duration of endotracheal intubation (4.6 vs. 7.7 days, $p = 0.004$), but the total duration of mechanical ventilation was longer in the NIPPV group, and weaning and mortality rates and ICU and hospital lengths of stay were similar between the groups.

More recently, Ferrer et al[170] randomized forty-three patients with "persistent" weaning failure (three consecutive failed T-piece trials) to be extubated to NIV or to remain intubated and be weaned using conventional methods. Patients randomized to NIV had shorter periods of intubation (9.5 vs. 20.1 days), shorter ICU (14 vs. 25 days) and hospital stays (14.6 vs. 40.8 days), a lower rate of nosocomial pneumonia (24% vs. 59%), and improved ICU and 90-day survivals (roughly 80% vs. 50%, all $p < 0.05$). This study lends strong support to the use of NIV to facilitate extubation, but it is worth noting that two-thirds of the patients had COPD or congestive heart failure.

In the most recent randomized (VENISE) trial that included 208 patients who had failed a spontaneous breathing trial, 69% of whom had COPD, the investigators included not only invasively ventilated and NIV groups, but also a group extubated early to oxygen therapy alone.[171] There were no differences in the main outcome variable: reintubation within 7 days (around one-third of patients in each group), or in most secondary outcome variables including mortality and lengths of stay in the ICU and hospital, complications and need for tracheostomy. Duration of intubation, however, was 1.5 days longer in the invasively ventilated group by design and the rate of postextubation acute respiratory failure was significantly less in the NIV group because NIV rescue was used after extubation in 57% and 45% of the oxygen therapy and invasively ventilated patients ($p > 0.05$), respectively, with an overall NIV rescue success rate of 52%. The authors concluded that, based on the reduction in postextubation acute respiratory failure, their results should "support the implementation of NIV" in difficult-to-wean patients, but recommended further study.

Thus, overall, the evidence favors the use of NIPPV to facilitate weaning and extubation in difficult-to-wean patients with COPD, mainly to reduce the occurrence of postextubation respiratory failure. In the absence of overwhelmingly favorable evidence, however, the following caveats should be borne in mind: (a) This approach should be reserved mainly for patients with COPD; (b) patients should be selected carefully, ascertaining that they are good candidates for NIPPV (see "Selection Guidelines" below); (c) patients should not have been difficult intubations; and (d) patients should be comfortable on levels of PSV that can used via mask after extubation.

Treatment of Extubation Failure

Another potential application of NIPPV in the weaning process is to avoid reintubation in patients who fail extubation. Epstein et al[172] reported that extubation failure is associated with much higher morbidity and mortality rates (43%) than successful extubations (approximately 10%). Some investigators have used NIPPV prophylactically to see if extubation failure can be avoided. Jiang at al[173] randomized consecutive extubated patients to receive NIPPV or conventional therapy and found a trend for a higher reintubation rate in the NIPPV group (28% vs. 15%), suggesting that indiscriminate use of NIPPV is not effective for preventing extubation failure. Other investigators have attempted to prevent extubation failure by initiating NIPPV when patients develop risk factors for extubation failure. Esteban et al[174] tried this approach in a multicenter, multinational randomized trial of 221 patients developing risk factors for respiratory failure within 48 hours after they were extubated, including hypercapnia, tachypnea, or hypoxemia. Reintubation rates (48%) and ICU lengths of stay (18 days) were identical in both groups, and the study was terminated prematurely because of a significantly increased ICU mortality in the NIV group (25% vs. 15%, $p = 0.048$). The mortality difference was attributable to a higher mortality in the reintubated NIV patients, reintubation occurring almost 10 hours later than in the standard-therapy group. The authors concluded that NIV is not effective in unselected patients at risk for extubation failure and speculated that the greater delay in reintubation was responsible for the higher mortality rate. It is worth noting, however, that twenty-eight patients in

the control group crossed over to NIPPV when they met failure criteria. Thus, the controls likely would have had a substantially higher reintubation rate had they not crossed over to NIPPV. Also, only 10% of patients enrolled in the study had COPD.

Another approach to treating extubation failure is to await the development of overt respiratory failure before initiating NIPPV. Hilbert et al[175] found that NIPPV used in this fashion lowered reintubation rate (20% vs. 67%) and shortened ICU lengths of stay in thirty patients with COPD and postextubation hypercapnic respiratory insufficiency compared with thirty historically matched controls. Keenan et al[176] randomized eighty-one patients to receive NIPPV or conventional therapy if they developed respiratory failure within 48 hours of extubation. The reintubation rate in this trial was roughly 70% in both the NIPPV group and controls, and no significant differences were found in hospital length of stay or survival. Patients with COPD, however, were excluded after the first year for ethical reasons, and only 12% of the patients had COPD. Furthermore, the pressures used (10 cm H_2O inspiratory and 5 cm H_2O expiratory) may have been insufficient to provide adequate ventilatory assistance.

Two subsequent randomized trials (consisting of ninety-seven and 162 patients, respectively,[177,178] approximately 30% to 40% of whom had COPD or congestive heart failure [CHF]) enrolled patients deemed to be at "high risk" for extubation failure. Both studies found that NIV reduced the need for reintubation, ICU mortality, and hospital length of stay, but hospital mortality was decreased only in the hypercapnic subgroup of the second study.[178] A more recent randomized trial of 106 patients with postextubation hypercapnia (Pa_{CO_2} > 45 mm Hg) showed a significant reduction in postextubation respiratory failure as well as 90-day mortality in the group randomized to NIPPV compared to oxygen-treated controls.[179] The main effect of NIPPV in this study was to prevent greater retention of CO_2. The reason for the reduced 90-day mortality when mortality was not significantly reduced at earlier time points was not apparent.

These more recent studies support the use of NIV for patients who are at "high risk" for extubation failure, particularly if they have COPD, CHF, and/or hypercapnia. A Cochrane systematic review concluded that for patients who mainly have COPD, the evidence "demonstrated a consistent, positive effect on mortality and ventilator-associated pneumonia."[180] Based on the Esteban study,[174] however, NIPPV to prevent extubation failure should be used very cautiously in at-risk patients who do not have COPD or other favorable characteristics because of the higher risk of NIPPV failure and its attendant morbidity and mortality. Such patients failing to improve promptly with NIPPV should be reintubated without delay.

Pediatric Applications

Use of NIPPV in the pediatric population has been increasingly reported in the medical literature,[181] but most studies are retrospective and very few randomized controlled trials have been performed. For more detailed assessments of this literature, the reader is referred elsewhere.[181,182] Pediatric applications of NIPPV parallel those in the adult, but the etiologies of respiratory failure, of course, reflect those encountered in children. In earlier reports, Fortenberry et al[183] found that respiratory rate, Pa_{CO_2}, and oxygenation improved promptly after initiation of nasal bilevel NIPPV in a retrospective series of twenty-eight children with acute hypoxemic respiratory failure, only three of whom required intubation. Padman et al[184] subsequently reported similar results in a prospective series of thirty-four pediatric patients with both hypoxemic and hypoventilatory respiratory insufficiency, again with only three patients requiring intubation. More recent applications have been reported in children with status asthmaticus[185] and atelectasis[186] and randomized, controlled trials have been performed in children with bronchiolitis[187] and tracheomalacia.[188] These studies consistently show more rapid improvements in vital signs and gas exchange with NIPPV compared to controls.

These favorable responses to NIPPV in children are not surprising, particularly when they are suffering from conditions reported to be treated successfully by NIPPV in adults. Concerns have been raised, however, about treating very young children and infants with NIPPV because of increased nasal resistance[189] and inability to cooperate.[182] In the series of Fortenberry et al[183] of twenty-eight patients, NIPPV was successful in avoiding intubation in the ten children who were younger than 5 years of age. More recently, a retrospective trial observed successful application of NIPPV in infants following liver transplantation.[190] In a randomized, prospective trial on infants (median age: 9.5 months) with various causes of upper airway obstruction, CPAP and BiPAP proved to be equally efficacious in reducing respiratory rate and breathing effort; both were well tolerated, although BiPAP was associated with more asynchrony.[188] The lack of controlled trials makes it difficult to formulate specific guidelines for NIPPV in children, although reported success rates appear to be comparable to those in adults, and tentative guidelines have been proposed[182] that are based on those used for adults.

NONINVASIVE VENTILATION FOR PATIENTS UNDERGOING PROCEDURES

Bronchoscopy and Endoscopy

NIPPV administered via T connector attached to a face mask can be used to assist ventilation and enhance oxygenation during fiber-optic bronchoscopy in high-risk patients. First reported to improve oxygenation and be well tolerated in a small series of immunocompromised hypoxemic patients,

NIPPV was shown subsequently to improve and sustain oxygenation better than conventional O_2 supplementation in a randomized, prospective trial in twenty-six patients with Pa_{O_2}/FI_{O_2} ratios of 200 or less and suspected nosocomial pneumonia.[191] More recently, NIPPV to assist ventilation during fiber-optic bronchoscopy was administered successfully using a "helmet" device (see techniques section below).[192] NIPPV also has been used to assist ventilation during upper endoscopy for gastric tube placement in patients with neuromuscular disease[193] and during performance of transesophageal echocardiography.[194]

Preoxygenation before Intubation

NIPPV can be used to improve O_2 saturation during and after intubation and decrease the incidence of O_2 desaturations below 80% during intubation according to a randomized trial in critically ill patients with hypoxemic respiratory failure.[195] This approach is promising but needs further evaluation before routine use can be recommended. This also begs the question whether, if NIV improves oxygenation substantially, intubation could be avoided in some of these patients.

SELECTION OF PATIENTS FOR NONINVASIVE POSITIVE-PRESSURE VENTILATION IN THE ACUTE CARE SETTING

Determinants of Success

Retrospective[133,196] and prospective[197–199] studies have identified predictors of NIPPV success (Table 18-2). Patients with baseline hypercapnia fare better than those with hypoxemia alone, but successful patients have lower baseline Pa_{CO_2} values (79 vs. 98 mm Hg) and higher pH values (7.28 vs. 7.22) than failure patients.[105] Pneumonia predisposes to failure whether alone or in combination with COPD (odds ratio [OR] 5.63 for COPD).[197,199] The strongest predictor of success, though, is prompt improvement in gas exchange and heart and respiratory rates within 1 to 2 hours of NIPPV initiation.[133,196–199] Confalonieri et al[198] have incorporated some of these predictors (Acute Physiology and Chronic Health Evaluation [APACHE] II score ≥ 29, pH < 7.25, Glasgow Coma Score ≤ 11, and respiratory rate ≥ 35 breaths/min) into two risk charts for NIPPV failure, one to be used at baseline and the other at 2 hours (Fig. 18-2). If these abnormalities were all present at baseline, the likelihood of failure was 82% and rose to 99% if they persisted at 2 hours.

Timing of initiation is another determinant of success. Ambrosino et al[133] advised that NIPPV "should be instituted early in every patient before a severe acidosis ensues." Initiation of NIPPV should be viewed as taking advantage of a "window of opportunity." The window opens when acute respiratory distress occurs and shuts when the patient deteriorates to the point of necessitating immediate intubation. In this context, it should be emphasized that NIPPV is used as a way of preventing intubation, not replacing it.

TABLE 18-2: PREDICTORS OF SUCCESS DURING ACUTE APPLICATIONS OF NONINVASIVE POSITIVE-PRESSURE VENTILATION

Younger age
Lower activity of illness (APACHE score)
Able to cooperate, better neurologic score
Able to coordinate breathing with ventilator
Less air leaking, intact dentition
Tachypnea, but not excessively rapid (> 24 but < 35 breaths/min)
Hypercarbia, but not too severe (Pa_{CO_2} > 45 but < 92 mm Hg)
Acidemia, but not too severe (pH < 7.35 but > 7.10)
Improvements in gas exchange, heart and respiratory rates within first 2 hours*

*Most powerful predictor.

Selection Guidelines

The preceding predictors of success and failure and the entry criteria used for enrollment of patients into the many studies have served as a basis for consensus guidelines on the selection of patients to receive NIPPV for acute respiratory failure.[200] These guidelines use a simple three-step approach outlined in Table 18-3. The first step asks whether the patient needs ventilator assistance. Patients with mild or no respiratory distress are excluded from consideration because they should do well without ventilator assistance. Those needing ventilator assistance are identified using clinical indicators of acute respiratory distress and gas-exchange derangement, as listed in Table 18-3. These criteria are most applicable to patients with COPD but can be used to screen those with other forms of expiratory failure, although some modifications are advisable. For example, studies on NIPPV in acute pulmonary edema and acute hypoxemic respiratory failure have used higher respiratory rates as enrollment criteria (> 30 to 35 instead of > 24 breaths/min) and a P_{CO_2}/FI_O ratio of less than 200.[111–114]

The second step is to screen out patients in whom use of NIPPV is contraindicated (see Table 18-3). Most are relative contraindications, and judgment should be exercised in implementing them. Also, some conditions that have been listed as contraindications in the past no longer preclude the use of NIPPV. For example, patients with coma, if related to hypercapnia, may be managed successfully with NIPPV. Diaz

Admission

FIGURE 18-2 Charts showing percentage likelihood of noninvasive positive-pressure ventilation (*NIPPV*) failure in patients with chronic obstructive pulmonary disease (*COPD*) based on pH and Acute Physiology and Chronic Health Evaluation (*APACHE*) score and Glasgow coma score (*GCS*). Chart on top refers to values at the time of admission, and bottom chart is at 2 hours. Numbers in boxes are percentages for likelihood of failure. At 2 hours, the combination of an APACHE score of less than 11, APACHE score of 29 or greater, and a Glasgow coma score of less than 11 predicts failure with a likelihood of 99%. Based on 1033 patients with COPD treated with NIPPV in thirteen different experienced units. (Used, with permission, from Antonelli, et al. Predictors of failure of noninvasive positive pressure ventilation in patients with acute hypoxemic respiratory failure: a multi-center study. *Intensive Care Med.* 2001;27:1718–1728. With kind permission from Springer Science and Business Media.)

et al[201] demonstrated that patients (mainly with COPD) with hypercapnic coma (Glasgow coma scores ≤ 8) had outcomes just as good as those with higher Glasgow coma scores. In another report,[152] nearly half the patients were obtunded or somnolent initially, yet most were managed successfully with NIPPV.

The underlying etiology and potential reversibility of acute respiratory failure are also important considerations in patient selection. As discussed previously, the strongest evidence supports the use of NIPPV for COPD and either NIPPV or CPAP for acute cardiogenic pulmonary edema. As illustrated in Figure 18-3, a reversible etiology permits the use of NIPPV as a "crutch" that assists the patient through a critical interval, allowing time for other therapies such as bronchodilators, steroids, or diuretics to reverse the underlying condition. More severe, less easily reversed forms of respiratory failure that will require prolonged periods of ventilatory support, such as status asthmaticus requiring controlled hypoventilation, complicated pneumonias, or ARDS, are best managed using invasive ventilation. Marginal patients might be considered for a trial of NIPPV but should be watched closely for further deterioration so that needed intubation is not delayed unduly.

NONINVASIVE POSITIVE-PRESSURE VENTILATION FOR CHRONIC RESPIRATORY FAILURE

Evidence for Efficacy

RESTRICTIVE THORACIC DISEASES

Restrictive thoracic disorders limit expansion of the thoracic cage either because of increased elastance (as with chest wall deformity), muscle weakness (as with neuromuscular diseases), or both. Experience gained during the polio epidemics of the 1930s through 1950s and subsequently with other neuromuscular disorders demonstrated that "body ventilators," even when used intermittently, were effective at stabilizing or even reversing chronic respiratory failure secondary to restrictive thoracic disorders.[202,203] Although NIPPV had been available for the therapy of restrictive thoracic diseases for decades,[204] its use beyond a few centers with special expertise was quite limited until the late 1980s. Mouthpieces or full-face masks designed mainly for administration of anesthesia were the only interfaces available, posing challenges for patient adaptation. Despite this, one center reported remarkable success with mouthpiece ventilation in

TABLE 18-3: SELECTION GUIDELINES: NONINVASIVE VENTILATION FOR PATIENTS WITH ACUTE RESPIRATORY FAILURE

Step 1. Identify patients with reversible causes for acute respiratory failure (ARF) in need of ventilator assistance
- a. Reversible cause for ARF such as COPD or acute cardiogenic pulmonary edema
- b. Symptoms and signs of acute respiratory distress:
  - i. Moderate to severe dyspnea, increased over usual
  - ii. Rate > 24 for COPD, rate > 30 for hypoxemic ARF
  - iii. Accessory muscle use, paradoxical breathing
- c. Gas-exchange abnormalities:
  - i. Pa_{CO_2} > 45 mm Hg, pH < 7.35
  - ii. Pa_{O_2}/FI_{O_2} < 200

Step 2. Exclude those at increased risk with noninvasive ventilation:
- a. Respiratory arrest
- b. Medically unstable (hypotensive shock, uncontrolled cardiac ischemia or arrhythmias)
- c. Unable to protect airway (impaired cough or swallowing mechanism)
- d. Excessive secretions
- e. Agitated or uncooperative
- f. Facial trauma or burns or anatomic abnormalities interfering with mask fit

a cohort of 257 patients with neuromuscular disease and chronic respiratory failure that was treated for an average of 9.6 years.[205] Bulbar function was intact, including speech and swallowing, but the patients were otherwise severely compromised. Of these patients, 144 required 20 to 24 hours of ventilator support daily and had vital capacities of only 10.5% of predicted. Nonetheless, sixty-seven were switched successfully from tracheostomies to NIPPV, and only thirty-eight died during the follow-up interval of up to 37 years. Although the study was uncontrolled, the authors concluded that mouthpiece NIPPV prolonged survival and enhanced convenience and communication in these severely compromised patients.

Despite this favorable experience, however, wider use of NIPPV awaited further developments during the early 1980s. One was the development of nasal CPAP for therapy of obstructive sleep apnea that encouraged the creation of more comfortable commercially available nasal masks.[206] Another was the suggestion by French investigators that nasal ventilation could be used in patients with muscular dystrophy to halt progression of the disease.[23] In 1987, several small series and case reports appeared describing successful management with nocturnal nasal ventilation of patients with chronic respiratory failure secondary to a variety of restrictive thoracic disorders.[207–208] Subsequently, additional small series have confirmed the earlier findings, but no prospective, randomized series have been performed, mainly for ethical reasons. Despite this, NIPPV has gained wide acceptance as the modality of first choice to treat patients with chronic respiratory failure.[200] Because most series have combined patients with different etiologies, the following will discuss evidence for benefits attributed to NIPPV for restrictive thoracic diseases in general, making reference to individual diagnoses as appropriate. Table 18-4 lists individual diagnoses of neuromuscular diseases reported to benefit from NIPPV.

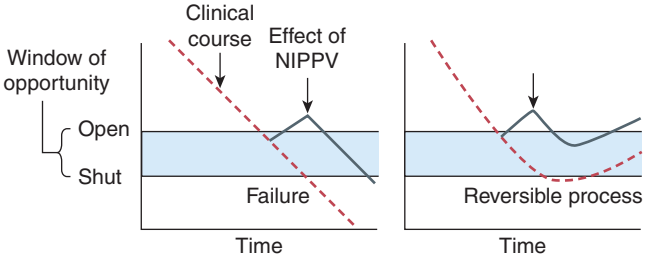

FIGURE 18-3 Schema to illustrate importance of reversibility in success of noninvasive positive-pressure ventilation (*NIPPV*) for acute respiratory failure. *Left:* Relentless downhill clinical course of underlying process (severe acute respiratory distress syndrome). NIPPV initiated when window of opportunity opens still fails because it is not sufficient to support the patient when the underlying process has progressed too far. *Right:* NIPPV succeeds when medical therapy reverses the underlying process (chronic obstructive pulmonary disease exacerbation).

EFFECTS ON SYMPTOMS AND DAYTIME GAS EXCHANGE

Numerous studies on the efficacy of NIPPV in a wide variety of neuromuscular and chest wall disorders have shown that intermittent NIPPV consistently improves symptoms

TABLE 18-4: RESTRICTIVE THORACIC DISEASES TREATED WITH NONINVASIVE VENTILATION

Recommended for the following diagnoses:
- Chest wall deformity
  - Kyphoscoliosis
  - Postthoracoplasty for tuberculosis
- Slowly progressive neuromuscular disorders
  - Postpolio syndrome
  - High spinal cord injury
  - Spinal muscular atrophy
  - Slowly progressive muscular dystrophies
    - Duchenne muscular dystrophy
    - Limb-girdle muscular dystrophy
    - Myotonic dystrophy
  - Multiple sclerosis
  - Bilateral diaphragmatic paralysis
- More rapidly progressive neuromuscular disorders*
  - Amyotrophic lateral sclerosis

Not recommended for†:
- Rapidly progressive neuromuscular disorders
  - Guillain-Barré syndrome
  - Myasthenia gravis

*Tracheostomy ventilation should be considered in far-advanced cases.

†Unless upper airway protective mechanisms intact.

of fatigue, daytime hypersomnolence, and morning headache.[210–213] Daytime gas exchange also improves, Pa_{CO_2} dropping on average from 63 mm Hg to 48 mm Hg and PA_{O_2} increasing from 54 to 71 mm Hg among multiple studies.[1] The improvement in gas exchange is gradual, usually occurring over a period of weeks, as patients increase their hours of use, mainly at night. In addition, nasal NIPPV has been shown to ameliorate chronic hypoventilation in patients with severe kyphoscoliosis who fail to improve with nasal CPAP alone.[214]

EFFECTS ON NOCTURNAL GAS EXCHANGE AND SLEEP

Neuromuscular and chest wall disorders cause protean sleep-related breathing disturbances depending on the specific syndrome and the involvement of respiratory muscles.[215] Abnormalities include obstructive and central sleep apneas, intermittent desaturations, particularly during rapid eye movement sleep in patients with diaphragmatic weakness, and sustained hypoventilation as global weakness and/or chest wall restriction advances. These abnormalities often lead to sleep disruption, characterized by diminished sleep duration, fragmentation related to arousals, and poor sleep quality secondary to diminished slow-wave and rapid eye movement sleep.

NIPPV ameliorates nocturnal hypoventilation and has been shown to eliminate the intermittent obstructive apneas and severe O_2 desaturations that occur during negative-pressure ventilation, particularly during rapid eye movement sleep.[215] Although no randomized, prospective trials have been performed to investigate effects of NIPPV on sleep, investigators have evaluated efficacy using temporary withdrawal of nocturnal nasal NIPPV from long-term users with restrictive thoracic diseases whose gas exchange had been improved by prior NIPPV use.[216,217] Temporary withdrawal of NIPPV caused a deterioration of nocturnal oxygenation and ventilation[215] (Fig. 18-4) and increased frequency of arousals.[216] All changes were reversed promptly on resumption of NIPPV. These findings indicate that NIPPV is important in preventing deterioration of nocturnal gas exchange that is thought to predispose to chronic hypoventilation and contribute to frequent arousals and fragmented sleep. Stabilization of nocturnal gas exchange and improved sleep quality are thought to be major reasons for the improvement in symptoms associated with NIPPV use. Although sleep quality is improved compared to no ventilator assistance, air leaking during NIPPV, however, can contribute to sleep fragmentation.[218] Atkeson et al[219] found that asynchrony with the ventilator was very prevalent in patients with amyotrophic lateral sclerosis (ALS) using NIPPV nocturnally. Twenty-three patients had an average asynchrony index of 69/hour constituting 17% of sleep time.

EFFECTS ON QUALITY OF LIFE

NIPPV improves health-related quality of life in patients with restrictive thoracic disorders.[220,221] The nature and duration of improvement, however, depend on the natural history of the underlying disorder. Among patients with

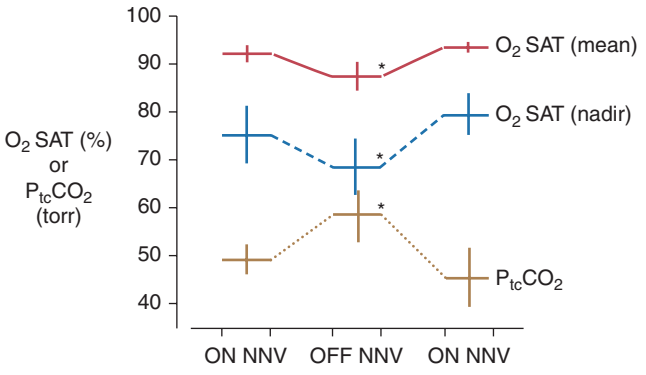

FIGURE 18-4 Effect of withdrawal of nocturnal nasal ventilation (*NNV*) on mean and nadir O_2 saturations and mean transcutaneous P_{CO_2} levels obtained during nocturnal monitoring. Values on the left labeled "on NNV" were obtained during NNV use on the night before NNV withdrawal, values in the middle were obtained on the last night of the NNV withdrawal period, and values on the right labeled "on NNV" were obtained a week after NNV was resumed. Data are mean ± standard error (SE). Asterisk indicates $p < .05$ compared with "on NNV" values ($n = 6$). (Used, with permission, from Hill NS, Eveloff SE, Carlisle CC, Goff SG. Efficacy of nocturnal nasal ventilation in patients with restrictive thoracic disease. *Am Rev Respir Dis.* 1992;145:365–371.)

ALS, the mental component summary score[222] and the vitality score[223] on the SF (short form)-36 questionnaire register sustained improvements. These improvements are seen even when the functional rating declines (Fig. 18-5), but attrition rates are high over time related to the high mortality of the underlying condition.[224] Bourke et al performed a randomized, controlled trial in forty-one patients with ALS, demonstrating improved quality of life in patients with normal or only mild to moderately impaired bulbar dysfunction, which was sustained for up to 2 years.[225] Even more sustained would be expected, of course, in conditions with lower rates of progression. Likewise, musculoskeletal functional gains would not be expected unless the underlying condition offers the potential for improvement (i.e., no quadriplegia).

Some studies have compared quality of life during use of NIPPV with that during use of tracheostomy positive-pressure ventilation among patients with restrictive thoracic diseases.[226–228] Both groups have high levels of satisfaction, but NIPPV was rated as preferable to ventilation via a tracheostomy with regard to comfort, convenience, portability, and overall acceptability.[226] Although tracheostomy ventilation received higher scores for quality of sleep and providing a sense of security, the vast majority of patients preferred NIPPV. Another survey of thirty-five ventilator users, with twenty-nine NIPPV users and six with tracheostomy ventilation, found satisfactory levels of psychosocial functioning and mental well-being, as determined by standard questionnaires.[227] The ratings compared favorably with those of a general population, and NIPPV and tracheostomy ventilation received similar scores. In another survey of home mechanical ventilation users, patients with scoliosis receiving tracheostomy ventilation had higher health-index ratings than those receiving NIPPV.[228] Thus, NIPPV offers many advantages over invasive mechanical ventilation, including

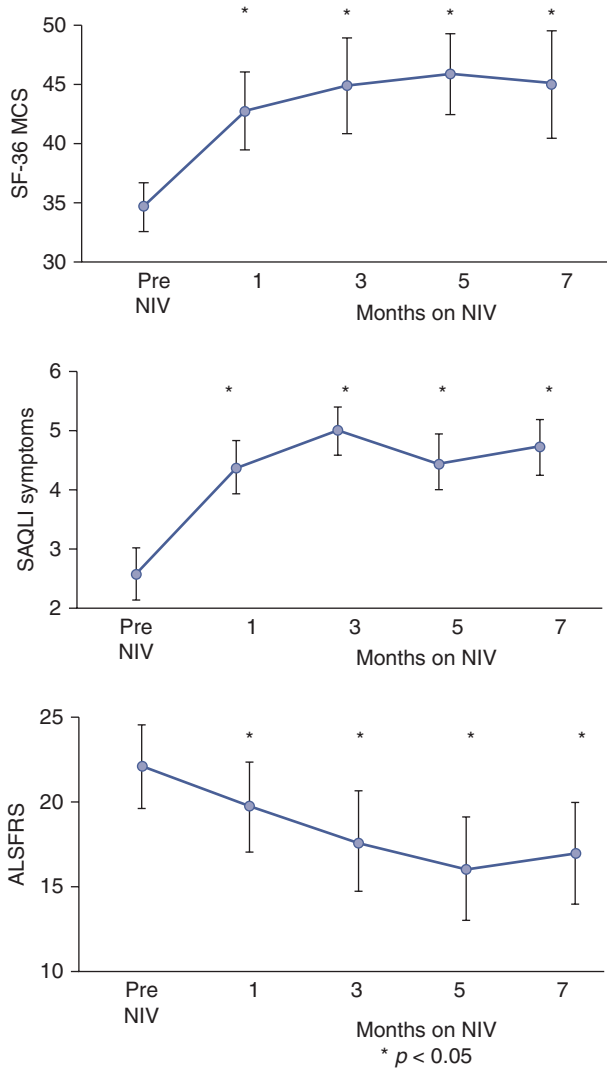

FIGURE 18-5 Serial data for the Short Form-36 Mental Component Summary (*SF-36 MCS*), Sleep Apnea Quality of Life Index (*SAQLI*) symptoms domain, and ALS Functional Rating Scale (*ALSFRS*) immediately before starting noninvasive ventilation (*NIV*) and after 1, 3, 5, and 7 months of NIV. The slight improvement in the ALSFRS score at 7 months is secondary to a survivor effect. (Used, with permission, from Lyall, et al. A prospective study of quality of life in ALS patients treated with noninvasive ventilation. *Neurology.* 2001;57:153–156.)

comfort, portability, cost, and convenience, but some ratings, including overall health and sense of security, may favor invasive mechanical ventilation.

EFFECT ON HOSPITAL UTILIZATION

In their long-term follow-up study of patients with kyphoscoliosis, sequelae of tuberculosis, and Duchenne muscular dystrophy, Leger et al[229] observed significant reductions in hospital days per patient per year from 34, 31, and 18 days for the year before starting NIPPV to 6, 10, and 7 days for the year after, respectively. These findings suggest that NIPPV may cut health care resource utilization in these patients, with the potential for substantial cost savings. More recently, Janssens et al[230] observed a similar reduction in hospital days per patient per year (median of 17 days for the year before and 6 days for the year after NIPPV) for patients with restrictive thoracic disorders in a long-term retrospective study from Switzerland. Although these uncontrolled studies do not preclude the possibility that changes in hospitalization practices over time could have been responsible for the reductions, it appears highly likely that NIPPV reduces the need for hospitalization among these patients.

EFFECT ON SURVIVAL

Long-term cohort series provide strong evidence that NIPPV prolongs survival in comparison with unventilated patients. The ability to prolong survival is obvious in patients using NIPPV continuously who would die if ventilator assistance stops for more than a few minutes.[205] Studies from France[229] and England[231] report on several hundred patients with chronic respiratory failure of various etiologies treated with intermittent nasal NIPPV for periods of up to 5 years (Fig. 18-6). Rather than survival rates, these studies used the rate for continuation of NIPPV, thought to correspond closely with survival for most diagnoses. The studies found very favorable continuation rates for postpolio and kyphoscoliosis patients (approximately 100% and 80%, respectively, after 5 years). Patients with sequelae of old tuberculosis had higher continuation rates in the British study compared with the French study (94% vs. 60%, respectively), perhaps reflecting the greater morbidity of the French patients at the time of enrollment. Also, patients with Duchenne muscular dystrophy in the French study had lower continuation rates (47%) than did those with other neuromuscular diseases, with 28% undergoing tracheostomy and the remaining 25% dying. A more recent follow-up on the English cohort observed much better survival rates for patients with Duchenne muscular dystrophy treated with NIPPV than those previously reported by the French group: 85% for 1 year and 73% for 5 years.[232] This disparity may reflect differences in the severity of illness between patients when begun on NIPPV, how cough was assisted, or practices on switching to tracheostomy. Overall, the continuation rates from these long-term follow-up studies are similar to those observed for patients treated with invasive ventilation reported earlier by the French group.[233]

Survival would be anticipated to be shorter in patients with ALS than in those with more slowly progressive neuromuscular diseases. In a prospective, nonrandomized trial on twenty consecutive patients, Pinto et al[234] treated the first ten with medical therapy alone and the next ten with NIPPV. After 2 years, 50% of the NIPPV patients were alive, whereas all the medical therapy patients had died. Aboussouan et al[235] compared the survival of thirty-one patients with ALS who continued NIPPV with that of twenty-one patients who were intolerant of NIPPV. The intolerant patients had a significantly greater risk of dying over the 3-year study period than were those who remained on NIPPV (relative risk: 3.1). As might be anticipated, patients with bulbar involvement were

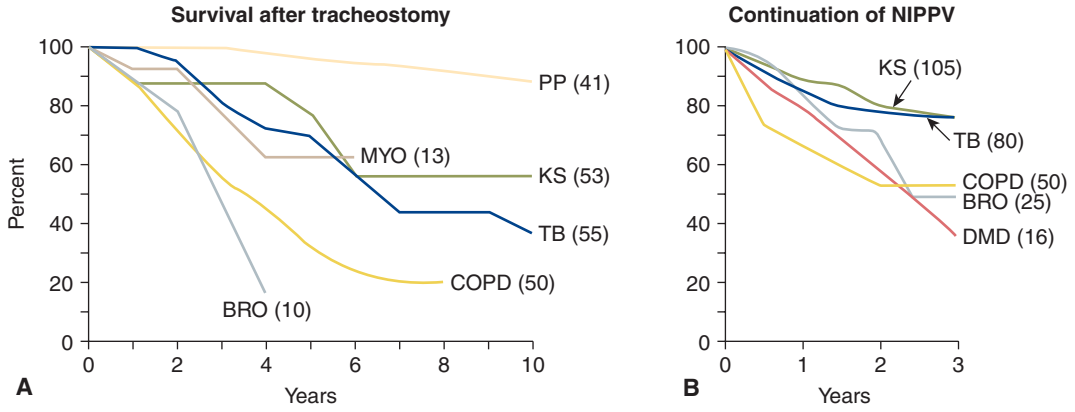

FIGURE 18-6 **A.** Survival after tracheostomy in 222 patients with chronic respiratory failure of various etiologies followed for as long as 10 years. (Redrawn, with permission, from Robert et al.[233]) **B.** Likelihood of continuing noninvasive positive-pressure ventilation (*NIPPV*) in 276 patients with chronic respiratory failure followed for as long as 3 years. (Redrawn, with permission, from Leger et al.[229]) *BRO*, bronchiectasis; *COPD*, chronic obstructive pulmonary disease; *DMD*, Duchenne muscular dystrophy; *KS*, kyphoscoliosis; *MYO*, myopathy; *PP*, postpolio syndrome; *TB*, history of tuberculosis.

unlikely to be tolerant of NIPPV (only six of twenty); if they could tolerate the therapy, however, it imparted an apparent survival advantage. Bach[236] has reported that NIPPV prolongs survival and postpones the need for tracheostomy in ALS. In the randomized, controlled trial on ALS by Bourke et al, patients without severe bulbar involvement had an average 205-day prolongation of survival.[225] Those with severe bulbar involvement tolerated NIPPV much less well than did those without, and had no survival benefit, but they did have some improvement of sleep-related symptoms if they were tolerant.

Based on the above observations, NIPPV is now used in approximately 15% of patients with ALS compared with only 2% using invasive mechanical ventilation, according to one recent cross-sectional U.S. survey.[237] On the other hand, Bach[236] also found that after 5 years of follow-up, only eight of twenty-five (32%) patients with ALS using NIPPV were alive compared with twenty-seven of fifty (54%) patients receiving tracheostomy ventilation. This suggests that NIPPV is less effective at prolonging survival than tracheostomy ventilation in ALS, as might be anticipated among patients with a neuromuscular disease that impairs bulbar function.

Selection of Patients with Restrictive Thoracic Disease to Receive Noninvasive Positive-Pressure Ventilation

Table 18-5 lists guidelines for the selection of patients with restrictive thoracic disorders to receive NIV based on American College of Chest Physicians consensus,[238] Canadian Thoracic Society clinical practice guideline,[239] and Medicare guidelines in the United States. Patients should have symptomatic nocturnal hypoventilation manifested by poor sleep quality, such as morning headache, daytime hypersomnolence, and low energy in combination with demonstrable daytime or sustained nocturnal hypoventilation. The duration of nocturnal O_2 desaturation used as an indicator of nocturnal

TABLE 18-5: SELECTION GUIDELINES: LONG-TERM NONINVASIVE VENTILATION FOR RESTRICTIVE THORACIC DISORDERS OR OBESITY HYPOVENTILATION

Indications

1. Symptoms: fatigue, morning headache, hypersomnolence, nightmares, enuresis, dyspnea, and so on
2. Signs: cor pulmonale
3. Gas-exchange criteria:
   - Daytime Pa_{CO_2} ≥ 45 mm Hg
   - Nocturnal oxygen desaturation (Sa_{O_2} ≤ 88% for more than 5 minutes sustained or >10% of total monitoring time)
4. Sleep evaluation:
   - Unnecessary in restrictive thoracic disorders if other criteria met
   - Should be obtained for obesity hypoventilation to assess obstructive sleep apnea*
5. Other possible indications
   - Recovering from acute respiratory failure with persistent CO_2 retention
   - Repeated hospitalizations for acute respiratory failure

Contraindications

- Inability to protect airway
  - Impaired cough
  - Impaired swallowing with chronic aspiration
- Copious secretions
- Need for continuous or nearly continuous ventilatory assistance
- Anatomic abnormalities that interfere with mask fitting
- Poorly motivated patient or family
- Inability to cooperate or comprehend therapy
- Inadequate financial or caregiver resources

*If obstructive sleep apnea is present, trial of continuous positive airway pressure may be warranted (see Table 18-6).

hypoventilation (< 88% for more than 5 consecutive minutes) was suggested by consensus,[238] but has never been validated. Even if symptoms are minimal or lacking, patients with severe CO_2 retention (> 50 mm Hg) and those recovering from bouts of acute respiratory failure are considered for long-term NIV, particularly if there is persistent CO_2 retention or a history of repeated hospitalizations. The consensus group of the American College of Chest Physicians as well as the Canadian Thoracic Society also recommended NIPPV for patients with severe pulmonary dysfunction (FVC < 50% of predicted or maximal inspiratory pressure < 60 cm H_2O), even in the absence of CO_2 retention, despite the lack of evidence from clinical studies to support the initiation of NIV on the basis of pulmonary function alone. Simonds also suggests that other possible indications for NIV in patients with chronic respiratory insufficiency include infectious complications, pregnancy, and the perioperative state.[240]

Relative contraindications to the use of NIPPV for chronic respiratory failure (see Table 18-5) include inability to protect the upper airway because of impaired cough or swallowing or excessive secretions. Aggressive treatment with techniques or devices to assist cough[241] may permit the use of NIPPV in such patients who otherwise would not be candidates, but if the condition is too severe, tracheostomy is indicated if the patient desires maximal prolongation of life. Tracheostomy ventilation has been recommended when the need for ventilator assistance exceeds 16 hours daily,[242] although many patients still prefer NIPPV.[226] Table 18-5 lists other relative contraindications to NIPPV. The clinician must render a judgment as to whether these are sufficient to preclude a trial of NIV.

The natural history of the restrictive thoracic disorder also should be considered when deciding about NIPPV. Patients with chest wall deformities and stable or slowly progressive neuromuscular disorders respond well to NIPPV and remain stable for long periods of time.[229,231] Patients with more rapidly progressive neuromuscular disorders such as ALS may respond well temporarily, but as debility progresses and bulbar function deteriorates, NIPPV loses its efficacy. Those who wish to optimize their chances for survival may prefer invasive ventilation, and others may desire hospice care. Patients with rapidly progressive neuromuscular conditions such as Guillain-Barré syndrome or myasthenia gravis in crisis usually are poor candidates for NIV because swallowing frequently is impaired when ventilatory dysfunction becomes severe.

When to Start Long-Term Noninvasive Positive-Pressure Ventilation for Restrictive Thoracic Disorders

NIPPV to treat chronic respiratory failure secondary to restrictive thoracic diseases has gained wide acceptance, but the optimal time for initiation has been debated. Prophylactic initiation in progressive neuromuscular diseases, before the onset of symptoms or daytime hypoventilation, has been proposed to retard the progression of respiratory dysfunction. Raphael et al[243] tested this hypothesis in seventy-six patients with Duchenne muscular dystrophy who had not yet developed symptoms or daytime hypoventilation, randomizing them to receive nasal NIPPV or standard therapy. Not only did NIPPV fail to slow disease progression, it also was associated with greater mortality, leading to premature termination of the trial. The authors surmised that mortality was increased because NIPPV gave patients a false sense of security that caused them to delay seeking medical attention when they developed respiratory infections. The study had numerous shortcomings, including failure to document patient adherence or to consistently use techniques to assist cough, but it has stemmed any enthusiasm about using prophylactic NIPPV in patients with Duchenne muscular dystrophy. Ward et al[244] randomized twenty-six patients with neuromuscular disease and nocturnal hypoventilation to start NIPPV right away or to await the onset of daytime hypercapnia before starting. Patients starting promptly had better gas exchange and quality of life, and a trend toward fewer hypercapnic crises compared to those starting later. The authors concluded that NIPPV is best started with the onset of symptomatic nocturnal hypoventilation and before the onset of diurnal hypercapnia.

Early initiation of NIPPV also has been proposed to treat patients with ALS.[245] Current guidelines based on expert consensus recommend starting NIPPV if FVC drops below 50% of predicted[246] or maximal inspiratory pressure drops below 60 cm H_2O. In a preliminary study,[247] twenty patients with ALS and FVC values ranging between 70% and 100% of predicted were randomized to receive NIPPV if they had an SaO_2 of less than 90% for more than 1 minute during nocturnal oximetry ("early intervention") or to await a drop in FVC to less than 50% of predicted ("standard of care"). The early intervention group had a significant increase in the vitality subscale on the SF-36, suggesting that earlier intervention might offer some benefit in patients with ALS, but more research is necessary.

Presently, awaiting the onset of symptoms of nocturnal hypoventilation before initiation of NIPPV is the most pragmatic approach because adherence to therapy is often poor unless patients are motivated by the desire for symptom relief. Symptomatic patients who have only nocturnal but no daytime hypoventilation, as demonstrated by frequent, sustained nocturnal O_2 desaturations, are good candidates for initiation. Masa et al[247] showed improvements in dyspnea scores, morning headache, and confusion after 2 weeks of nocturnal NIPPV in twenty-one such patients, whose proportion of sleep time with an SaO_2 of less than 90% averaged 40% to 50% on room air before initiation of NIPPV and fell to 6% afterward. The timing of initiation requires a judgment based on the anticipated progression of the disease (sooner for more rapid progression), the patient's symptoms, pulmonary function, and daytime and nocturnal gas exchange. The aim is to begin when there are symptoms with significant pulmonary function and/or gas-exchange abnormalities,

which is when the patient still has time to adapt but well before the occurrence of a respiratory crisis.

Central Hypoventilation/ Obstructive Sleep Apnea

The first case reports describing the use of nasal ventilation for chronic respiratory failure were in young children with central hypoventilation, who had resolution of gas-exchange abnormalities and symptoms after initiation of therapy.[248,249] No controlled studies have examined this application, but enough anecdotal evidence has accrued that consensus groups consider therapy of central hypoventilation as an appropriate indication for NIPPV.[200,238]

Nasal CPAP is considered the therapy of first choice for obstructive sleep apnea. NIPPV, however, may be successful in improving daytime gas exchange and symptoms in hypoventilating patients with obstructive sleep apnea who have persistent CO_2 retention after use of nasal CPAP alone. Among thirteen patients with severe obstructive sleep apnea whose hypercapnia (average Pa_{CO_2} of 62 mm Hg) was unresponsive to CPAP, NIPPV using volume-limited ventilators lowered the Pa_{CO_2} to 46 mm Hg, and nine of the patients eventually stabilized on CPAP alone.[250]

Independently adjusted inspiratory and expiratory pressure or "bilevel" positive-pressure ventilation was first developed as a way of controlling obstructive sleep apnea while using lower expiratory pressures than with CPAP alone, thus potentially enhancing comfort and adherence with therapy.[251] Reeves-Hoche et al[252] were unable to demonstrate improved adherence rates in patients with obstructive sleep apnea treated with bilevel ventilation compared with CPAP alone. Even so, bilevel devices are still used commonly to treat patients intolerant of CPAP alone, but a stronger rationale supports the use of bilevel NIPPV for obstructive apnea if patients have persisting hypoventilation despite adequate CPAP therapy.

Obesity-Hypoventilation Syndrome

Respiratory impairment is common among obese patients, including those with restricted lung volumes secondary to increased chest wall and lung elastance, abnormal blood gases, and breathing disturbances during sleep. When obese patients hypoventilate, the term *obesity-hypoventilation syndrome* is applied, a condition that is multifactorial in etiology. The altered chest wall mechanics are accompanied by reductions in respiratory drive (either acquired or congenital), as well as obstructive sleep apnea (in 80% to 90% of patients), giving rise to the hypoventilation.[253] This is a morbid condition associated with cor pulmonale and a high mortality rate over time, but it responds favorably to NIV.

Morbidly obese subjects have significantly increased work of breathing at baseline, and NIPPV (inspiratory pressure of 9 to 12 cm H_2O, expiratory pressure of 4 cm H_2O) lowers that work.[254] NIPPV also raises tidal volumes and lowers end-tidal P_{CO_2} more in patients with obesity hypoventilation than in obese patients without sleep-disordered breathing or in nonhypoventilating subjects with obstructive sleep apnea.[254] NIPPV lowers and improves symptoms as effectively in patients with obesity hypoventilation as in those with severe kyphoscoliosis,[255] associated with an increase in respiratory drive.[255] CPAP alone, however, may be as effective as NIPPV in some patients.[253] Some investigators also have started with NIPPV and converted to CPAP once hypoventilation has been controlled.[250] In a recent randomized controlled trial of thirty-seven patients with obesity hypoventilation and mild hypercapnia, 1 month of NIV (inspiratory and expiratory pressures 18 and 11 cm H_2O, respectively; backup rate: 13 breaths/min), eighteen NIV patients had improved sleep architecture and gas exchange, but indices of inflammation, endothelial function, and arterial stiffness did not improve compared to a control group given lifestyle advice.[256] These studies support the use of NIPPV for obesity hypoventilation to improve symptoms, sleep quality, and gas exchange.

As obesity has become an increasingly prevalent problem, obesity-hypoventilation syndrome has become an increasingly common indication for using long-term NIPPV. The Swiss survey found that during the 1990s it became the most common diagnosis among patients using long-term NIPPV at home in the Geneva region (Fig. 18-7).[230] Adherence was excellent with the therapy, exceeding 70%, average Pa_{CO_2} normalized, and hospital days fell significantly following NIPPV initiation. A subsequent large cohort of obesity-hypoventilation patients from France was followed long term and manifested favorable sustained responses to NIPPV, with a 3-year continuation rate of 80%, sustained improvements in gas exchange, and a 5-year survival of 77.3%.[257]

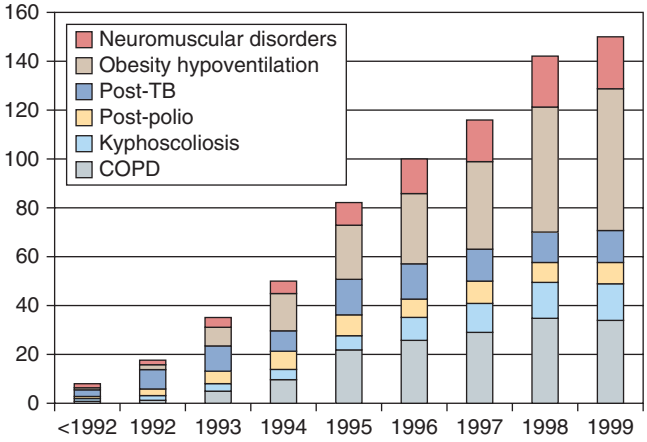

FIGURE 18-7 Yearly count of the cumulative population of patients treated by noninvasive positive-pressure ventilation during the study period (1992 to 2000) according to diagnostic category. Changing patterns in long-term noninvasive ventilation: a 7-year prospective study in the Geneva Lake area. *Chest.* 2003;123:67–79.)

Selection of Patients with Central Sleep Apnea/Obesity-Hypoventilation Syndrome for Noninvasive Positive-Pressure Ventilation

Firm indications and selection guidelines for central hypoventilation/central sleep apnea/obesity-hypoventilation syndrome have not been established although the Canadian Thoracic Society consensus is that NIPPV is the treatment of choice unless CO_2 retention is no more than mild, in which case CPAP alone might suffice.[239] Patients who are symptomatic with frank hypoventilation or who have prolonged central apneas clearly are good candidates for NIPPV. The more severe the hypoventilation, the more important it would be to start with a mode that augments minute volume, and using a backup rate would be important for those with prolonged central apneas. Medicare guidelines in the United States (Table 18-6) require a polysomnogram to document the central apneas, prolonged O_2 desaturations (≤88% for more than 5 minutes) as evidence of nocturnal hypoventilation and, if the patient has obstructive sleep apnea, evidence of CPAP failure with improvement on NIPPV, as determined by oximetry or a repeat polysomnogram.

OBSTRUCTIVE LUNG DISEASES

Chronic Obstructive Pulmonary Disease

During the 1960s, McClement et al[258] speculated that improved ventilation–perfusion relationships, reduced O_2 consumption, and mobilization of secretions would benefit patients with COPD who were treated with negative-pressure ventilators. During the early 1980s, Braun and Marino[259] tested the theory that respiratory muscles are chronically fatigued and will benefit from intermittent rest. They treated sixteen patients with severe COPD using wrap negative-pressure ventilators for 5 hours daily over 5 months and observed improvements in vital capacity, maximal inspiratory and expiratory pressure, and daytime Pa_{CO_2} during spontaneous breathing. Although these results were interpreted as supporting the "muscle rest" hypothesis, controls were lacking, and other aspects of rehabilitation or passage of time alone could have been responsible for the improvements.

Subsequently, several controlled studies showed improvement in respiratory muscle strength after short-term (days to a week) use of negative-pressure ventilation.[260–262] These studies documented respiratory muscle rest by showing significant reductions in the diaphragmatic electromyographic signal. Subsequent controlled trials, however, of longer duration (up to several months) showed no benefit.[263–265] Notably, baseline Pa_{CO_2} among the latter unfavorable trials was approximately 47 mm Hg, substantially lower than that in the favorable studies (57 mm Hg). This raises the possibility that respiratory muscles in patients with severe CO_2 retention are more likely to benefit from intermittent negative-pressure ventilation than patients with little or no CO_2 retention, perhaps because of relief of the unfavorable effect of hypercapnia on respiratory muscle function.[266]

Negative-pressure ventilation was tolerated poorly in the preceding trials, so subsequent trials tested NIPPV to see if better tolerance might achieve more consistent benefits. In addition, patients with severe COPD are known to have more frequent nocturnal desaturations related to hypoventilation than normal subjects. These desaturations are associated with arousals that shorten the duration and diminish the quality of sleep, an effect that can be ameliorated by O_2 supplementation, at least in "blue and bloated" patients.[267] Furthermore, patients with COPD have a 32% drop in inspiratory flow rate during rapid eye movement sleep that is associated with a reduced tidal volume.[268] By assisting ventilation, NIPPV offers the potential of restoring inspiratory flow, eliminating episodes of hypoventilation, and improving nocturnal gas exchange, as well as the duration and quality of sleep.

Studies using NIPPV in patients with severe obstructive lung diseases have yielded conflicting results. Initial small uncontrolled cohort series on the use of nasal NIPPV in patients with severe stable COPD lent support to the idea that NIPPV would improve sleep efficiency and daytime and nocturnal gas exchange.[269,270] A 3-month crossover trial by Strumpf et al,[36] however, found improvement only in neuropsychological function but not in nocturnal or daytime gas exchange, sleep quality, pulmonary functions, exercise tolerance, or symptoms. This study also encountered a high dropout rate, with seven patients withdrawing because of mask intolerance and only seven of nineteen entered patients actually completing the trial. In contrast, in a study of nearly identical design, Meecham-Jones et al[271] enrolled eighteen patients with severe COPD, fourteen of whom completed the study. Nocturnal and daytime gas exchange, total sleep time, and symptoms improved during NIPPV use. These salutary effects of NIPPV on sleep duration and efficiency in patients with severe stable COPD also were observed in a 2-night crossover trial in six patients with an initial Pa_{CO_2} of 58 mm Hg.[272] Some of the disparity between these studies may be explained by the observation that patients in the study of Strumpf et al had more severe airway obstruction (FEV_1 of 0.54 vs. 0.81 L) despite having less CO_2 retention

TABLE 18-6: GUIDELINES FOR NONINVASIVE POSITIVE-PRESSURE VENTILATION IN OBSTRUCTIVE SLEEP APNEA/CENTRAL SLEEP APNEA*

1. Polysomnogram demonstrating OSA, CSA, or mixed apneas
2. If OSA, patient failed to improve or tolerate CPAP alone
3. Sustained oxygen desaturation nocturnally (≤88% for >5 min)
4. Significant improvement in nocturnal gas exchange during NIPPV use, as documented by oximetry or polysomnography

Abbreviations: CSA, central sleep apnea; *NIPPV*, noninvasive positive-pressure ventilation; *OSA*, obstructive sleep apnea.

*Based on Center for Medicare and Medicaid Services Guidelines.

(Pa_{CO_2} of 47 vs. 57 mm Hg) than did patients in the study of Meecham-Jones et al. This suggests that different subsets of patients with COPD were entered into the studies and that those with greater CO_2 retention ("blue bloaters") may be more likely to benefit from NIPPV.

Two other randomized, controlled trials failed to substantiate the hypothesis that greater CO_2 retention predicts NIPPV success in patients with severe COPD, despite attempts to enroll hypercapnic subjects. Gay et al[273] screened thirty-two hypercapnic patients, but only thirteen remained after exclusion for obstructive sleep apnea or other terminal illness. Only four of the seven patients randomized to NIPPV completed the trial and, not surprisingly, no significant differences emerged. Lin et al[274] performed an 8-week crossover trial consisting of consecutive, randomized 2-week periods of no therapy, O_2 alone, NIPPV alone, and NIPPV combined with O_2. Among twelve patients with a mean initial Pa_{CO_2} of 50.5 mm Hg, NIPPV not only conferred no added benefit over O_2 alone with regard to oxygenation, ventricular function, or sleep quality, but it also reduced sleep efficiency and total sleep time. The authors, however, used inspiratory pressures of only 12 cm H_2O, which may have provided insufficient ventilator assistance, and 2 weeks may have been too brief to permit adequate adaptation to NIPPV.

Several longer-term controlled trials have been performed subsequently. Casanova et al[275] performed a randomized year-long trial in forty-four patients with severe COPD, finding no improvements in gas exchange, survival, or hospitalization rate, although one test of neuropsychological function improved. This study, however, also used relatively low inspiratory pressures and did not assess sleep quality or health status. In an Italian multicenter trial, Clini et al[276] screened 120 patients with severe COPD and chronic CO_2 retention (Pa_{CO_2} of 50 mm Hg or more). Ninety patients were enrolled. After dropouts and deaths, forty-seven were left, divided between the NIPPV plus O_2 and O_2 alone groups. Patients treated with NIPPV had less of an increase in Pa_{CO_2} over the 2-year period than controls (55 to 56 vs. 55 to 60 mm Hg, respectively, $p < 0.05$), less deterioration in the Maugeri Respiratory Failure (MRF-28) functional score (although the St. George's Respiratory Questionnaire was no different), and a trend toward fewer hospital days per patient per year (20 days before and 14 days after initiation of NIPPV). No differences were detected in the 6-minute walk distance, dyspnea score, sleep symptoms, or mortality rate. An Australian trial of 144 patients with severe COPD and baseline Pa_{CO_2} is in the low 50 to 53 mm Hg randomized patients to NIPPV or long-term oxygen therapy.[277] The NIPPV group had improved adjusted (OR: 0.63; confidence interval [CI]: 0.40 to 0.99) but not unadjusted survival, and a worse score on the St. George's health status scale for general and mental health. There were no differences in gas exchange after the first 6 months. Only forty-one of the seventy-two patients randomized to NIPPV used it for more than 4 hours nightly and were included in the survival analysis, and average inspiratory and expiratory pressures were 12.9 and 5.1 cm H_2O, respectively.

These studies have lacked statistical power and results have been inconsistent, with some showing benefit only for physiologic variables such as respiratory muscle strength and Pa_{CO_2} or total sleep time. Some have shown improved mortality, functional status and quality of life, but most have not. Furthermore, continuation rates have been relatively low compared to neuromuscular or chest wall disorders (see Fig. 18-7). This suggests that patients with COPD are less tolerant of or benefit less from NIPPV than neuromuscular or obesity hypoventilation patients. Criner at al[278] initiated NIPPV in twenty patients with neuromuscular disease and twenty with COPD during a several-week stay in a specialized ventilator unit. Despite these optimal conditions, only 50% of patients with COPD as compared with 80% of those with neuromuscular disease were still using NIPPV after 6 months.

One concern has been that ventilator pressures have been too low in many of the studies to adequately enhance gas exchange. Windisch et al[279] have pioneered the use of "high-intensity" NIPPV to allay these concerns in patients with COPD. In a cohort of seventy-three patients, average inspiratory pressure of 28 mm Hg was used, and patients had a relatively low hospitalization rate (22%) during the subsequent year and higher-than-expected survival at 3 and 5 years (82% and 58%, respectively). In a follow-up study, Dreher et al[280] performed a 6-week crossover trial comparing high-intensity versus low-intensity NIPPV (average inspiratory pressure: 28.6 and 14.6 cm H_2O, respectively). At the end of the trial, the high-intensity group used NIPPV 3.6 hours more per day than did the low-intensity group, and there were significant improvements in exercise-related dyspnea, daytime Pa_{CO_2}, FEV_1, vital capacity, and the Severe Respiratory Insufficiency Questionnaire Summary score.

Overall, the results of these long-term trials testing the efficacy of NIPPV in severe stable COPD have been disappointing, and this application remains controversial.[281] A meta-analysis of the earlier controlled trials concluded that the studies were too small to discern a "clear clinical direction."[282] It should be acknowledged that three subsequent randomized trials[276,277,280] yielded favorable findings, although all have methodologic limitations. Despite controversy about the strength of the evidence for benefit, NIV is used widely in chronic stable COPD in some countries.[283] The high-intensity approach advocated by Windisch et al also shows promise, but requires further validation at other centers.

Noninvasive Positive-Pressure Ventilation to Enhance Rehabilitation in Chronic Obstructive Pulmonary Disease

NIPPV may serve as an adjunct to exercise training in rehabilitation for patients with severe stable COPD. Two different approaches have been used: one employs NIPPV to unload the inspiratory muscles during exercise and to permit a greater exercise intensity to magnify the training effect; the other rests muscles between sessions (mainly at

night) to enhance daytime function during the sessions. Investigations show that CPAP and PSV singly and in combination increase exercise capacity in patients with severe COPD.[284,235] Bianchi et al[286] showed that compared with CPAP or PSV, proportional-assist ventilation brought about the greatest improvement in cycling endurance and reduction in dyspnea in fifteen stable hypercapnic patients with COPD. This enhanced exercise capacity during ventilator use, however, has not yet been shown to translate into a greater training effect or functional improvement during spontaneous breathing.[287] Garrod et al[288] tested the second approach among forty-five patients with severe COPD (FEV_1 < 50% of predicted), showing that nocturnal NIPPV between rehabilitation sessions increased the shuttle-walk distance and improved quality of life compared with standard therapy. Duiverman et al[289] tested a similar approach, randomizing seventy-two patients with severe COPD to nocturnal NIPPV plus rehabilitation and rehabilitation alone. The combination group had greater improvements in some domains of quality of life as well as daytime Pa_{CO_2}, daily step count, and minute ventilation. These studies indicate that NIPPV, used either during or between exercise sessions, has the potential to enhance benefits accruing from pulmonary rehabilitation, but more confirmatory studies are needed.

Cystic Fibrosis and Diffuse Bronchiectasis

Small case series[290,291] have reported stabilization and sometimes even improvement of gas-exchange abnormalities for periods ranging up to 15 months in severely hypercapnic (Pa_{CO_2} > 54 mm Hg) patients with end-stage cystic fibrosis awaiting lung transplantation. Gozal et al[292] observed markedly improved gas exchange in all sleep stages in six patients with cystic fibrosis treated with NIPPV plus O_2 therapy in comparison with patients treated with O_2 therapy alone, although sleep duration and architecture were similar in the two conditions. Cystic fibrosis is now a common reason among children for the use of NIPPV at home, constituting 17% of such children in a French survey.[293]

The mechanism by which NIPPV assists cystic fibrosis patients is not entirely clear. NIPPV reduces the work of breathing significantly,[294] but a study in thirteen hypercapnic patients with cystic fibrosis (average Pa_{CO_2} of 51 mm Hg) found no improvements in sleep quality, daytime arterial blood gases, pulmonary function tests, respiratory muscle strength, or exercise tolerance after 2 months of NIPPV, even though eight of the patients felt improved symptomatically.[295] Madden et al[296] found improved hypoxemia but again no improvement in hypercapnia among 113 patients treated long term with NIPPV; these authors still considered NIPPV useful as a bridge to lung transplantation. NIPPV also can be useful for administration of aerosol to cystic fibrosis patients. Fauroux et al[297] found that it was superior to a standard nebulizer in a small group of cystic fibrosis patients. Thus, NIPPV appears to have a role in supporting deteriorating patients with cystic fibrosis and serving as a bridge to transplantation, even though improvements in gas exchange and sleep parameters are not seen consistently.

In diffuse bronchiectasis patients, Benhamou et al[298] found that the use of NIPPV was associated with improved Karnovsky function scores and a reduction in days of hospitalization from 46 days for the year before to 21 days for the year after starting NIPPV. Compared with a historical control group, however, rates of deterioration in oxygenation were similar, and no survival benefit was apparent. In fact, in the long-term English follow-up study,[231] patients with end-stage bronchiectasis had poorer survivals than other patient subgroups, most dying within 2 years. Dupont et al[299] retrospectively reviewed the outcomes of forty-eight patients with diffuse bronchiectasis following their first ICU admission over a 10-year period; 27% were treated with NIPPV and 54% required intubation. One-year mortality was 40%. Age older than 65 years, a higher simplified acute physiology score II score (>32), and the need for intubation were identified as predictors of mortality. These studies suggest a role for NIPPV in treating patients with cystic fibrosis and diffuse bronchiectasis who have developed severe CO_2 retention, as well as in serving as a bridge to transplantation, but the capacity to prolong life may be limited.

A recent Cochrane analysis[300] concluded that NIPPV may be helpful in facilitating secretion clearance in patients with cystic fibrosis and when combined with O_2 supplementation, may improve nocturnal gas exchange, but cited the lack of controlled trials as a limitation in making recommendations. Lacking such controlled trials, definitive recommendations on how to select patients with cystic fibrosis or diffuse bronchiectasis for NIPPV or when to start are unavailable; most clinicians use guidelines similar to those used for severe COPD (see below), paying particular attention to the inclusion of techniques to aid in secretion clearance.

Selection of Patients with Chronic Respiratory Failure and Obstructive Lung Diseases to Receive Noninvasive Ventilation

An earlier consensus statement noted the discordant results of the available trials and concluded that more study is needed before NIPPV can be recommended in severe stable COPD.[200] A subsequent consensus conference agreed that the data are scanty and conflicting but opined that the available evidence suggests that certain subgroups of patients with COPD may benefit.[238] Most trials that have observed benefit from either negative-pressure or positive-pressure NIV in severe stable COPD have enrolled patients with more CO_2 retention at baseline than trials with negative results. Thus, the consensus opinion was that a trial of NIPPV in severe stable COPD patients is justified if CO_2 retention is severe (i.e., Pa_{CO_2} > 55 mm Hg).

Considering that one of the four controlled trials reporting beneficial effects of NIPPV in severe stable COPD patients[271] enrolled patients with frequent hypopneas

(ten per hour) and O_2 desaturations during sleep, another indication suggested by the consensus group was sustained, severe nocturnal O_2 desaturation (< 88% for more than 5 consecutive minutes). O_2 therapy alone, however, has been shown to improve sleep quality, reduce drowsiness, and improve neuropsychological function in such patients.[267,268] Therefore, the recommendation was made that sleep monitoring be performed during O_2 supplementation and that NIPPV not be initiated unless symptoms fail to respond to a trial of long-term O_2 therapy. If patients have a daytime Pa_{CO_2} between 50 and 54 mm Hg, the consensus group opined that NIPPV should be used if such patients have evidence of nocturnal hypoventilation, as indicated by nocturnal oximetry, or if there is a history of repeated hospitalizations. Patients whose CO_2 retention worsens substantially during O_2 therapy should also be considered for NIPPV, because such patients responded favorably to NIPPV in an uncontrolled trial.[301]

In the absence of more controlled trials with favorable findings, however, these guidelines are tentative. Also, even for patients who meet the criteria, patient tolerance of NIPPV may be poor.[278] To maximize patient compliance, only motivated symptomatic patients, such as those with fatigue or daytime hypersomnolence, who can cooperate and comprehend the purpose of the therapy should be selected. As outlined in Table 18-7, NIV should not be initiated unless other therapies have been optimized, including O_2 supplementation and CPAP (if indicated). These guidelines have led to reduced use of NIPPV for severe stable COPD in the United States since the late 1990s, when certain home respiratory companies were encouraging widespread use. Use is currently more prevalent in certain European countries, such as Switzerland, where a survey found that COPD was the second most common reason for use of NIPPV in the home.[230] A pan-European survey on home mechanical ventilation showed enormous variability between countries in the proportion of patients receiving ventilation for neuromuscular versus lung diseases and between those receiving noninvasive versus tracheostomy ventilation.[283]

TABLE 18-7: RECOMMENDED GUIDELINES FOR SELECTION OF PATIENTS WITH OBSTRUCTIVE LUNG DISEASES TO RECEIVE LONG-TERM NONINVASIVE POSITIVE-PRESSURE VENTILATION*

1. Symptoms: fatigue, hypersomnolence, dyspnea, and so on
2. Failure to respond to optimal medical therapy:
   Maximal bronchodilator therapy and/or steroids
   O_2 supplementation if indicated
3. Gas-exchange abnormalities:
   $Pa_{CO_2} \geq 52$ mm Hg
   $Sa_{O_2} < 88\%$ for more than 5 consecutive minutes nocturnally despite O_2 supplementation
4. Obstructive sleep apnea excluded on clinical grounds or failure to respond to CPAP therapy if moderate to severe obstructive sleep apnea detected on sleep study
5. Reassess after 2 months' therapy; continue if adequate compliance (>4 hours a day) and favorable therapeutic response

*Based on Center for Medicaid and Medicare Services reimbursement guidelines.

CONGESTIVE HEART FAILURE

As discussed earlier, evidence supports the use of NIV (either CPAP alone or NIPPV) in the therapy of acute heart failure, and it also may have a role in chronic CHF. Increases in intrathoracic pressure have long been known to have salutary hemodynamic effects in some patients with congestive heart failure. Naughton et al[21] found that CPAP (10 cm H_2O) reduced both ventilatory work (by minimizing negative intrathoracic pressure swings) and cardiac load (by reducing transmural pressure) in fifteen patients with congestive heart failure. A subsequent study found that longer-term nocturnal CPAP (9 cm H_2O) improved inspiratory muscle strength (maximal inspiratory pressure increased from 79.3 to 90.7 cm H_2O) in a group of eight patients with CHF.[302] One month of nocturnal CPAP also increased left-ventricular ejection fraction (33.8% vs. 25%) and lowered systolic systemic pressure (116 vs. 126 mm Hg) in patients with CHF and obstructive sleep apnea compared with healthy subjects.[303]

Whether NIPPV is better than CPAP alone in these patients has been controversial. Willson et al[304] found dramatic improvements in sleep parameters (apnea-hypopnea index: 49–6; arousal index: 42–17) in patients with CHF and Cheyne-Stokes respiration after treatment with a portable bilevel device. Conversely, Kohnlein et al[305] performed a crossover trial consisting of randomized 2-week periods of NIPPV and CPAP in thirty-five patients with Cheyne-Stokes respiration. Both modalities improved apnea-hypopnea and arousal indexes dramatically, but there was no difference between the two. Teschler et al[306] randomized fourteen patients with CHF and Cheyne-Stokes respiration to control, O_2 alone, CPAP alone, bilevel NIPPV, and adaptive pressure-support servo ventilation on five separate randomly ordered nights. They observed equal reductions in apnea-hypopnea and arousal indexes with O_2 alone and CPAP alone, a greater reduction with bilevel ventilation, and the greatest improvement with adaptive pressure-support servo ventilation. This study supports the idea that customized modes designed to respond to the apneas of Cheyne-Stokes respiration (such as adaptive pressure-support servo ventilation) may be especially effective. But no adequately powered trials addressing important clinical outcomes have yet been performed.

The Canadian CPAP (CanPAP) trial randomized 258 patients with CHF and central sleep apnea to receive CPAP or no CPAP. CPAP attenuated central sleep apnea, improved nocturnal oxygenation, increased the left ventricular ejection fraction, lowered norepinephrine levels, and increased the distance walked in six minutes by 21 meters. It did not,

however, improve quality of life or survival and the authors concluded that their data "do not support the use of CPAP to extend life" in patients with CHF and central sleep apnea.[307] In post hoc analysis, however, these authors subsequently reported that in a subgroup of patients whose apnea-hypopnea index was lowered to below 15/hour by CPAP, transplantation-free survival was significantly improved.[308] Thus, the role of NIPPV in patients with CHF is currently unclear. Most clinicians currently use CPAP alone for patients with CHF and obstructive sleep apnea and optimal medical therapy, including O_2 supplementation, for those with Cheyne-Stokes breathing. Some favor adaptive pressure-support servo ventilation as the preferred noninvasive mode for patients with CHF and "complex" sleep apnea characterized by periodic central apneas (Cheyne-Stokes breathing),[309] but further studies are needed before firm recommendations can be made.

PEDIATRIC USES OF NONINVASIVE POSITIVE-PRESSURE VENTILATION FOR CHRONIC RESPIRATORY FAILURE

Since the first case reports on the successful use of nasal NIPPV in children with central hypoventilation,[199,200] relatively few reports of NIPPV have appeared in the pediatric literature. Nonetheless, some of the experience in adults can be applied to children because such conditions as Duchenne muscular dystrophy or cystic fibrosis may impair respiratory function in older children, and these have been included in a number of the published reports.[248,249] In their experience with fifteen children having neuromuscular disease or cystic fibrosis treated with nasal NIPPV and followed for periods ranging from 1 to 21 months, Padman et al[184] found that average Pa_{CO_2} and hospital utilization fell; only one child required an artificial airway. Fauroux et al[310] undertook a French survey on the use of NIPPV by children at home. Of 102 children followed at fifteen centers, 7% were younger than 3 years of age, 35% were 4 to 11 years of age, and 58% were 12 years of age, and 34% had neuromuscular disease, 30% had obstructive sleep apnea or craniofacial abnormalities, 17% had cystic fibrosis, 9% had central hypoventilation, and 8% had scoliosis. In a subsequent report, Fauroux et al[311] described flattening of the face in 48% of patients. Nevertheless, pediatric patients appear to respond as well to NIPPV as most adults with chronic respiratory failure. In a long-term follow-up study of thirty pediatric patients (average age: 12.3 years) with mainly non-Duchenne neuromuscular syndromes, Mellies et al[312] observed clinical stability exceeding an average of 2 years in duration. Nocturnal and diurnal gas exchange, quality of sleep, and symptoms were improved, and these deteriorated promptly on temporary withdrawal of NIPPV. The authors concluded that NIPPV is effective and should be used in children with symptomatic sleep-disordered breathing associated with neuromuscular syndromes.

PRACTICAL APPLICATION OF NONINVASIVE POSITIVE-PRESSURE VENTILATION

Despite the accumulating evidence on NIPPV indications that helps in selecting appropriate patients, the delivery of NIPPV remains very much an art. After the decision is made to treat a patient with NIPPV, the clinician must decide on a mask (or interface), ventilator, settings, and adjuncts. NIPPV must be delivered in a safe and adequately monitored location. Implementation of each step requires knowledge and experience. More than with invasive ventilation, the interaction between patient and clinician is central to success. The following will provide an overview of the steps in this process.

Initiation

Although little scientific evidence is available to guide the decisions surrounding initiation, they should be made carefully because success or failure depends on them. Focusing on the major goals of NIV may help (Table 18-8). NIV shares with invasive ventilation the goals of improving gas exchange, either nocturnal, daytime, or both, and minimizing complications. Even more than with invasive ventilation, though, NIV seeks to alleviate symptoms and optimize comfort. Because of the open-circuit design of noninvasive positive-pressure ventilators, success depends largely on patient cooperation and acceptance. Patient tolerance is an important goal because the other goals are not achievable unless the patient accepts the therapy. The goals of acute and long-term applications are overlapping, but alleviation of increased work of breathing is an important goal in acute applications, whereas improvement in sleep duration and quality is more important during long-term applications.

TABLE 18-8: GOALS OF NONINVASIVE VENTILATION

Acute applications
Relieve dyspnea
Optimize patient comfort
Reduce work of breathing
Improve or stabilize gas exchange
Minimize complications
Avoid intubation
Avoid delay of needed intubation
Long-term applications
Ameliorate symptoms
Improve or stabilize gas exchange
Improve sleep duration and quality
Maximize quality of life
Enhance functional status
Prolong survival

The following gives recommendations for initiation, citing evidence when available, pointing out controversy where it exists, and offering opinion where necessary. Most sections offer comments on both acute and long-term applications.

Location

ACUTE

NIV can be initiated wherever the patient presents with acute respiratory distress—in the emergency department,[60,313] ICU,[17,61] intermediate-care or respiratory-care unit, or hospital ward.[62,314] A survey of acute care hospitals in Massachusetts and Rhode Island found that a third of NIPPV initiations were in the emergency department, and half were in the ICU.[315] Following initiation, transfer to a location that offers continuous monitoring is recommended until the patient stabilizes. The patient's acuity of illness and risk of deterioration if an accidental disconnection occurs should dictate the intensity of monitoring. One study used 15 minutes of stability following discontinuation of NIPPV as a criterion for admission to a regular ward,[316] but a longer period of time (30 minutes for example) may be safer. During transfers, ventilator assistance and monitoring should be continued because rapid deteriorations can occur.

NIPPV is used on regular wards in many hospitals because of the scarcity of ICU beds, but some guidelines have recommended that NIPPV be applied only in the ICU because of concerns about patient safety.[317] Others have suggested that if pH < 7.30 in patients with COPD, ICU transfer is advisable. Farha et al[318] reported on their experience with seventy-six patients treated on a regular ward with NIPPV. Of the sixty-two patients without a do-not-intubate status, 31% required intubation and were transferred to the ICU. The authors considered this comparable to the experience with patients treated in more closely monitored settings, concluding that NIPPV can be administered safely on regular floors. But unless the ward has considerable experience administering NIPPV, only stable patients should be treated there.

CHRONIC

Stable patients with chronic respiratory failure may start NIPPV during an inpatient admission, in a sleep laboratory during the daytime or an overnight stay, in a physician's outpatient office (with therapists from the home respiratory vendor present), or at home. In a randomized controlled trial of twenty-eight patients, mainly with neuromuscular disease, patients initiated at home experienced just as good outcomes after 2 months as those begun as inpatients, including gas exchange and ventilator adherence, except that an average 3.8-day hospitalization was avoided.[319] Thus, routine hospitalization is unnecessary unless warranted by the patient's medical condition. Initial use of a sleep laboratory offers the advantage of precise titration of initial pressure or volume settings during sleep monitoring but adds to costs and may delay implementation because of scheduling problems. Also, no titration protocol has been validated, and selecting pressures to eliminate apneas and hypopneas, as is done with sleep apnea, may not be adequate to reverse hypoventilation in patients with chronic respiratory failure. Until outcome studies demonstrate the superiority of one location over another, the choice of location will be based on practitioner preference. Perhaps more important than the specific location is the availability of skilled, attentive practitioners to help during the initiation and adaptation processes.

Masks (Interfaces)

A daunting array of interfaces has become available to deliver NIPPV, and detailed descriptions can be found elsewhere.[320] In brief, the most commonly used interfaces in both acute and long-term settings are nasal and oronasal (or full-face) masks. Nasal masks usually are triangular clear plastic domes that have soft silicone sealing surfaces. Oronasal (or full-face) masks are similar in appearance but are larger and fit over the nose and mouth. Nasal interfaces offer many modifications, however, including nasal pillows with soft rubber cones that insert directly into the nares, so-called minimasks that fit over the tip of the nose, and gel-filled seals designed to enhance comfort. Various oronasal masks are available, including those with foam-filled or air-filled seals and a chin support. A larger version of the full-face mask is available that seals around the perimeter of the face, potentially enhancing comfort and eliminating the development of nasal bridge ulcers.[321] Oral interfaces also are used occasionally, mainly in the long-term setting in patients with neuromuscular disease.[205]

More recently, a number of studies have evaluated the "helmet," a novel interface for NIV that consists of a clear plastic cylinder that fits over the head and seals on the shoulders. The Food and Drug Administration has not yet approved this application in the United States. It avoids contact with the nose and mouth, eliminating nasal ulceration and potentially enhancing comfort.[322] CPAP delivered via the helmet to patients with acute respiratory failure is better tolerated than the full-face mask in historically matched controls.[323] Compared with the full-face mask used to deliver PSV in patients with COPD in acute respiratory failure[324] the helmet similarly improved vital signs, achieved similar intubation and mortality rates, and reduced complications. A more recent randomized trial showed that the Helmet is less efficient than a full face mask at CO_2 removal and can cause problems with triggering and cycling during pressure-support ventilation.[325] Pa_{CO_2} tends to be higher in patients treated with the helmet, raising concerns about rebreathing. High flow rates must be used to avoid this problem,[326] but this contributes to noise levels that may exceed 100 dB.[327]

Oral interfaces have been used successfully for many years in patients with slowly progressive neuromuscular diseases.[205] Long-term nasal ventilation appears to offer improved tolerance compared with mouthpiece ventilation in some patients.[211] Either may be effective, even in patients with minimal pulmonary reserve, and both may be used in the same patient, nasal ventilation during sleep at night, for

example, with mouthpiece ventilation used as needed during the daytime.[211]

Selection of Interfaces

ACUTE

Ideally, interfaces for the acute setting should be inexpensive and disposable or reusable without sacrificing comfort. A randomized, controlled trial in seventy patients with acute respiratory failure showed that full-face and nasal masks similarly improve dyspnea, vital signs, and gas exchange, but the nasal mask had a higher initial intolerance rate (34% vs. 12%), attributed to air leaking through the mouth.[328] Mouth leaks have been reported to occur in as many as 94% of patients receiving NIPPV for hypercapnic acute respiratory failure and commonly contribute to mask failures.[329] Thus, the full-face mask is usually the first choice in the acute setting, although claustrophobic patients or those with a need to expectorate frequently may fare better with nasal masks. In a recent randomized trial, the larger Total-face mask that seals around the perimeter of the face was equivalent to the standard full-face mask with regard to patient comfort and NIPPV failure rate, but some patients declined early on to use it because of its imposing appearance.[330] Concerns have been raised about the dead space attributable to the large volumes of these face masks, but "streaming" of airflow directly from the inlet to the patient's nose and mouth appears to minimize this problem.[331,332]

The oral interface is used sometimes in the acute setting to facilitate initial patient adaptation.[333] In a comparison study, however, of four different NIPPV interfaces in patients with acute respiratory failure, the mouthpiece had the largest leak, while there was no significant difference between the Total-face mask, oronasal mask, or nasal mask.[334] In a short-term randomized crossover evaluation in healthy volunteers, higher pressures (15 inspiratory, 10 expiratory cm H_2O) were more uncomfortable than lower pressures (10 inspiratory, 6 expiratory cm H_2O) regardless of mask; the Total-face mask avoided nasal bridge discomfort and has less rebreathing, the nasal mask caused less oral dryness, and the standard full-face mask was associated with bothersome air leaking into the eyes.[335]

The above findings emphasize that many different mask types are available, all of which may be acceptable depending on caregiver preferences, proper fitting, ventilator settings, individual patient characteristics, and other factors. Thus, when initiating NIPPV, clinicians should have a variety of interfaces readily available; a "mask bag" can be suspended from the ventilator so that individual patient needs can be accommodated.

CHRONIC

Comfort and tolerance are even more important in the long-term setting because interfaces must be used for months, mainly during sleep, before being replaced. Many different interfaces are available partly because of the demand driven by the large population of patients with obstructive sleep apnea using similar technology. Standard nasal masks are the most commonly used interfaces in the chronic setting, and a short-term controlled trial on naive patients with restrictive and obstructive forms of chronic respiratory failure found that patients rated these nasal masks as more comfortable than nasal prongs or full-face masks.[336] A polysomnographic comparison of the two masks in patients with chronic respiratory failure[337] found that nasal and full-face masks were equivalent with regard to apnea-hypopnea index, gas exchange, and sleep quality, but the nasal mask required chin straps to control mouth leaks, and sleep efficiency was less with the full-face mask.

Once again, clinicians must be prepared to try a number of different interfaces to optimize comfort. Fitting gauges should be used when available to facilitate proper sizing, and strap tension should be the minimum that controls leaks. Headstrap materials, tightness, and attachments to the head and mask are also important for comfort. Many different types of headstraps are available, although they usually are designed for a particular mask.

Selection of a Ventilator

ACUTE

A steadily expanding number of ventilators is available for NIPPV in the acute setting. Bilevel devices are portable PSV ventilators, first developed for home applications, that cycle between higher inspiratory and lower expiratory pressures.[11,25] These ventilators have been used widely in acute settings because of their ease of administration and low cost, but they have been limited by a lack of alarms, monitoring capabilities, and O_2 blenders. Newer bilevel devices have been designed specifically for acute applications of NIPPV. They have features aimed at enhancing leak compensation and patient comfort, such as adjustable triggering and cycling mechanisms and rise times (the time to reach the preset inspiratory pressure). In addition to oxygen blenders, they also include graphic interfaces comparable to standard critical care ventilators, battery backup for in-hospital transport, and a variety of modes including proportional assist ventilation.

"Critical care" ventilators are those designed for invasive ventilation and, by virtue of microprocessor technology, offer a wide variety of modes, extensive alarm and monitoring capabilities, and O_2 blenders. In the past, these devices have been limited by triggering of nuisance alarms and limited leak-compensating abilities when used for NIPPV.[338] Many, however, now offer "NIV modes" that use a PSV mode, silence alarms, and add leak compensation and algorithms that facilitate triggering and cycling, even in the face of leaks. A laboratory study comparing bilevel ventilators with a critical care ventilator found that triggering, cycling, and leak-compensatory mechanisms were superior in several of the bilevel ventilators.[339] A more recent laboratory evaluation of NIV modes on critical care ventilators observed that most

require additional adjustments in the face of leaks to function adequately.[340]

Because they use a single tube for both inspiration and expiration, bilevel ventilators contribute to CO_2 rebreathing unless used with a nonrebreathing exhalation valve that may increase expiratory resistance and expiratory work of breathing.[341,342] This rebreathing can be minimized by using an expiratory pressure greater than 4 cm H_2O[341,342] and masks with an in-mask exhalation valve situated over the bridge of the nose.[331,332] Comparisons of bilevel and critical care ventilators in intubated patients have demonstrated that gas exchange is equivalent, but work of breathing is increased during bilevel ventilation if minimal expiratory pressure levels (2 to 3 cm H_2O) are used.[344] When expiratory pressures of 5 cm H_2O are used, however, the two types perform equally well in supporting gas exchange and reducing work of breathing, presumably because of counterbalancing of auto-PEEP. For delivery of NIV, clinical outcome studies using bilevel ventilators report success rates that compare favorably with those for critical care ventilators,[60,62] although no randomized, controlled trials have compared the two directly. Thus, the selection of either system can be justified, and the choice is often based on availability and financial considerations. Further, recent developments as described above have blurred the distinctions between the various types of ventilators.

CHRONIC

Blower- or turbine-based portable pressure-limited bilevel ventilators are used most often in the long-term setting to deliver NIPPV. In a 9-year Swiss survey,[230] volume-limited devices predominated initially, but pressure-limited devices accounted for more than 90% of ventilator applications during the latter years. This shift has been driven by the low cost, ease of use, and portability of the pressure-limited devices. In addition, manufacturers have been steadily adding features that enhance monitoring. Some now offer wireless Internet connections that permit home monitoring of respiratory rate, oximetry, airway pressures, tidal volumes, and air leaks. Portable volume-limited positive-pressure ventilators are still preferred by some clinicians for specific applications. Because they offer sophisticated monitoring, they are used in patients requiring nearly continuous ventilator support. Because of their high pressure-generating capabilities, they may be preferred in patients with high respiratory system impedances, such those with morbid obesity or chest wall deformity, or they may be used to "stack" breaths to attain a higher inspired lung volume to increase cough flows.[241] Also, because volume-limited ventilators usually are driven by intermittent piston action rather than continuously operating blowers, backup battery life can be considerably longer. On the other hand, pressure-limited ventilators compensate for leaks more effectively than do volume-limited ventilators, although the compensatory flow goes, not surprisingly, mainly into "feeding" the leaks.[345] Studies in the long-term setting have not shown consistently better outcomes with one type of ventilator over the other,[346,347] however, and the choice usually becomes one of clinician and/or patient preference. In addition, a number of more recently introduced ventilators are "hybrid" devices that have the capability of delivering both pressure-limited and volume-limited breaths.

Selection of a Ventilator Mode

ACUTE

Although no studies have demonstrated superior efficacy in terms of avoiding intubation or mortality of one ventilator mode over another in the acute setting, some practitioners have found enhanced patient comfort or compliance with PSV.[348,349] Thus, although either volume-limited or pressure-limited modes can be used with the expectation of similar rates of success, pressure-limited modes appear to be accepted more readily by patients and are more commonly used (>90% of applications in some studies).[315] Some newer hybrid ventilators designed specifically for NIV are able to deliver both volume-limited or pressure-limited modes, with the capability of adjusting triggering and cycling sensitivity, rise time, and inspiratory duration to optimize patient comfort.[350] Proportional-assist ventilation, a unique mode that tracks instantaneous patient airflow, is capable of closely matching patient breathing pattern and hence potentially enhancing synchrony and comfort (see Chapter 13).[351] The flow signal is fed back to the ventilator as a raw signal (flow assist) or integrated over time (volume assist). Gains are imposed on both these signals and on a composite signal (proportional assist) that can be adjusted to assist a "proportion" of the patient's breathing effort. Theoretically, flow and volume assist are adjusted to match resistive and elastic work, respectively, which must be measured. These specific adjustments, however, are unnecessary when proportional-assist ventilation is used to deliver NIPPV clinically. Proportional-assist ventilation has been shown to be as effective and a more comfortable means of administering NIPPV than PSV delivered via a critical care ventilator[352] or a bilevel device.[353]

CHRONIC

In the long-term setting, pressure-support and volume-limited ventilators achieve similar levels of overnight oxygenation.[347] Thirty consecutive patients, mainly with restrictive forms of chronic respiratory failure, received nasal volume-limited ventilation for 1 month followed by pressure-limited ventilation.[346] Only two patients failed to improve with volume-limited ventilation, whereas ten had increased Pa_{CO_2} or symptomatic deterioration when switched to pressure-limited ventilation. Conversely, ten patients in another study had improved daytime blood gases when switched from volume-limited to pressure-limited ventilation.[354] Although these were not prospective, randomized trials, they show no clear advantage of one ventilator mode over the other. Thus, the choice between the two hinges on clinician preference and consideration of specific ventilator properties such as

portability, pressure-generating capabilities, backup-battery life, ability to stack breaths, and other factors. In general, though, volume-limited ventilators have greater pressure-generating and alarm capabilities. A more recent approach has been to use hybrid modes such as volume-assured pressure preset ventilation that automatically adjusts the inspiratory pressure within preset limits to achieve a target minute volume. Thus far, the mode appears to function as well as standard pressure preset modes and may lower CO_2 levels more in patients with obesity hypoventilation than with standard bilevel therapy,[355] but not in patients with COPD and hypercapnia.[356] Similarly, a randomized crossover trial of twenty patients with restrictive thoracic disease showed no advantage of an autotitrating bilevel mode over a standard bilevel mode.[357]

Ventilator Settings

ACUTE

Two strategies have been described: the *high-low approach,* which starts with a higher inspiratory pressure (20 to 25 cm H_2O) and lowers it if patients are intolerant,[17] and the *low-high approach,* which starts with a low inspiratory pressure (8 to 10 cm H_2O) and raises it gradually as tolerated by the patient.[60] The former approach prioritizes rapid alleviation of respiratory distress; the latter aims to optimize patient comfort in an effort to maximize patient tolerance. Paramount with both approaches is the realization that subsequent adjustments are necessary depending on patient response. Higher initial pressure often must be adjusted downward, and it is very important that low initial pressure be raised (usually to 12 to 20 cm H_2O) within the first hour, if possible, to provide adequate ventilator assistance. The high-low approach may be preferable in patients with hypoxemic respiratory failure who often have high minute volumes and are very dyspneic. L'Her et al[358] demonstrated that in patients with acute lung injury treated with NIPPV, higher pressure support levels were effective at relieving dyspnea while increases in PEEP were effective at improving oxygenation.

Expiratory pressure (or PEEP) is used routinely with bilevel ventilators and is optional with volume-limited ventilators. Bilevel ventilators require a bias flow during expiration to flush CO_2 from the single ventilator tube and avoid rebreathing.[341] Minimal expiratory pressure with these ventilators is in the 3 to 4 cm H_2O range. Higher expiratory pressures (typically 4 to 8 cm H_2O) are used to counterbalance intrinsic PEEP during treatment of exacerbations of COPD or to enhance oxygenation. It is important to recall that the difference between inspiratory and expiratory pressure is the level of PSV, so inspiratory pressure must be increased in tandem with expiratory pressure if the same level of ventilatory assistance is to be maintained. Adjusting the rate of pressurization (or rise time) may be useful to enhance comfort; patients with COPD prefer slightly more rapid rise times than restrictive patients. Very rapid pressurization rates minimize the work of breathing in patients with COPD but may be sensed as less comfortable by patients than slightly lower pressurization rates.[359]

CHRONIC

No consensus has been reached on how to select ventilator settings for patients in the long-term setting. In the sleep laboratory, one approach is to increase expiratory pressure until apneas are eliminated and inspiratory pressure until hypopneas are eliminated without inducing excessive arousals. The American Academy of Sleep Medicine has proposed guidelines for achieving this titration.[360] This approach, however, is based largely on expert opinion and does not ensure that the pressures selected will alleviate hypoventilation, nor does it facilitate initial adaptation if the patient finds the recommended initial pressures intolerable. Thus, I prefers a gradual up titration of pressures over weeks or even months as tolerated by the patient. Initial inspiratory pressure is 6 to 10 cm H_2O, with increases weekly by 1 to 2 cm H_2O as tolerated. Expiratory pressure is set at 3 to 4 cm H_2O and rarely is increased above 6 cm H_2O unless sleep apnea is deemed an important contributor. For volume-limited ventilation, an initial tidal volume of 10 to 15 mL/kg has been recommended, in excess of the standard recommendations for invasive ventilation, because of the need to compensate for air leaks.[361] Parreira et al[362] found that a tidal volume of 13 mL/kg optimized assisted minute volume in a group of patients with restrictive thoracic disorders.

A backup rate sufficiently high to control breathing nocturnally has been recommended for patients with neuromuscular disease to maximize respiratory muscle rest and prevent apneas. In patients with severe stable COPD, on the other hand, the need for a backup rate is not clear, considering that one controlled trial of NIPPV found significant benefit using a spontaneous ventilator mode without a backup rate.[332] Compared with a spontaneous mode, these authors found that use of a backup rate had no effect on nocturnal gas exchange in patients with COPD and chronic respiratory failure. On the other hand, Parreira et al[362] found that minute volume was optimized when patients with restrictive thoracic disorders used a relatively high backup rate of 23 breaths/min.

Adjuncts to Noninvasive Ventilation

With bilevel ventilators, supplemental O_2 can be provided directly through tubing connected to a nipple in the mask or to a T connector in the ventilator tubing, with liter flow adjusted to keep SaO_2 above 90% to 92%. Maximal FI_{O_2} using this setup is only 45% to 50%. FI_{O_2} delivered via bilevel ventilators depends on a number of factors, including O_2 flow rate, breathing pattern, ventilator settings, and location of the O_2 connection (connection to the mask gives a higher FI_{O_2}).[363] With critical care ventilators and some bilevel devices designed for acute applications, standard O_2 blenders are used to accurately provide the desired. Thus, these

latter ventilators are preferred for patients with hypoxemic respiratory failure.

Humidification may enhance comfort during NIPPV and is advised if NIPPV is to be used for more than a few hours, although effects on NIV failure rates have not been established.[364] A heated humidifier is preferred over a heat and moisture exchanger because the latter adds to work of breathing[365] and may interfere with triggering and cycling. Also, with excessive air leaking, a heated humidifier lowers nasal resistance.[23] In the long-term setting, humidification usually is provided, particularly during the winter months in colder climates. Nasogastric tubes are not recommended routinely as adjuncts to NIV, even when oronasal masks are used.

Noninvasive Techniques to Assist Cough

Because it provides no direct access to the lower airways, as does invasive ventilation, NIPPV depends on the integrity of airway protective reflexes for its success. In the acute setting, patients with excessive secretions or severe cough impairment are intubated rather than managed noninvasively. In the long-term setting, however, a number of techniques have been developed to enhance secretion removal in patients with compromised secretion-clearance capabilities. These techniques are of greatest value in patients with neuromuscular disease and weakened expiratory muscles. Severe bulbar involvement, such as occurs with ALS, is treated most effectively with invasive ventilation. Secretion retention related to abnormal mucus, such as occurs with cystic fibrosis, is beyond the scope of this chapter.

An effective cough depends on the ability to generate adequate expiratory airflow, estimated at more than 160 L/min.[366] Expiratory airflow is determined by lung and chest wall elasticity, airway conductance, and at least at higher lung volumes, expiratory muscle force. By generating an adequate vital capacity (> 2.5 L) to take advantage of respiratory system elasticity, inspiratory muscle function also contributes to cough adequacy. In addition, an effective cough requires the ability to close the glottis so that explosive release of intrathoracic pressure can generate high peak expiratory cough flows.[367] When patients with severe neuromuscular disease are too weak to take advantage of these mechanisms and have insufficient cough flows, techniques to assist cough should be applied.

The simplest maneuver to augment cough flow is manually assisted or "quad" coughing. This consists of firm, quick thrusts applied to the abdomen using the palms of the hands, timed to coincide with the patient's cough effort.[241] The technique should be taught to caregivers of patients with severe respiratory muscle weakness with instructions to use it whenever the patient has difficulty expectorating secretions. With practice, the technique can be applied effectively and frequently with minimal discomfort to the patient. Peak expiratory flows can be increased severalfold when manually assisted coughing is applied successfully.[368] To minimize the risk of regurgitation and aspiration of gastric contents, the patient should be semi-upright when manually assisted coughing is applied, and the technique should be used cautiously after meals. The technique can be used, though, in patients with gastric feeding tubes.

Although manually assisted coughing may enhance expiratory force, it does not augment inspired volume. Thus, patients with severely restricted volumes may not achieve sufficient cough flows even when assisted by skilled caregivers. To overcome this problem, the inhaled volume should be augmented. One approach is to "stack" breaths using glossopharyngeal breathing[368] or volume-limited ventilation and then to augment the cough using manual assistance. Another is to use a mechanical insufflator–exsufflator, a device that was developed during the polio epidemics to aid in airway secretion removal.[368] This device delivers a positive inspiratory pressure of 30 to 40 cm H_2O via a face mask and then rapidly switches to an equal negative pressure. The positive-pressure ensures delivery of an adequate tidal volume, and the negative pressure has the effect of simulating the rapid expiratory flows generated by a cough. Use of the insufflator–exsufflator has been combined with manually assisted coughing in an effort to further augment cough flows.[369]

The mechanical insufflator–exsufflator increases cough flows in patients with neuromuscular weakness but is less effective in patients with kyphoscoliosis, and in one study, actually decreased cough flows of patients with COPD.[370] In another study, however, mechanical insufflation–exsufflation decreased dyspnea and improved oxygenation not only in neuromuscular patients but also in patients with airflow obstruction.[371] Although no controlled trials have evaluated the efficacy of the cough insufflator–exsufflator, anecdotal evidence suggests that it enhances removal of secretions in patients with impaired cough. It has been reported to reduce failures (need for intubation) in neuromuscular patients in critical care settings,[372] reduce the occurrence of atelectasis and pneumonias in children with neuromuscular disease,[373] and improve cough flows in patients with ALS unless there is bulbar dysfunction, which may predispose to upper airway collapse.[374] It has been particularly useful in patient homes to treat episodes of acute bronchitis, permitting avoidance of hospitalization.[375] One recent European study demonstrated cost savings by staying in telephone contact with patients and using the cough insufflator–exsufflator on an "on-demand" basis to treat exacerbations.[376] Other devices that aid expectoration, such as the percussive ventilator, Hayek oscillator, and vibratory vest, have some theoretical advantages over other techniques for assisting secretion removal.[241] Their use of high-frequency vibrations (up to 15 Hz) may facilitate mobilization of airway secretions. Unfortunately, even anecdotal evidence to support their use is lacking.

Clinicians caring for patients with severely impaired cough should be familiar with the various techniques available to assist expectoration. These are particularly important with NIV because there is no direct access to the airway, and

secretion retention is a frequent complication and common cause for failure. Although controlled data are lacking, these techniques appear to help in maintaining airway patency in patients with cough impairment during use of NIV in both acute and chronic settings.

Role of the Clinician: Time Demands, Importance of Experience, and Guidelines

An experienced clinician conveying an air of assuredness to patients is thought to be crucial to the success of NIPPV. The clinician should motivate the patient, explaining the purpose of each piece of equipment and preparing the patient for each step in the initiation process. Patients should be reassured, encouraged to communicate any discomfort or fears, and coached in ways to coordinate their breathing with the ventilator. When using nasal masks, patients are instructed to keep their mouths shut.

Time demands on medical personnel have been a concern for the delivery of NIPPV. Chevrolet et al[377] were the first to draw attention to this potential problem, reporting large time demands on nurses during administration of NIPPV. Conversely, Kramer et al[60] found that compared with controls, NIPPV patients tended to require more time from respiratory therapists during the first 8 hours, an amount that fell significantly during the second 8 hours. Nava et al[378] also found that respiratory therapists spent more time during the first 48 hours caring for NIPPV patients than invasively ventilated patients. These findings indicate that NIPPV initially requires more time to administer than conventional therapy, for interface fitting and initial ventilator adjustment, although these demands diminish rapidly after the first few hours. Nurses, respiratory therapists, physicians, or some combination of these must spend the additional time, depending on institutional practices.

As might be anticipated, the experience of personnel also appears to be important for the success of NIPPV. Girou et al[15] reviewed the experience of a twenty-six-bed French ICU between January 1994 and December 2001 on 479 patients with either COPD or cardiogenic pulmonary edema requiring ventilator assistance, invasively or noninvasively. Use of NIV increased from approximately 20% to 90% (of the patients) during the course of the study, associated with a decrease in the rate of nosocomial pneumonias from 20% to 8% and in ICU mortality from 21% to 7% (all $p < 0.05$). The authors speculated that a "learning effect" over the course of the study was responsible for the improved outcomes. Over an 8-year period in their ICU, Carlucci et al[379] found that NIPPV success rates increased in patients with COPD despite a worsening of the severity of illness as staff gained experience with the technique. Whether or not guidelines for NIPPV implementation can improve patient outcomes remains to be established. Sinuff et al[380] found that clinician behavior changed after implementation of a guideline at their single academic institution, but overall patient outcomes were not altered. More recently, Kikuchi et al[381] observed a decreased mortality after institution of a NIPPV protocol for acute respiratory failure, although the before/after study design cannot control for other changes related to passage of time.

MONITORING

Patients receiving NIV are monitored to determine whether the goals are being achieved (see Table 18-8).

Subjective Responses

The key aims of NIPPV are alleviation of respiratory distress in the acute setting and of fatigue, hypersomnolence, and other symptoms of impaired sleep in the chronic setting while achieving patient tolerance. Agitation and mask discomfort are challenges during NIPPV. These aspects can be assessed easily using bedside observation and patient queries. Some patients minimize or deny discomfort and still may have great difficulty adapting successfully to NIV, so clinicians not should only query patients but also should observe for nonverbal signs of distress or discomfort.

Physiologic Responses

Evidence of physiologic improvement within the first 2 hours, including decreases in respiratory and heart rates, diminished sternocleidomastoid muscle activity, and elimination of abdominal paradox, portends a favorable NIPPV outcome.[133,196] Patients should be breathing in synchrony with the ventilator, and air leaking should be minimal. Some clinicians also monitor tidal volumes, aiming for delivered volumes in excess of 7 mL/kg.[382] Relying on ventilator monitoring to follow tidal volumes may be misleading, however, particularly during use of bilevel ventilators, because these integrate the inspired flow signal and may be very inaccurate in the face of air leaks.

Gas Exchange

Improvement in gas exchange as determined by continuous oximetry and occasional blood gases is a key aim in acute application of NIPPV, although improvement in ventilation may occur gradually over hours.[17] In chronic stable patients, the improvement in daytime gas exchange occurs even more slowly, over a period of weeks, depending on the duration of daily ventilator use. Some patients adapt slowly and require up to several months before they sleep through the night using the ventilator. Arterial blood-gas measurement should be delayed until the patient is consistently using the ventilator for a period of time likely to improve gas exchange: usually at least 4 to 6 hours a day. No consensus on an ideal level for daytime Pa_{CO_2} has been reached; most investigators target

levels in the middle 40s. In my experience, a daytime Pa_{CO_2} of up to 60 mm Hg, or even higher, may be tolerated without hypersomnolence or evidence of cor pulmonale as long as oxygenation is adequate. Noninvasive CO_2 monitoring may be useful for trending purposes in patients with normal lung parenchyma such as those with neuromuscular disease. Transcutaneous Pa_{CO_2} is probably the most useful because variable air leaks and breathing patterns and dilution secondary to bias flow with some ventilators render end-tidal CO_2 recordings inaccurate, particularly if the patient has parenchymal lung disease.[383]

Sleep

Little is known about sleep during NIPPV in the acute setting, and the role of sleep monitoring in the long-term setting is controversial. As noted earlier, some clinicians prefer to use the sleep laboratory to decide on initial settings for NIPPV. Others begin most patients, particularly those with neuromuscular disease, without a polysomnographic evaluation. If both approaches prove to be equal in achieving the goals of NIV, it would be difficult to argue that routine sleep studies are necessary. The relative utilities of polysomnography, multichannel portable recordings, and nocturnal oximetry are also unclear in follow-up of long-term NIPPV, but one pragmatic approach is to screen patients using home oximetry and to perform more sophisticated studies when the oximetry results indicate the need for further evaluation.

ADAPTATION

Acute

It is critically important to ascertain that the delivered pressures are sufficient to alleviate respiratory distress; a common mistake is to fail to increase pressures quickly enough, and the patient fails because of inadequate ventilator support. The patient also should use the ventilator for more time initially, with increasing periods of time off the ventilator as the underlying condition improves. Some clinicians encourage use most of the time initially, as dictated by the degree of respiratory distress during ventilator-free intervals.[60] Others employ sequential use,[384] wherein periods of use alternate with lengthy ventilator-free periods; total daily use averages only 6 hours, although this would be suitable only for mildly ill patients. When no respiratory distress recurs during ventilator-free intervals, ventilator assistance is discontinued. Total duration of ventilator assistance depends on the speed of resolution of the respiratory failure. Patients with acute pulmonary edema require an average of 6 to 7 hours of ventilator use,[114] whereas patients with COPD average 2 days or more.[60] Some patients may continue nocturnal ventilation after discharge from the hospital, following guidelines for long-term use of NIPPV.

Chronic

Patients start more gradually and increase periods of use as tolerated. Anxious patients may begin with only 1 to 2 hours of daytime use followed by gradually increasing periods of nocturnal use over several weeks or even months. Compared with the acute setting, urgency in the chronic setting is less, and because the intent is to use the ventilator during sleep, great care must be exercised in optimizing patient comfort. During this period, visits from a home respiratory therapist are helpful to assess comfort and address any problems that arise. Criner et al[278] found that 36% of patients required further adjustments in mask or ventilator settings, even after discharge from a several-week stay in an inpatient ventilator unit.

ADVERSE EFFECTS AND COMPLICATIONS

In properly selected patients, NIPPV is safe and well tolerated, and most of the adverse effects are related to the interface or ventilator (Table 18-9). Approximately 10% to 15% of patients fail to tolerate interfaces despite adjustments in strap tension, repositioning, and trials of different sizes and types of interfaces. These patients may have claustrophobia or high levels of anxiety and fail even after multiple attempts at mask readjustment and judicious use of sedation. Other mask-related adverse effects include erythema, pain, and ulceration on the bridge of the nose. Minimizing strap tension and advances in mask technology, with softer silicon seals and routine use of artificial skin on the bridge of the nose, are associated with less frequent nasal bridge ulceration, which had been as high as 40% in earlier studies.[385]

Air pressure-related and flow-related adverse effects include oronasal dryness or congestion that may respond to humidification or decongestants, sinus and ear pain, eye irritation from air leakage under the mask seal on the sides of the nose, and gastric insufflation. Readjusting the mask seal to reduce air leaking or reducing inspiratory pressure, if possible, may help.

Air leaking is ubiquitous during NIV, either under the seal or through the mouth with nasal ventilation. Air leaking adds to discomfort and may interfere with ventilator triggering and cycling, as well as efficacy of ventilation. The leaks usually are tolerated as long as the ventilator compensates adequately, as most bilevel ventilators do. As discussed earlier, bilevel ventilators cannot function properly without a small intentional leak in the tubing, which is necessary for removal of CO_2 to prevent rebreathing. Most volume-limited modes compensate poorly for leaks, but large air leaks may compromise the effectiveness of any form of NIPPV. Attempts to control air leaks should start with a reassessment of mask fit and readjustment of the head straps. To reduce air leaking through the mouth during nasal ventilation, edentulous patients should not be

TABLE 18-9: FREQUENCY OF ADVERSE SIDE EFFECTS AND COMPLICATIONS OF NONINVASIVE POSITIVE-PRESSURE VENTILATION WITH POSSIBLE REMEDIES

Complication	Occurrence (%)*	Possible Remedy
Mask-related		
Discomfort	30% to 50%	Check fit, adjust strap, new mask type
Facial skin erythema	20% to 34%	Loosen straps, apply artificial skin
Claustrophobia	5% to 10%	Smaller mask, sedation
Nasal bridge ulceration	5% to 10%	Loosen straps, artificial skin, change mask type
Acneiform rash	5% to 10%	Topical steroids or antibiotics
Air pressure or flow related		
Nasal congestion	20% to 50%	Nasal steroids, decongestant/antihistamines
Sinus/ear pain	10% to 30%	Reduce pressure if intolerable
Nasal/oral dryness	10% to 20%	Nasal saline/emollients, add humidifier, decrease leak
Eye irritation	10% to 20%	Check mask fit, readjust straps
Gastric insufflation	5% to 10%	Reassure, simethicone, reduce pressure if intolerable
Air leaks	80% to 100%	Encourage mouth closure, try chin straps, oronasal mask If using nasal mask, reduce pressures slightly
Major complications		
Aspiration pneumonia	< 5%	Careful patient selection
Hypotension	< 5%	Reduce pressure
Pneumothorax	< 5%	Stop ventilation if possible, reduce pressure; if not, use thoracostomy tube if indicated

*Occurrences estimated from literature and my experience.

treated with nasal masks, others are coached to keep their mouths shut, chin straps may be used, or an oronasal mask may be tried.

Major complications, such as pneumothoraces, are unusual, probably because inflation pressures are low compared with those used with invasive ventilation. Lack of patient cooperation interferes with efficacy and may be ameliorated by judicious use of sedation, such as low doses of benzodiazepines. Unremitting agitation should be considered an indication for intubation. Aspiration is a reported complication,[386] but should be unusual if patients with swallowing dysfunction and problems clearing secretions are excluded. Routine insertion of nasogastric tubes has been recommended at some centers to lower the risk of aspiration during use of face masks,[382] but there are no data available to support this practice, and it is no longer recommended. Progressive hypoventilation occurs in a small minority of patients, usually necessitating intubation. Uncooperativeness, lack of synchronization with the ventilator, inability to tolerate adequate inflation pressures, and excessive air leaking are common causes for this predicament, and measures aimed at correcting these may be helpful. Rarely, nasal obstruction contributes and may respond to decongestant sprays.

In the acute setting, NIPPV fails in roughly a third to a quarter of patients, depending on many factors, including skill and experience of the team, occurrence of adverse effects and complications as discussed earlier, and underlying severity of the patient's illness. Progression of the underlying process, such as worsening hypoxemia, also may be responsible for failure. Close monitoring with proactive efforts to address and minimize adverse effects should minimize failure rates.

SUMMARY AND CONCLUSIONS

In the acute setting, evidence now supports NIPPV in the treatment of respiratory failure secondary to acute exacerbations of COPD, acute cardiogenic pulmonary edema (which can be managed with CPAP as well), and immunocompromised states and to facilitate weaning in patients with COPD. Weaker evidence supports NIPPV in the treatment of other forms of respiratory failure, including respiratory insufficiency in patients with asthma, post–lung resection, or those who decline intubation. NIPPV should not be used routinely in patients with ARDS or severe pneumonia. Regardless of the underlying cause of the respiratory failure, patients to receive NIPPV must be selected carefully. Those with mild deteriorations likely will succeed without ventilator assistance, and prompt intubation usually is preferred in severely ill patients. Patients with unstable medical conditions, inability to protect the airway or clear secretions, or uncooperativeness are excluded from consideration. Patients selected according to these guidelines and monitored closely can be managed with NIPPV with the expectation that intubation and its inherent complications will be avoided.

In the chronic setting, NIPPV has long been considered the modality of first choice for patients with respiratory failure secondary to neuromuscular disease or chest wall

deformity. Randomized, controlled trials have not been done because of ethical concerns, but the ability of NIPPV to improve symptoms, gas exchange, quality of life, and survival in these patients is widely accepted. NIPPV for patients with severe stable COPD has been more controversial because of conflicting data, but it may prevent deterioration of gas exchange, improve quality of life, and reduce the need for hospitalization in patients with severe CO_2 retention and nocturnal hypoventilation who adhere to therapy (which is often not the case). In some countries, the obesity-hypoventilation syndrome has become the largest diagnostic category for NIPPV at home, perhaps because of increasing recognition and the obesity epidemic.

In both the acute and chronic settings, experience and skill with the implementation of NIPPV are important. Proper fit and application of the mask are keys to success. Although the type of ventilator is not as important, ventilator mode and settings affect comfort and effectiveness. In carefully selected patients initiated according to current recommendations and monitored in an appropriate setting, NIPPV can be delivered safely with no or minor adverse effects. The failure rate remains substantial at roughly a quarter to a third of patients, but hopefully will decline as clinicians gain experience, selection criteria are refined, and technology improves. NIPPV has assumed an important role in acute and chronic care settings and should be considered a lung-protective strategy for certain forms of respiratory failure. In addition, clinicians caring for patients with respiratory failure should have the necessary skill and experience with NIPPV applications.

HIGH-FREQUENCY VENTILATION

Alison B. Froese
Niall D. Ferguson

High-frequency ventilation has been an unconventional option for more than three decades and during that period several varieties of high-frequency ventilators have come and gone. Currently, interest in high-frequency ventilation in adult critical care is part of a larger search for ventilator strategies that can support gas exchange in the severely hypoxemic patient without contributing additional ventilator-induced lung injury. Over the past 30 years, high-frequency ventilators provided an experimental tool that identified many of the mechanisms that contribute to ventilator-induced lung injury. It became clear that ventilator-induced lung injury is minimized by ventilator patterns that achieve homogeneous aeration of as much of the lung as possible, avoiding both injury from overdistension (volutrauma) and that arising from the repetitive opening and closing of lung units in regions of atelectasis (atelectrauma) (Fig. 19-1).[1] Failure to operate in the "safe zone" initiates biotrauma.[2,3]

The concept of a "safe zone" within which to ventilate the atelectasis-prone lung has been reflected in numerous clinical trials of lung-protective ventilation over the last 15 years. Conventional ventilator protocols have found survival benefit from shrinking the tidal volume and minimizing peak or plateau distending pressures.[4] Studies such as that of Roupie et al[5] and Terragni et al[6] suggest that very small tidal volumes—even lower than 6 mL/kg predicted body weight—may be needed in some patients (those with the worst lung injury) to avoid overdistension. Very high levels of positive end-expiratory pressure (PEEP) would be needed in some patients to avoid derecruitment.[7] Concurrently, high-frequency ventilation—both in oscillatory and jet forms—has become an established lung-protective modality in neonatal and pediatric intensive care (see Chapter 23).[8–14] The question, however, persists: in severe acute respiratory distress syndrome in adult patients, will use of a high-frequency device result in clinically important outcome differences compared with lung-protective conventional ventilation, or are newer conventional ventilator protocols now equally able to protect the lung?[15–17]

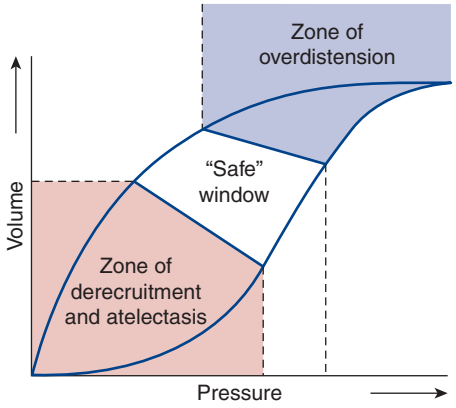

FIGURE 19-1 Pressure-volume curve of a moderately diseased lung, as in a patient with acute lung injury. Ventilator-induced lung injury occurs at both extremes of lung volume. In the zone of overdistension, damage arises from edema fluid accumulation, surfactant degradation, and mechanical disruption. In the zone of derecruitment and atelectasis, lung injury arises from the direct trauma of repeated closure and reexpansion of small airways and alveoli, through accumulation and activation of inflammatory cells with release of cytokines (biotrauma), through interactions with local hypoxemia, by inhibition of surfactant, and through compensatory overexpansion of the rest of the lung as the lung "shrinks." High end-expiratory pressures plus small tidal volume cycles are needed to stay in the safe window. (Reproduced, with permission, from Lippincott Williams & Wilkins, Froese AB, High-frequency oscillatory ventilation for adult respiratory distress syndrome: let's get it right this time. *Crit Care Med.* 1997;25:906–908.)

HISTORICAL OVERVIEW

Several existing reviews detail the history of high-frequency ventilation.[18,19] Early developments often were driven by issues peripheral to pulmonary critical care. Sjöstrand et al[20] wanted to eliminate respiration-related variations in vascular pressures so that they could investigate carotid sinus reflexes and developed high-frequency positive-pressure ventilation. Lunkenheimer et al[21] wanted to use the lungs as a route to deliver oscillatory pressure pulses to the myocardium. They needed apnea for this and were amazed to find gas exchange occurring while they applied their high-frequency flow oscillations. Emerson[22] thought that high-frequency flow oscillations might provide internal physiotherapy and help to mobilize secretions. In Toronto, Bryan[23] initially was curious to see whether an external "shaker" could enhance the gas mixing produced by cardiogenic oscillations. Klain and Smith[24] explored jet ventilation at increasing frequencies to solve the problem of achieving alveolar ventilation in respiratory systems with a big leak, such as a bronchopleural fistula.

These devices often became intriguing phenomena in search of a reason for being. Devices such as high-frequency positive-pressure ventilation and high-frequency jet ventilation were particularly useful for surgical procedures when both anesthesiologist and surgeon needed access to the airway. The notion, however, that high rates and small tidal volumes might be of broader therapeutic value needed a pathophysiologic rationale.

An emerging concept in the 1970s was that many of the pulmonary perturbations that put patients into intensive care units were problems of low lung volume. Low lung volumes were associated with poor lung compliance, increasing airway and vascular resistances, increased work of breathing, airway closure, low ventilation–perfusion ($\dot{V}_A/\dot{Q}$) ratios, atelectasis, hypoxemia, and high oxygen (O_2) exposure. Neonatal outcome was improving simply from the introduction of continuous positive airway pressure to improve alveolar aeration.[25]

A crucial insight occurred early in our experience with high-frequency oscillatory ventilation (HFOV) when we explored a variety of mean airway pressure settings while ventilating an infant with neonatal respiratory distress syndrome (Fig. 19-2).[26] The infant was stable in terms of both hemodynamics and CO_2 elimination over the whole range of mean pressures tested, but oxygenation varied markedly. One could either ventilate with a low mean airway pressure (mPaw) and high fractional inspired oxygen concentration (FI_{O_2}) or a higher mean pressure and low FI_{O_2}. A choice had to be made. We gave priority to the reversal of low lung volumes. We argued that the small-volume cycles of HFOV should allow one to optimize alveolar aeration by using higher mean pressures than were considered safe during conventional mechanical ventilation while still keeping peak pressures less than those needed to eliminate CO_2 at conventional rates. This pathophysiologic rationale continues to guide high-frequency applications to this day.

Many devices invented along the way, such as high-frequency positive-pressure ventilation, have since disappeared from use. High-frequency jet ventilation was explored in many adult intensive care units in the 1980s for difficult cases of bronchopleural fistula or tracheal disruption.[27] It

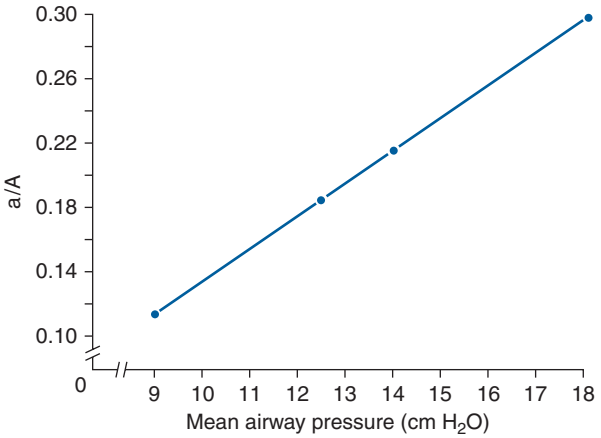

FIGURE 19-2 Relationship of oxygenation, as reflected in the ratio of the arterial and alveolar oxygen tensions (a/A ratio), to the mean airway pressure (mPaw) applied during HFOV, at constant tidal volume and frequency, in an infant with respiratory distress syndrome. No circulatory instability occurred over the entire range of mean pressures. CO_2 elimination could be achieved equally well using a high FI_{O_2} and a low mPaw or a low FI_{O_2} and a higher mPaw. A choice of operating conditions had to be made. (From Marchak, et al. Treatment of RDS by high-frequency oscillatory ventilation: a preliminary report. *J Pediatr.* 1981;99:287–292. Reproduced with permission of Mosby, Inc.)

gradually became clear that any oxygenation benefits occurring during high-frequency jet ventilation resulted from increases in mean lung volume, not from some unusual properties of gas distribution.[28] With an high-frequency jet ventilation device, the end-expiratory lung volume is a complex product of jet diameter and placement, driving pressure, jet frequency, and the time available for expiration.[29,30] Safe use requires accurate intrapulmonary pressure monitoring, which was rarely provided with early devices. Inadvertent hyperinflation could cause problems with both circulatory depression and/or barotrauma. No North American, commercial, adult-sized jet ventilator was ever marketed with a safe, effective humidification system such as that available in Europe.

The largest early comparative trial of high-frequency jet ventilation versus conventional mechanical ventilation in hypoxemic lung disease was performed before the importance of atelectasis reversal was established. Consequently, it was carried out with the goal of supporting gas exchange with the lowest possible peak and mean pressures, and proved of no benefit.[31] For all these reasons, high-frequency jet ventilation in adults has become a rare event. Jet ventilation at high or low frequencies continues to be a useful approach to situations in which airway access must be shared during surgical procedures[32] or alveolar ventilation needs to be maintained in the presence of severe bronchopleural fistulas.[29]

High-frequency jet ventilation has persisted in neonatal and pediatric critical care largely because of the continuous design refinements of the Bunnell Life Pulse device.[13,14] Early problems with poor humidification causing desiccation of tracheal mucosa were corrected, appropriate pressure-monitoring systems were devised, and expert training and technical support were provided.

A hybrid device combining high-frequency ventilation and conventional pressure-cycled ventilation (e.g., the high-frequency percussive ventilation/volume diffusive respirator [Percussionaire 4, Bird Technologies, Sandpoint, ID]) is used in many burn units.[33] Its use was reviewed recently.[34] Currently, the main high-frequency ventilatory options in the critical care of adults or larger children are HFOV or the high-frequency percussive ventilation/volume diffusive respirator Percussionaire. For neonates and small infants, high-frequency oscillatory ventilators, high-frequency jet ventilators, and the high-frequency percussive ventilator remain available. In view of HFOV's increasing role in adult intensive care, this chapter focuses on HFOV.

BASIC PRINCIPLES OF HIGH-FREQUENCY OSCILLATORY VENTILATION

HFOV achieves gas transport with stroke volumes approximating anatomic dead space. Quasi-sinusoidal flow oscillations applied at the airway opening induce rapid gas mixing within the lungs. A number of physical transport mechanisms contribute to this mixing process. They have been reviewed in detail elsewhere.[35]

In practical terms, HFOV can be viewed as a mixing device that rapidly blends high O_2/low CO_2 gas from the top of the endotracheal tube with gas in the alveoli (Fig. 19-3).

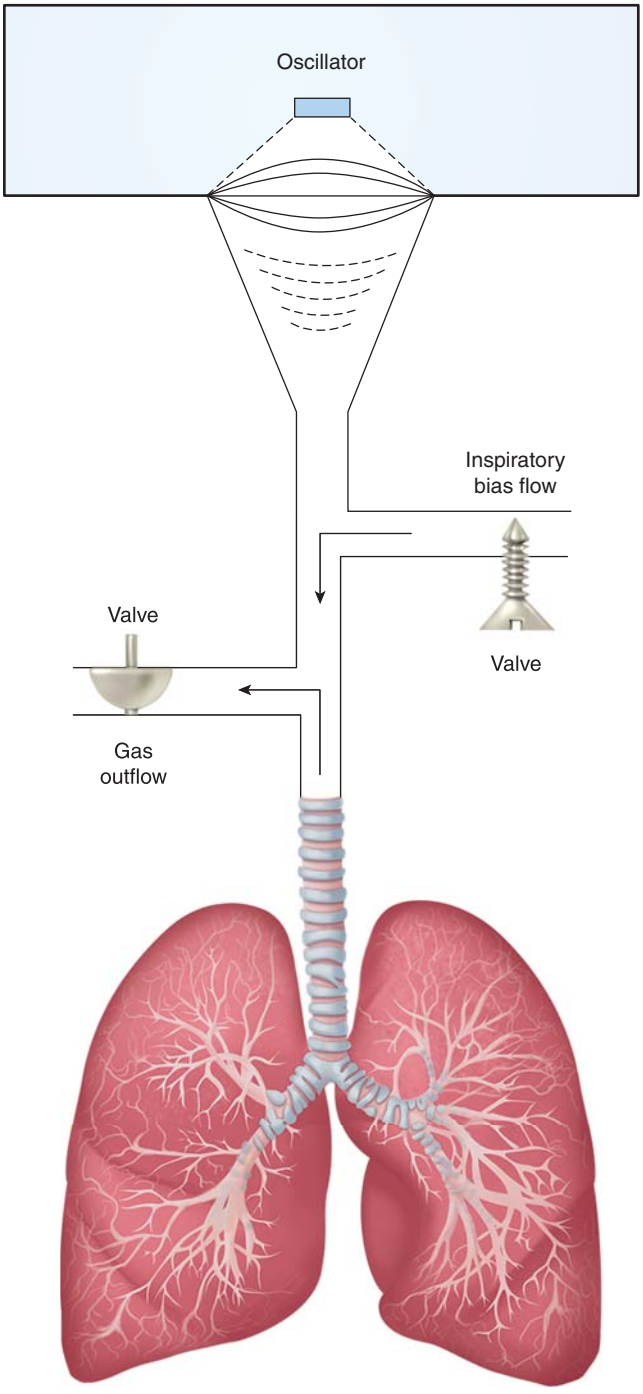

FIGURE 19-3 Schematic of a circuit for delivery of HFOV. Quasi-sinusoidal flow oscillations are generated by a diaphragm or piston pump and directed to the endotracheal tube. A bias flow of humidified gas flushes the CO_2 that is transported out of the lungs out of the circuit. Mean airway pressure is regulated by adjustments of the bias flow and the resistance of the expiratory limb. (From Krishnan, et al. High-frequency ventilation for acute lung injury and ARDS. *Chest.* 2000;118:795–807. Reproduced with the permission of the American College of Chest Physicians.)

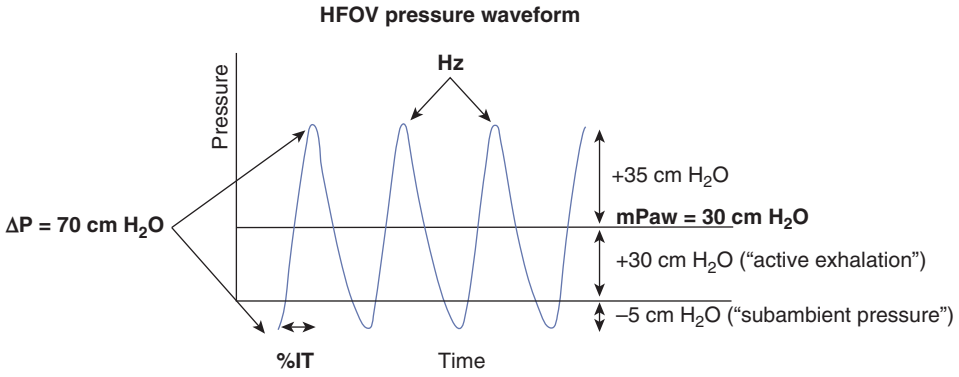

FIGURE 19-4 Waveform of high-frequency pressure oscillations in the circuit above the endotracheal tube. Both inspiratory and expiratory flows are actively driven by the oscillator diaphragm. Pressure cycles equally above and below the mean level. When the oscillatory pressure amplitude (ΔP) is more than twice the mean airway pressure (mPaw), subambient pressures may occur in the circuit without inducing air trapping or choke points in the lung.[37] The endotracheal tube filters the pressure swings, decreasing ΔP in the trachea and alveoli. Filtering is greater with smaller endotracheal tubes and higher frequencies.[71,84,96] (From Derdak S. High-frequency oscillatory ventilation for acute respiratory distress syndrome in adult patients. *Crit Care Med.* 2003;31:S317–S323. Reproduced with permission from Lippincott, Williams & Wilkins.)

Net transport occurs along the partial-pressure gradients for O_2 and CO_2, with CO_2 moving out of the lung along its partial-pressure gradient and O_2 moving inward to the alveolar–capillary interface. These flow oscillations cause symmetric oscillations of intrapulmonary pressure (ΔP) around a mean distending airway pressure (mPaw) (Fig. 19-4). Although subambient pressures can occur in the circuit, intrapulmonary air trapping or "choke points" are unlikely with appropriate mPaw settings.[36,37] One can view HFOV as a means of delivering "continuous positive airway pressure" with a built-in "shaker" to facilitate CO_2 elimination.

In contrast to current conventional approaches to supplying PEEP with additional inspiratory assist for CO_2 elimination, the mean distending pressure during HFOV is midway between the minimal and maximum values, introducing less risk of derecruitment during the expiratory phase for any given peak distending volume or pressure.[38] One attraction of HFOV has been the way in which it uncouples the regulation of oxygenation and CO_2 elimination into two separate control systems, unlike the situation with conventional ventilators, where it is often difficult to adjust one (i.e., the CO_2 level) without also affecting the other. Oxygenation is regulated by reversing atelectasis and then finding the mean distending pressure that maintains alveolar expansion. The FI_{O_2} then is set at a level that maintains appropriate arterial oxygenation goals. CO_2 elimination is relatively independent of mean airway pressure,[39] being regulated by frequency and stroke volume (i.e., power or ΔP) adjustments.[40,41]

Oxygenation

ACHIEVING ALVEOLAR AERATION

Although lung-volume optimization has become an accepted goal of HFOV, the "best way" to achieve this optimization remains controversial (Fig. 19-5). The small volume cycles of HFOV are simply not powerful enough to reopen atelectatic alveoli rapidly without some type of recruitment measure.

Ventilating on the "Deflation Limb". All initial animal studies and one early human trial used a brief recruitment maneuver to near total lung capacity, followed by reduction of mPaw to a maintenance level that prevented derecruitment.[42–46] This is termed getting the lung *onto the deflation limb* of its pressure–volume relationship. Recent investigations in both animal models and humans reinforce the value of ventilating on the deflation limb.[47–54] After a recruitment maneuver, oxygenation goals are achieved at substantially lower maintenance mPaw values (near the point of maximum curvature),[48,51,52] alveolar expansion becomes more homogeneous (which should reduce shear forces during ventilation and reduce volutrauma),[50,55] and the percentage transmission of HFOV pressure cycles into the lung is decreased relative to settings producing equal shunt reduction on the inflation limb.[49] Most studies in animals and humans have used one or more sustained inflation recruitment maneuvers to get the lung onto the deflation limb. A recent study in saline-lavaged pigs concluded that an escalating stepwise slow recruitment maneuver was more effective in opening the lung than brief sighs or a 20-second sustained inflation.[56] This study, however, is limited by the low pressures employed and the incomplete recruitment seen with all techniques tested.

Ventilating on the "Inflation Limb". Following the High-Frequency Intervention (HIFI) trial of the late 1980s,[57] fear of intraventricular hemorrhage in the fragile brain of the premature patient led most neonatologists to pursue stepwise increases in mPaw until either X-ray and blood-gas evidence of lung reexpansion was achieved or the mPaw level reached whatever level was deemed the "maximum allowable" level for a given institution.[58] Physiologically, this

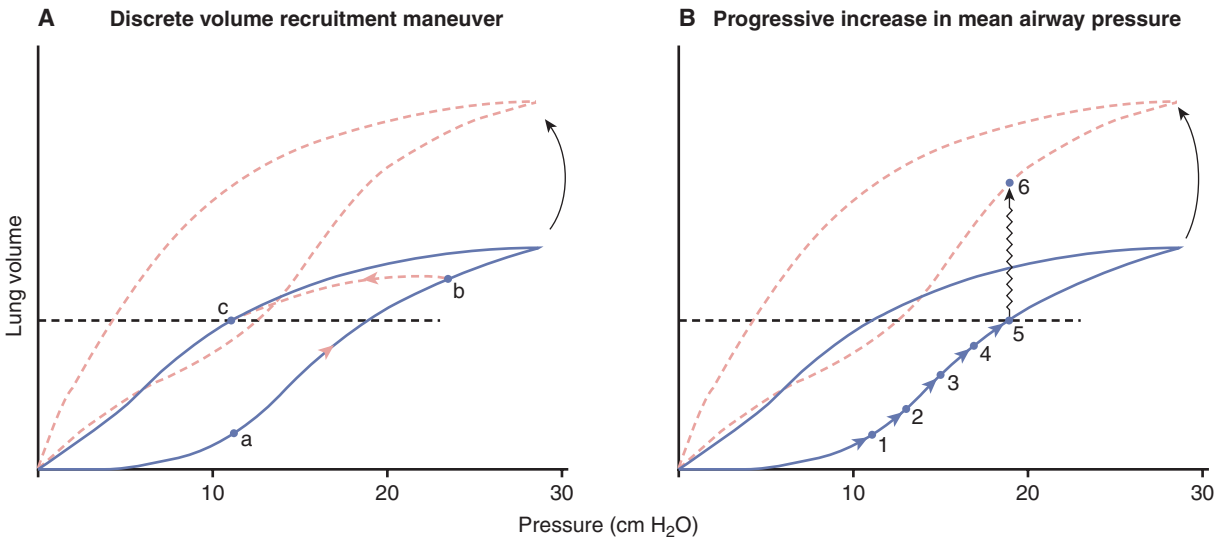

FIGURE 19-5 Schematic of two approaches to alveolar reexpansion during HFOV. The *horizontal dashed line* indicates the desired maintenance mean lung volume. The *solid line* is the pressure–volume relationship of a moderately diseased lung that still exhibits hysteresis. The *dashed line* indicates the pressure–volume relationship after some recovery has occurred. **A.** A brief sustained increase in mean airway pressure (mPaw) from *a* to *b* inflates the lung to near total lung capacity, putting it on the deflation limb of its pressure–volume curve. After this discrete recruitment maneuver, the target volume *c* is maintained at an mPaw of 11 cm H_2O. If the pressure–volume relationship happens to change (as with position, diuresis, etc.), the operational lung volume remains constant. This is the approach used in the Treatment with Oscillation and an Open Lung Strategy (TOOLS) trial.[54] **B.** A gradual march up the inflation limb of the pressure–volume relationship. Progressive increases in mPaw are used to achieve the target lung volume. An mPaw of 19 cm H_2O is now needed to maintain lung volume at *c*. Also, if the pressure–volume relationship of the respiratory system changes, overdistension of the lung could occur (i.e., movement from point 5 to point 6). This is the approach used in the majority of neonatal and adult trials of HFOV to date. When actual lung volumes are measured, settings thought to have optimized lung volume clinically by these stepwise increases in mPaw often prove to be inadequate.[61] (Froese AB. Neonatal and pediatric ventilation: Physiological and clinical perspectives. In: Marini JJ, Slutsky AS, eds. *Physiological Basis of Ventilatory Support.* 1998:1315–1357.)

can be described as "marching up the inflation limb" of the pressure–volume curve, as in Figure 19-5 *B.* Most post-HIFI trial neonatal/pediatric trials (including the largest recent randomized, controlled trials in 2002[59,60]) used stepwise increases in mPaw to "optimize" lung volume to oxygenation and chest X-ray targets. Unfortunately, when the actual lung volumes achieved by such clinical protocols are measured, many lungs prove to be suboptimally expanded.[61] It follows that many comparative trials of HFOV and lung-protective conventional ventilation over the last 25 years have not achieved optimal homogeneous alveolar aeration at the lowest effective mean airway pressure, thus missing some of the potentially protective features of HFOV. A recent analysis of neonatal trials identified many design problems and stressed the need for further well-designed and monitored comparisons of ventilator options in this population.[62] All early adult trials of HFOV started at mPaw levels of 3 to 5 cm H_2O above the mPaw on conventional ventilation and then increased mPaw incrementally—again marching up the inflation limb.[63–67]

A few human trials have used protocols that rapidly place the lung "on the deflation limb" of its pressure–volume relationship.[53,54] Although large comparative trials of the relative safety of these different recruitment protocols are not available, no evidence of risk from either barotrauma or intraventricular hemorrhage (IVH) has emerged using any of the neonatal or pediatric approaches since optimization of lung volume became an accepted goal of HFOV.[8,9] What we do know is that lung-volume optimization is essential for HFOV to be protective of the lung, and alveolar aeration is more homogeneous and achieved at a lower mPaw after a recruitment maneuver, with or without use of the prone position, has moved the lung onto the deflation limb of the pressure–volume relationship. In a recent human trial, the oxygenation improvements gained in the prone position were only sustained when patients were managed with HFOV after being placed supine again.[68] These observations suggest that the higher mPaw and small pressure and volume cycles of HFOV preserve alveolar reexpansion better than the current lung-protective tidal volumes of conventional ventilation.

Atelectrauma: The Costs of Inadequate Recruitment. The relationship between the pressure swings at the airway opening (ΔPao) and those applied to the airways and alveoli (ΔPtr/ΔPao) is multifactorial. Atelectasis markedly impacts the percentage pressure transmission.[69–72] Premature lambs,[69] lavaged pigs,[49] and lavaged rabbits[72] all demonstrate the high cost of failure to reverse atelectasis, as reflected in the percentage of ΔPao transmitted to the trachea, bronchi, and alveoli (Fig. 19-6). Pressure swings and the risk of overdistension of aerated lung reduce rapidly to normal values following lung recruitment. Failure to reverse atelectasis during HFOV exposes airways and alveoli unnecessarily to potentially damaging shear forces. When

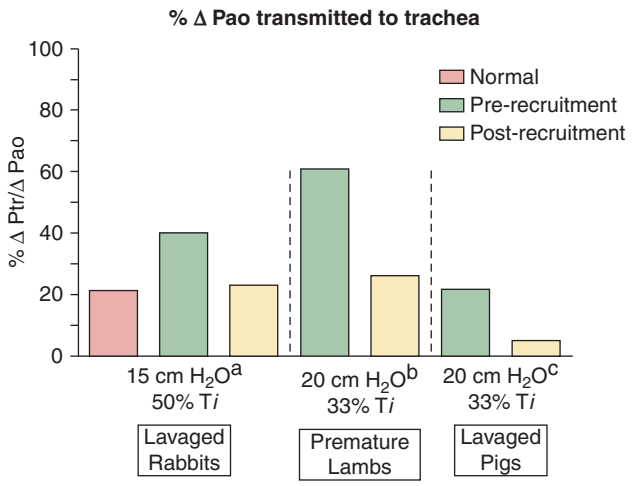

FIGURE 19-6 Effect of a recruitment maneuver (RM) on the transmission of ΔP from the oscillator circuit (ΔPao) to a tracheal sampling site (ΔPtr). Alveolar reexpansion from an RM substantially reduced the amplitude of the peak-to-trough pressure swing applied to the trachea in lavaged rabbits,[72] premature lambs,[69] and lavaged pigs.[49] Reversal of atelectasis protects lung tissue from potentially damaging shear forces. Note that ΔPmachine = ΔPcircuit = ΔPao in various sources.

van Genderingen et al[49] analyzed intrapulmonary pressure transmission in terms of the ratio of intratracheal and circuit (machine displayed) ΔP values, termed the *oscillatory pressure ratio,* pressure transmission into the lung increased substantially at low lung volume. In vivo, adequate alveolar reexpansion optimized oxygenation while also minimizing intrapulmonary pressure swings. For a given level of shunt reduction, both the oscillatory pressure ratio and the mPaw needed to achieve optimal gas exchange were substantially lower after a recruitment maneuver.

Inadequate alveolar recruitment also may trigger inappropriate increases in ΔP or decreases in frequency because of hypercapnia, when what was really needed was alveolar reexpansion. All high-frequency oscillators currently available are load-dependent and deliver less tidal volume at any given setting when the lung is stiffer, as with ongoing atelectasis.[73,74] If one's goal is to explore HFOV for the potential lung-protective effects of maintaining O_2 and CO_2 transport at the smallest possible intrapulmonary pressure and volume swings, then lung-volume optimization is essential.

Volutrauma: The Cost of Excessive Recruitment. In the presence of recruitable lung, it costs less to pursue lung recruitment vigorously than to accept ongoing atelectasis.[75] In late-phase disease with bronchiectasis, cysts, and progressive fibrosis, the opportunity for effective recruitment is past and should not be pursued. Similarly, in patients with milder acute lung injury (ratio of arterial partial pressure of oxygen to FI_{O_2} is 200 to 300) whose lungs are already reasonably well aerated, attempts at further lung recruitment will likely only result in overdistension of the already open lung.[76] All clinical trials done to date—from neonate to adult—that have mandated earlier lung-volume optimization have reported similar or decreased incidences of barotrauma, a transient need for inotropic support, and a decreased need for nitric oxide to reduce pulmonary vascular resistance despite using mean pressures in the thirties or forties when necessary to achieve oxygenation.[11,64,77–80] Recent computed tomography studies during HFOV in eight adult patients with acute respiratory distress syndrome documented substantial (approximately 800 mL) increases in normally aerated volume with only a minor increase in hyperinflated lung (<50 mL).[81] Overdistension certainly can occur, particularly if inappropriately high mPaw levels are maintained as the lung normalizes during treatment. Avoidance of this requires awareness and periodic reassessment of lung expansion.

Some algorithms warn against using mean distending pressures on HFOV higher than the plateau pressure limit of 30 cm H_2O currently advocated for conventional ventilation. This warning may produce inadequate volume optimization, particularly in extrapulmonary acute respiratory distress syndrome. The risk of a given "maximum pressure" will vary with the size of the lung and the size and rate of delivery of the tidal volume engendering that plateau pressure. If 60% or 70% of the lung is not participating in gas exchange, then a tidal volume of even 6 mL/kg may induce dangerous overdistension of the ventilated alveolar units, as well as exerting shear forces on any alveolar units reexpanded during the course of the breath. If, instead, 70% or 80% of the lung is kept expanded throughout the ventilatory cycle, then a mean distending pressure of 30 cm H_2O or more is safe, as proven in numerous clinical trials of HFOV,[65,77,78,82] presumably because that distending pressure is now accommodated within many more participating lung units, fewer units are sheared open during the course of a cycle,[38] and volume swings of only 1.5 to 2 mL/kg at high rates minimize peak distension. Conversely, if one fails to open the lung during HFOV and then keep it open, one will expose the lung to unwanted shear forces many more times per minute, particularly if forced to use lower rates and larger volume cycles because of inadequate recruitment.

MAINTENANCE MEAN AIRWAY PRESSURE

Numerous studies have tried to predict an optimal maintenance mPaw from some feature of the static pressure–volume curve of the respiratory system, such as the inflection point on the inflation limb.[51] These studies demonstrate a general property of the respiratory system, namely, that the mPaw needed to maintain a given level of oxygenation is substantially less after the lung has been inflated briefly to a pressure of 30 to 40 cm H_2O so that it is "operating on the deflation limb."[49] Because recruitment and derecruitment pressures vary markedly between lung regions[50,83] and between lung-injury models, generalizations to human ventilator management must be made cautiously. In clinical practice, a gradual deterioration in oxygenation over time that corrects with a recruitment maneuver indicates that the mPaw needs to be increased to keep alveoli/airways

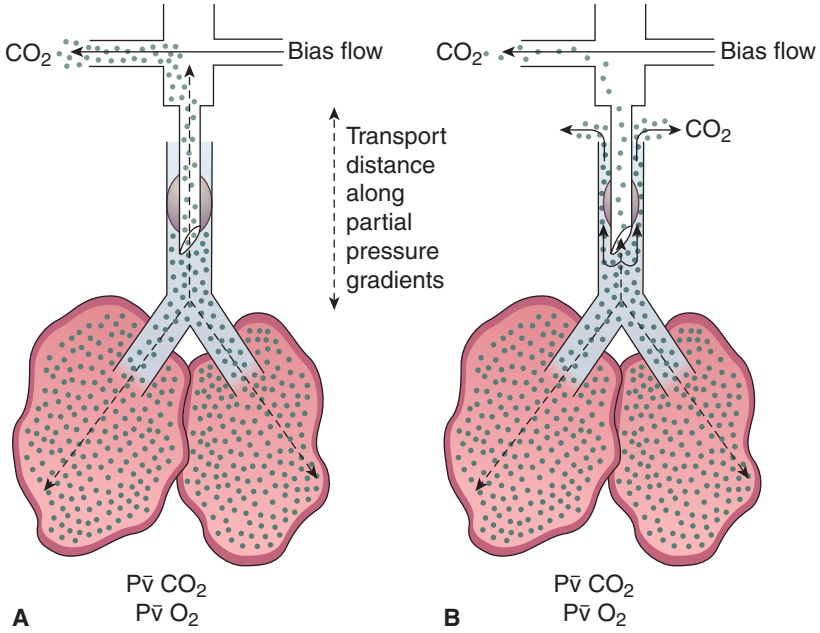

FIGURE 19-7 Schematic of the gas transport pathways during HFOV before and after establishment of a cuff leak. Transport distances are shown for CO_2. *On the left,* with the endotracheal tube (ETT) cuff occluding the trachea, the fresh-gas front for both CO_2 and O_2 is at the top of the ETT. Gas transport mechanisms must bring CO_2 from the alveoli to the top of the ETT before CO_2 is flushed away by the bias flow. *On the right,* with partial ETT cuff deflation, some of the bias flow passes down the ETT and flushes CO_2 molecules out beside the ETT, in effect reducing the transport distance substantially. The ETT represents 50% of the transport impedance during HFOV.[71,91] Introduction of a cuff leak reduces the tidal volume needed to support CO_2 elimination and decreases the intrapulmonary ΔP imposed on lung tissue.[84] A cuff leak also may increase tracheal contamination by oral secretions. The risk-to-benefit ratio of a cuff leak is not yet established.

above their closing pressures. Conversely, a rise in the partial pressure of arterial carbon dioxide (Pa_{CO_2}) at constant mPaw and power settings may indicate the lung is improving and is now overdistended, in which case a decrease in mPaw is needed.[84] Nothing can replace thoughtful reassessment of both patient and machine factors.[85] New bedside regional lung-volume monitoring techniques, such as electrical impedance tomography or respiratory inductance plethysmography, have the potential to clarify mPaw adjustments and may become more commonly used in the future.[48,86–88]

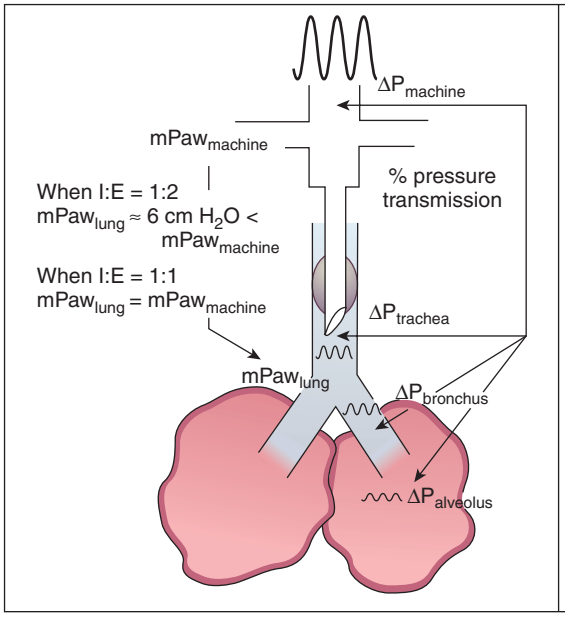
Carbon Dioxide Elimination

The basic transport studies of the 1980s were executed with accurate measurements of delivered stroke volumes over a wide range of frequencies using sinusoidal flow oscillations.[40,89,90] They established that the volume of CO_2 eliminated per minute ($\dot{V}_{CO_2}$) was proportional to the product of oscillatory frequency and the approximate square of the stroke volume ($\dot{V}_{CO_2} = V_T^{\sim 2} \cdot f$). The endotracheal tube contributes a substantial impedance to gas transport during HFOV.[91] If one uses an uncuffed endotracheal tube, or employs a partial cuff leak around a cuffed tube, such that the fresh-gas front moves to the bottom of the tube and CO_2 exits around rather than through the tube, the stroke volume needed to achieve normocapnia decreases by up to 50% (Fig. 19-7). The bias gas-flow rate also influences transport efficiency through its effect on gas tensions at the fresh-gas front.[92] Uncuffed tubes are used routinely in neonates and infants. Cuff leaks substantially assist CO_2 elimination in adults,[41,66] at the same time reducing intrapulmonary pressure swings.[84]

FREQUENCY SELECTION

Early HFOV trials in neonates used a frequency of 15 Hz and an inspiration-to-expiration (I:E) ratio of 1:1. Demonstration of small interregional mean pressure gradients at 15 Hz and 50% inspiratory period (T_I)[93] subsequently induced a shift to a lower operating frequency of 10 Hz and a 33% T_I in many centers. It is worth noting that although pressure gradients definitely occur in the lung during HFOV, their magnitudes are small (i.e., on the order of 1 to 3 cm H_2O from apex to base).[94] With a 33% inspiratory period, the mPaw measured in the circuit and displayed on the ventilator exceeds the mPaw within the lung by an amount that increases with tidal volume, frequency, and smaller endotracheal tube diameters, often in the range of 5 to 6 cm H_2O (Fig. 19-8).[95]

Frequency selection directly affects the pressure cycles applied to the lung. A smaller percentage of the circuit ΔP is transmitted down an endotracheal tube at higher frequencies.[71,96]



Factors affecting the percentage of the ΔP generated by the oscillator (machine ΔP) that is transmitted into the lungs

- ↓↓↓ with decreasing endotracheal tube diameter
- ↓↓ with increases in frequency (Hz)
- ↓ as lung compliance increases
- ↓ as aerated volume increases
- ↓ with introduction of a cuff leak
- ↓ with tracheal gas insufflation
- ↓ with increased length of ETT

Note: These factors can combine such that little or no ↑ in $\Delta P_{alveolar}$ may occur despite an ↑ in ΔP displayed on the oscillator. The converse can also occur.

FIGURE 19-8 Schematic of alterations in mPaw (*left side* of figure) between the oscillator circuit and lung using two different I:E ratios. Although mPaw values are relatively constant from the machine to the parenchyma with I:E = 1:1, mPaw decreases substantially along the endotracheal tube using an I:E = 1:2.[73,95] On the *right side* of the figure the peak-to-trough pressure amplitude (ΔP on the machine) is markedly dampened by passage through the endotracheal tube and airways to the alveoli. Oscillatory waveforms are drawn to scale using data from Sakai.[72] The associated table indicates multiple factors that reduce ΔP transmission into the lung.

Venegas and Fredberg[97] approached the question of optimizing frequency during conventional ventilation as a problem of providing adequate alveolar ventilation at minimal pressure cost in a variety of clinical scenarios. Their approach provided graphic depictions of the shifting boundary conditions for safe ventilator settings with varying lung pathology. Although the normal lung can be ventilated over a wide range of frequencies and PEEP levels without inducing dangerous overdistension, in the lung with poor compliance but relatively normal airways PEEP selection becomes critical during conventional ventilation, with penalties in terms of pressure cost and overdistension with either too low or too high a level of PEEP. At high frequencies, the zone of safe PEEP widens, making it easier to maintain more of the lung homogeneously aerated. In lungs with increased airways resistance, the optimal frequency moves to a lower rate. The relationship between frequency and the pressure cost of alveolar ventilation has been developed further by Pillow for HFOV.[70,71]

TIDAL VOLUME

Tidal volume delivery during HFOV is influenced by many factors (Table 19-1).[26,98] Adult HFOV initially used frequencies much lower than those used in infants and most animal experiments because machine power appeared inadequate to achieve CO_2 elimination at higher rates. Although the notion that HFOV delivers small tidal volumes has been challenged, newer data in adults suggest that very small tidal volumes can be delivered using adult HFOV, but at very low frequencies, tidal volumes may not be negligible.[96,99] For optimal lung protection, theoretically one should use the smallest tidal volume and highest frequency that achieves Pa_{CO_2} elimination targets. Fessler et al[100] studied thirty adult patients on HFOV after failing conventional lung-protective ventilation. CO_2 elimination was adequate in 83% of them using mean maximal frequencies of 9.9 ± 2.1 Hz. Introduction of a cuff leak is recommended before decreasing frequency below 7 Hz.[101] Even higher frequencies and small tidal volumes may prove preferable. The relative risk-to-benefit of early cuff leak versus lower frequencies requires further investigation.[85,102] Resonant amplification of the delivered volume has been demonstrated,[103,104] although at a median of 19 Hz in babies, well above rates used clinically.

TABLE 19-1: FACTORS DECREASING DELIVERED TIDAL VOLUME

- ↓ Endotracheal tube diameter (includes secretions, edema fluid)
- ↑ Endotracheal tube length
- ↑ Frequency (most HFOV devices)
- ↓ Power or amplitude
- ↓ Percent inspired time
- ↓ Respiratory system compliance

Although inability to eliminate CO_2 occurred in one of seventeen patients in the original report of Fort et al,[77] the incidence of ventilation failure (i.e., pH ≤7.15 with bicarbonate ≥19 mEq/L) was the same in both HFOV and conventional ventilation groups in the subsequent larger Multicenter Oscillatory Ventilation for Acute Respiratory Distress Syndrome Trial (MOAT)[82] and is rare if one follows current recommendations (see "Troubleshooting" below).

PHYSIOLOGIC EFFECTS OF HIGH-FREQUENCY OSCILLATORY VENTILATION

Cardiopulmonary Interactions

Much like high levels of PEEP on conventional ventilation, HFOV is a sensitive detector of intravascular hypovolemia. Patients need intravascular volume repletion before one initiates HFOV and optimizes lung volume. Fortunately, clinical experience and animal studies demonstrate that despite this need for an adequate volume status, treatment with HFOV does not induce "wet lungs."[105] Alveolar expansion has a powerful impact on pulmonary vascular resistance. Pulmonary vascular resistance goes up both in areas of atelectasis and overdistension. Therefore, the impact of HFOV on pulmonary artery pressure will be influenced strongly by the extent to which homogeneous alveolar expansion can be achieved. This varies with lung pathophysiology, decisions made about mPaw and recruitment techniques, and body position. In clinical experience, pulmonary hypertension secondary to the use of higher mPaw during HFOV has not been a problem. Rather, HFOV often has enhanced the responsiveness to inhaled nitric oxide in both infants and adults.[66,106–108] As with conventional lung-protective ventilator patterns, patients with preexisting right-ventricular failure need to be watched closely for the possible adverse effects of measures to optimize lung volume on right-ventricular output.

Cardiac output decreases as mPaw increases with any ventilator modality.[109] In early HFOV trials in the premature baboon, cardiac output was less during HFOV[45] unless mPaw was weaned as lung aeration improved.[110] Similar interactions of cardiac output and mPaw occur in infants.[111] Lesser hemodynamic impact can be expected when ventilating "on the deflation limb," where alveolar expansion can be maintained at a lower mPaw cost.[47,52] In adult clinical trials, such as the MOAT[82] and TOOLS[54] trials, there were no significant deleterious effects on mean arterial pressure, central venous pressure, pulmonary artery occlusion pressure, or cardiac output compared with conventional ventilation. Small (1 to 2 mm Hg), often transient increases in central venous pressure and pulmonary artery occlusion pressure were observed after transition to HFOV.[67] Echocardiography has proven useful to assess preload adequacy when clarification is needed.

Interaction with Spontaneous Breathing

Spontaneous breaths contribute forces that can help reexpand alveoli in dependent lung regions[112] and improve $\dot{V}_A/\dot{Q}$ distributions.[113–115] Forel et al,[116] however, reported a decreased proinflammatory response in patients given neuromuscular blocking agents for the first 48 hours. A subsequent larger trial found a 28-day mortality difference using lung-protective conventional ventilation with 48 hours of neuromuscular blockade.[117] With current HFOV circuit designs (i.e., the lack of an inspiratory demand flow), vigorous respiratory efforts in large patients may cause pressure swings that activate alarms, interrupt oscillations, and produce significant desaturations. For this reason, adults and large children need to have their respiratory efforts suppressed while on HFOV, and initial oscillator trials in adults recommended routine muscle paralysis. Current protocols attempt to balance the potential pros and cons of neuromuscular blockade in these patients by using paralysis when patients have extremely severe hypoxemia or are generating very large pressure swings despite adequate sedation.[41,85]

RATIONALE, ADVANTAGES, AND LIMITATIONS

If we accept that both overdistension and ongoing atelectasis damage lung tissue, then HFOV offers the ability to cycle the largest possible percentage of the total lung within that "safe" range of volume excursion. The key is to decipher exactly when small pressure and volume excursions will make a difference. All therapeutic advances in neonatal and pediatric ventilatory care over the past 30 years that have had a significant impacted on survival have exhibited one unifying feature: all have produced more homogeneous lung expansion (Table 19-2).

Advantages of High-Frequency Oscillatory Ventilation

It is much easier in theory than in practice to ventilate the lung within the safe zone of pressure and volumes in *all* lung regions.[118] Although much has been written about using

TABLE 19-2: PULMONARY THERAPIES DECREASING MORTALITY IN NEONATAL RESPIRATORY DISTRESS SYNDROME SINCE 1970

Early use of continuous positive airway pressure
Exogenous surfactant replacement therapy
HFOV/high-frequency jet ventilation with "optimized lung volume"
Conventional ventilation with "optimized lung volume" strategy

Note: All these produced more homogeneous lung aeration.

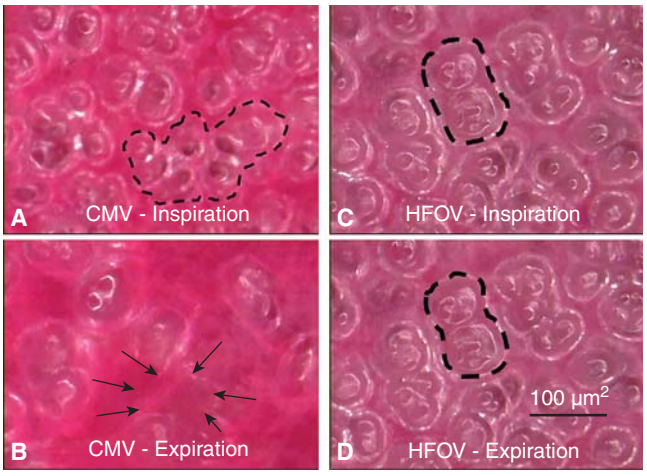


FIGURE 19-9 In vivo photomicrographs of subpleural alveoli of a rat after inducing lung injury by saline lavage. Animals were ventilated to equal oxygenation and targets using either conventional mechanical ventilation (*CMV*) or high-frequency oscillatory ventilation (*HFOV*). Alveoli in **A.** were inflated at end-inspiration during CMV to a peak pressure of 34 cm H_2O but collapsed during expiration **B.** with a PEEP of 9 cm H_2O (*arrows*). Alveoli were very stable during HFOV at a mean airway pressure of 19 cm H_2O. The same alveolus is seen at inspiration and expiration in panels **C** and **D** (*dots*). (Reproduced, with permission, from Lippincott Williams & Wilkins, Carney D, DiRocco J, Nieman G. Dynamic alveolar mechanics and ventilator-induced lung injury. *Crit Care Med.* 2005;33:S122–S128.)

the static pressure–volume curve of the respiratory system to guide ventilator settings, any single curve is only a crude composite of the family of pressure–volume curves occurring in different parts of the lungs. A safe peak or plateau pressure will be lower in nondependent and more normal lung regions; closing pressures will be higher in dependent, inflamed, or edematous regions than suggested by a single overall curve.[7,47,50,55,81] Studies in adults with acute lung injury and acute respiratory distress syndrome demonstrate that derecruitment often begins at PEEP levels substantially above the values recommended as protective of the lung.[7,119] As one raises PEEP, even acceptable degrees of permissive hypercapnia may be unattainable without exceeding safe peak and plateau pressures at conventional ventilator rates. In such patients, HFOV has the potential to keep that lung in the safe zone with a much larger margin of safety simply because of its ability to sustain gas transport with small volume cycles (Fig. 19-9).[38] This is particularly so at higher frequencies because of the impact of time-constant variability on alveolar filling.

A very old but elegant study demonstrated some fundamental features of lung reexpansion risk.[120] In essence, unless one exceeds airway/alveolar opening pressures, reexpansion will not occur. If one exceeds opening pressure with a long inspiratory period, atelectatic areas open, but normal areas become overdistended. Even very high pressures, however, will not overdistend normal lung if applied very briefly (<0.15 second in this study) because the time constant of highly compliant alveoli is long. Therefore, pressures high enough to exceed opening pressures are safer if applied as brief pulses, as with HFOV. As one turns down the frequency, this safety feature diminishes.

Lung-volume optimization and outcomes equivalent to HFOV have been achieved using recruitment maneuvers followed by rapid conventional ventilation with careful PEEP titration in saline-lavaged animal models.[121–123] Whether this equivalency extends to more established disease with greater inhomogeneity of opening and closing pressures has not been tested.

Limitations

Most of the perceived limitations of HFOV currently are really limitations of the machines available rather than the technique per se. Even minor modifications trigger expensive Food and Drug Administration (FDA) approval processes. Consequently, oscillator design in North America has been frozen for years.

INCREASED USE OF MUSCLE PARALYSIS

The adult-size oscillator currently available in North America does not support concurrent spontaneous ventilation. Infants and children are rarely paralyzed during HFOV. Paralysis of adults on HFOV can be minimized by titrating sedative agents, using higher bias flows to minimize air hunger, and reserving paralytic agents for as-needed bolus use rather than constant infusions.[41,85,124] Shallow breathing is tolerated in some adults without significant desaturation, particularly during the recovery phase of their disease. Currently, the lack of demand flow to augment spontaneous breaths requires adults to be transitioned to conventional ventilation for final weaning and extubation.[85]

INFECTION CONTROL

The lack of an expiratory filter initially limited the use of HFOV in patients with infections such as severe acute respiratory syndrome. A suitable filter on the expiratory limb of the circuit is now available (CareFusion, Yorba Linda, CA).

AEROSOL DELIVERY

Metered-dose inhalers are ineffective during HFOV. The Aeroneb nebulizer (Aeroneb Pro, Aerogen, Sunnyvale, CA) delivered the highest percentage of drug in test lung studies.[125]

TRANSPORT DURING HIGH-FREQUENCY OSCILLATORY VENTILATION

It is simplest to execute anticipated transports, such as for computed tomography scan, before starting HFOV, as there is no transport version of HFOV. Many patients receiving HFOV as rescue therapy may be too unstable to transport out of the intensive care unit unless absolutely indicated.

Cartotto et al[66] describe an effective protocol for transport during HFOV, such as to the operating room. It involves clamping the endotracheal tube while on HFOV, transitioning to a self-inflating bag with a 20 cm H_2O PEEP valve, unclamping of the endotracheal tube with vigorous manual ventilation during transport, and reversing these procedures once an oscillator has been set up at the destination. Recruitment maneuvers then are used as needed to reestablish oxygenation at the pretransport HFOV settings.

MONITORING

HFOVs have few ventilator alarms to alert one to a mainstem intubation, tension pneumothorax, or endotracheal tube obstruction. Patterns of possible changes in ventilator readouts with such events have been modeled.[85] This lack of monitoring on the ventilator makes it critical that clinicians pay attention to both the monitors and the general condition of the patient on HFOV (arterial oxyhemoglobin saturation, heart rate, blood pressure, and so on), and ensure that patients have symmetric chest movements with the oscillations. Absent chest wall movement suggests endotracheal tube obstruction or other ventilator malfunction, while asymmetry may indicate a pneumothorax or mainstem bronchus intubation; sudden increases in ΔP may be seen in both these situations. Also, ventilator noise necessitates brief piston interruption to auscultate heart or breath sounds.

UNFAMILIARITY OF PERSONNEL

A major limitation to the use of HFOV is the level of discomfort of personnel (i.e., physicians, respiratory therapists, and nurses) who encounter it rarely, often as a therapy of last resort.[126] If one does not understand that a mean pressure of 35 cm H_2O that is stenting 70% to 80% of a stiff lung open while supporting CO_2 elimination with small volume cycles may well induce less lung injury than a PEEP of 15 cm H_2O, plateau pressure of 30 cm H_2O, and larger tidal volumes being distributed to 30% to 40% of that lung, then HFOV "feels" dangerous. Only experience gained in less dire circumstances can produce a comfortable level of understanding of the interaction of ventilator decisions and lung pathophysiology. Then, and only then, can one really test the applicability of any high-frequency modality.[102]

PROTOCOL AND ALGORITHM LIMITATIONS

When protocols are generalized to patients outside the population on which the protocol was devised, HFOV may be used inappropriately. Several HFOV protocols specify maximum mean airway pressure limits that were derived in patients with primary pulmonary diffuse airspace disease. If these limits are applied to patients with major extrapulmonary factors, such as abdominal distension or chest wall burn eschar, adequate atelectasis reversal is unlikely because 30% to 70% of the applied mPaw will be lost to inflate the chest wall.[81]

INDICATIONS AND CONTRAINDICATIONS

Indications

Is HFOV still needed in the current era of "gentler" conventional ventilation? When HFOV first came into clinical use, large tidal volumes were considered safe during conventional ventilation as long as high peak pressures were avoided.[11] In this milieu, randomized, controlled trials in neonates demonstrated substantial outcome advantages from HFOV.[127] Conventional ventilator protocols then were modified to pursue the same lung protection.

In two recent randomized neonatal studies, significant differences between lung-volume optimizing HFOV and conventional ventilation protocols were seen only in the study in which just 40% of the infants meeting very-low-birth-weight criteria were randomized. These neonates required an FI_{O_2} of approximately 0.6 on an mPaw of 8 cm H_2O. In this trial, more neonates managed with HFOV (until extubation) survived without chronic lung disease and were extubated successfully 1 week earlier than were neonates receiving lung-protective ventilation at conventional frequencies.[60] When all very-low-birth-weight babies were randomized regardless of O_2 requirements, and on HFOV for only 72 hours, outcome with both ventilators was the same.[59] This neonatal experience reflects the predictions of the Venegas-Fredberg analysis.[97] If the lung is fairly normal, a wide range of tidal volumes, PEEP levels, and frequencies can be used without inducing atelectasis or overdistension. Ventilator choice becomes a matter of user preference. As the lung becomes more prone to atelectasis, the range of safe PEEP values shrinks, and injurious extremes of alveolar volume are avoided more reliably at higher frequencies. These are the lungs in which HFOV improves outcome.

NEONATAL AND PEDIATRIC PATIENTS

Current criteria for using HFOV vary among institutions. Experience in animal models, infants, and children has demonstrated the importance of instituting HFOV early in the lung at risk.[58,79,80,128,129] Increasingly, extremely low-birth-weight neonates are switched to HFOV as their first-intention ventilator in the presence of a rising FI_{O_2} requirement, Pa_{CO_2} greater than 60 mm Hg and/or falling aerated lung volume.[53,60,130,131] (Courtney SE, personal communication.) A postrecruitment FI_{O_2} of less than 0.30 is taken as evidence of adequate alveolar reexpansion following early institution of HFOV.[62,130]

Tissieres et al[131] found that 41.7% of neonates managed with early lung recruitment on HFOV achieved adequate oxygenation without exogenous surfactant, required shorter periods of ventilator support, and had a lower incidence of hemodynamically significant patent ductus. In pediatric patients, Duval et al[126] switched to HFOV at an oxygenation index greater than 13 or a pH less than 7.25 despite

a bicarbonate level of 20 mmol/L or greater and peak pressures of more than 30 cm H_2O. In older children, Doctor and Arnold[132] recommend institution of HFOV if an "open-lung strategy" using conventional ventilation generates a peak pressure of greater than 35 cm H_2O despite permissive hypercapnia or mPaw values approach 15 to 18 cm H_2O and the FI_{O_2} still exceeds 0.6.

Pulmonary hypertension occurs frequently in neonates. It can generally be reversed using HFOV (or high-frequency jet ventilation) to achieve better CO_2 elimination and normalize pH values. Randomized, prospective studies indicate that when inhaled nitric oxide is needed, therapeutic response is improved with concurrent institution of HFOV in both neonates and children.[108,133,134] All these guidelines represent an attempt to define the characteristics of a lung for which HFOV might be more protective than a conventional lung-protective strategy.

ADULT PATIENTS

Indications for HFOV are evolving in adult lung disease. These generally fall into two categories: first, use of HFOV when the patient is failing conventional therapy, either because of frank desaturations on high FI_{O_2} or the requirement of high airway pressures to achieve adequate gas exchange (Fig. 19-10). Second, use of HFOV for the primary prevention of ventilator-induced lung injury, in patients with severe acute respiratory distress syndrome. Although it may not be an independent predictor of mortality,[135] a consistent theme for both indications is that survival is better with early (<3 days) rather than late (>7 days) institution of HFOV.[65,77]

Clinicians typically turn to HFOV as a potential therapy[77,78,136] in the difficult-to-oxygenate patient when FI_{O_2} is above 0.8 despite a trial of high PEEP. In this setting, data from observational studies and randomized controlled trials suggest that HFOV is safe and effective in improving oxygenation.[85,101,102] Whether HFOV is more effective than lung-protective conventional ventilation at preventing ventilator-induced lung injury and reducing mortality remains a question for debate. The largest randomized controlled trial comparing HFOV with conventional ventilation in adults published to date (N = 148) found a trend toward improved mortality with HFOV (absolute risk difference: 0.15; $p = 0.1$).[82] The tidal volumes used in the control arm of this trial exceeded current recommendations. This may have contributed to excess mortality in the control arm.

Recently, all of the randomized controlled trials comparing HFOV to CV have been summarized in a metaanalysis (eight trials; $N = 419$).[15] Although none of the trials individually showed a mortality benefit, the combined results suggest a statistically significant reduction in mortality (relative risk [RR] 0.77; 95% confidence interval [CI] 0.61 to 0.98; $p = 0.03$). We view this as a hypothesis-generating result, given that it is a meta-analysis of several small trials, many with methodologic problems.

In experienced centers, a trial of HFOV may be considered when the FI_{O_2} requirements remain greater than 0.6, the plateau pressure approaches 30 cm H_2O, and PEEP is 10 to 15 cm H_2O.[85,101,102] The current challenge is to define the pulmonary characteristics that indicate that the lung is at risk of ventilator-induced lung injury using conventional ventilation and then to test whether HFOV is of benefit in

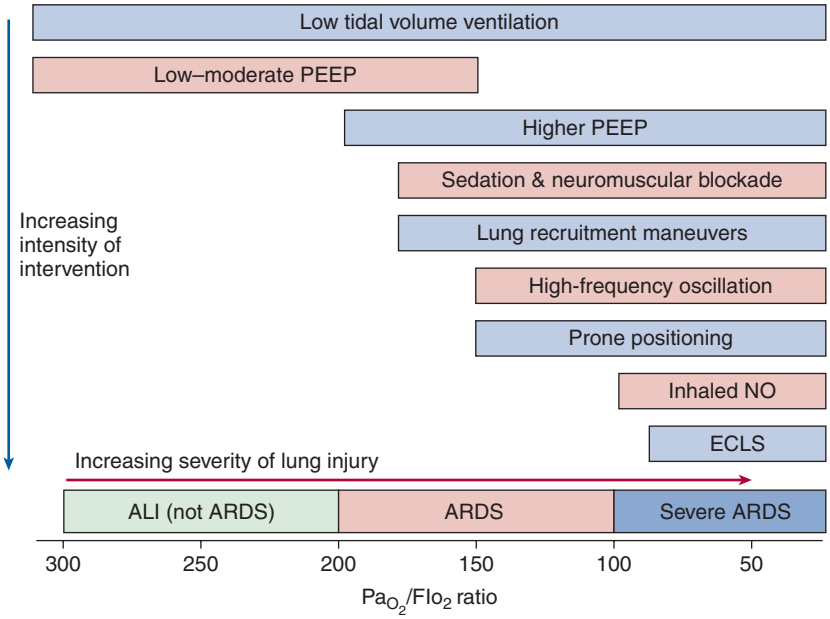

FIGURE 19-10 Schematic of various therapies for acute lung injury and acute respiratory distress syndrome and their applicability across the spectrum of disease severity. Some interventions (e.g., low tidal-volume ventilation) are broadly applicable, whereas others, such as extracorporeal life support (ECLS) and inhaled nitric oxide (iNO), should be reserved for the most severely hypoxemic patients.[16,17]

that population. The goal is to identify a group of patients with a significant inflammatory lung injury who may benefit from lung recruitment. Indicators such as PEEP responsiveness,[137] dead-space measurements,[138] and biomarkers[139] are being explored. Until additional information becomes available, indications are that it is patients with the most severe lung injury who are likely to be the most recruitable and most at risk for ongoing ventilator-induced lung injury with lung-protective conventional ventilation.[6,76] Indicators ideally would include an accurate bedside method to determine the extent of inhomogeneity of alveolar expansion across lung regions, both at end inspiration and at end expiration.[47,81,87]

Contraindications

Early literature advised against the use of HFOV in obstructive airway diseases, such as asthma, because of the theoretical risk of inadvertent gas trapping and hyperinflation. Recent reports demonstrate that HFOV can be used in such patients, even in patients demonstrating gas trapping on conventional settings. Case reports of patients with severe asthma and a series of infants with respiratory syncytial virus infection with severe bronchiolitis describe what is being termed the *open-airway strategy* for the management of such patients.[36,140] The goal in these patients is to find the narrow window of mean airway pressure that stents the diseased airways open enough to support high-frequency gas transport without inducing excessive lung distension with hemodynamic impairment. Extensive experience with HFOV is recommended before one pursues this application.[36] HFOV remains contraindicated in localized airway obstruction or bullous disease.

Before development of an expiratory gas filter, severe acute respiratory syndrome and other highly contagious airborne pathogens were a relative contraindication to HFOV.[141]

COMPARISON WITH OTHER MODES

Limited comparisons are available among various high-frequency modalities. When high-frequency jet ventilation was introduced into adult and neonatal use, the primary goal was to support gas exchange at the lowest possible peak and mean airway pressures to facilitate resolution of barotrauma. When HFOV was introduced in an early neonatal clinical trial, the primary goal was to optimize the volume of aerated lung. Both devices, in fact, can be used with either a low-pressure or open-lung strategy.[58] The strategy must be matched to the patient's pathophysiology. Only one study systematically compared three high-frequency options in an animal model of the atelectasis-prone lung.[142] Optimal outcome occurred with the mode (HFOV) in which the end-expiratory pressure was closest to the mean pressure level and the least time was spent at the end-expiratory level.

VARIATIONS IN DELIVERY

The performance of several commercially available devices for delivery of HFOV to neonates has been evaluated both in bench studies and in animal models. Substantial differences in performance have been demonstrated.[73,74,143] Any ventilator introduced into an intensive care unit should be thoroughly understood before clinical use. For example, all neonatal ventilators tested by Hatcher et al[73] and Pillow et al[74] showed a decrease in delivered volume with a decrease in lung compliance, but one ventilator (no longer available) exhibited the reverse phenomenon.[143] That outlier characteristic may explain puzzling episodes of hypercapnia during the weaning of infants with that ventilator. One ventilator failed to increase delivered volume at settings between 50% and 100% of its amplitude dial. It also was the only ventilator that markedly increased tidal volume as mean pressure increased.[73,143] Ventilators varied in the relationship of displayed mPaw and intrapulmonary mean pressure measured during endotracheal tube occlusion.[73] Threefold differences were documented in maximum tidal volume among ventilators tested at 15 Hz,[73,74] and frequency dependence of tidal volume varied substantially. It is amazing that HFOV has been used as safely and effectively as it has considering these major discrepancies in ventilator performance among the devices used.

At the time or writing, only one oscillator is approved in the United States and Canada (it is also available in Europe) for use in adults and large children (SensorMedics 3100B, CareFusion, Loma Linda, CA). Another device is approved in Europe and Japan, marketed as the Vision α (Novalung, Baden-Württemberg, Germany) or the R100 (Metran Corporation, Tokyo, Japan). In contrast to the 3100B, the Vision α also provides the ability to deliver several conventional modes of ventilation with the same circuit. The two devices also differ in how they generate and modulate the oscillatory waveforms during HFOV. We are not aware of any published studies comparing the technical or clinical performance of these two oscillators.

ADJUSTMENTS AT THE BEDSIDE

Preparation for Initiation of High-Frequency Oscillatory Ventilation

Table 19-3 lists suggested strategies for management of HFO in adults with recent-onset acute lung injury and acute respiratory distress syndrome.

Documentation of a patent endotracheal or tracheostomy tube is essential.[41] Partial obstructions impede gas transport much more during HFOV than with conventional modes. Tubes that allow passage of a suction catheter still may have a narrow lumen. If the patient has been intubated for more than 2 or 3 days, a preemptive bronchoscopy may be useful to verify tube patency as well

TABLE 19-3: SUGGESTED STRATEGIES FOR MANAGEMENT OF HIGH-FREQUENCY OSCILLATION IN ADULTS WITH RECENT-ONSET ACUTE LUNG INJURY AND ACUTE RESPIRATORY DISTRESS SYNDROME

	Titration Using a mPaw/FI_{O_2} Table	Alveolar Reexpansion Given Priority
Initial Settings	FI_{O_2} 1.0; mPaw 30 to 35 cm H_2O; I:E 33%; amplitude (ΔP) = 90 cm H_2O; frequency based on recent pH	
O_2 Management	• Initial RM (40 cm $H_2O \times 40$ s) ± repeat RM • Use mPaw/FI_{O_2} table to decrease both concurrently • Move up or down mPaw/FI_{O_2} table as needed according to SpO_2 • Repeat RM before increases in mPaw to >25 cm H_2O • Repeat RM for hypoxemia with disconnects etc.	• Initial RM (40 cm $H_2O \times 40$ s) ± repeat RM • Increase RM pressure and mPaw as needed to decrease required FI_{O_2} balancing pressure cost vs. recruitability • Hold mPaw that maintains oxygenation after RM • Wean FI_{O_2} until = 0.4 • Wean mPaw incrementally as long as FI_{O_2} stable • Repeat RM before any increases in mPaw • Repeat RM for hypoxemia with disconnects etc.
CO_2 Management	• Target pH 7.25 to 7.35 using highest frequency (*f*) possible; maintain ΔP = 90 cm H_2O • Consider a partial endotracheal tube cuff leak if $f \leq 6$ Hz	
Transition to CV	• Convert when $FI_{O_2} = 0.4$, mPaw = 20 to 24 cm H_2O and stable >12 hours • Initial settings: V_T 6 mL/kg PBW; FI_{O_2} 0.5; PEEP 16; RR 25	
Return to HFO	• Return to HFO if required $FI_{O_2} \geq 0.6$ to 0.7 on PEEP ≥14 • Return to HFO if pH <7.25 with V_T 6 mL/kg PBW and P_{PLAT} >30 cm H_2O	• Return to HFO if $FI_{O_2} \geq 0.5$ on above settings • Return to HFO if pH <7.25 on above settings

Abbreviations: CV, conventional ventilation; *ΔP,* oscillatory pressure amplitude; FI_{O_2}, fractional inspired oxygen concentration; *HFO,* high-frequency oscillation; *I:E,* inspiratory-to-expiratory ratio; *mPaw,* mean airway pressure; *PBW,* predicted body weight; *PEEP,* positive end-expiratory pressure; P_{PLAT}, inspiratory pressure plateau; *RM,* recruitment maneuver; SpO_2, oxygen saturation; V_T, tidal volume.

Note: This table outlines an overall approach while indicating areas in which different experts use somewhat different decision algorithms.

Source: Modified, with permission, from Fessler HE et al.[101]

as provide opportunity for removal of any mucus plugs. Hypovolemic patients will not tolerate the high mPaw used with HFOV; adequate volume status should be ensured before initiating HFOV.

Sedative and analgesic drugs should be titrated while the patient is still receiving conventional ventilation. Although muscle paralysis was used in most adult published trials, subsequent experience has found continuous paralytic infusions unnecessary in many cases when appropriate levels of sedation are established.[41,101] Small as-needed doses of muscle relaxants may facilitate the initial period of adjustment to HFOV and may be needed intermittently during periods of agitation to facilitate retitration of sedative and analgesic agents.[85,124] Preservation of some spontaneous respiratory effort is valuable, as with any type of prolonged ventilation, provided those efforts do not produce marked fluctuations in mPaw (>5 cm H_2O) or O_2 saturation (>3% to 5%). Careful observation for spontaneous breathing following transition to HFOV allows proper adjustment of high-pressure and low-pressure alarms. Patient comfort may be enhanced when bias flows of 40 to 60 L/min are used to achieve the target mPaw in adults.

Oxygenation

The approach used in most early algorithms and trials initiated HFOV with an FI_{O_2} of 1, an mPaw 5 cm H_2O higher than the mean pressure on conventional ventilation, and a 33% inspiratory time. Inability to reduce the FI_{O_2} below 0.6 was managed primarily with stepwise increases in mPaw, in essence gradually moving the respiratory system up the inflation limb of the pressure–volume relationship. More recent protocols apply one or more lung-recruitment maneuvers when HFOV is initiated, along with rapid upward titration of mPaw, with the goal of optimizing alveolar reexpansion to place the lung on the deflation limb.[54,101] Starting mPaw levels of 30 to 35 cm H_2O are now recommended in moderate to severe acute respiratory distress syndrome. Table 19-3 highlights two current approaches to optimizing oxygenation during HFOV.[101] Both utilize initial recruitment maneuver(s) but then differ on whether both mPaw and FI_{O_2} should be reduced in tandem (using a table) or whether measures to reduce FI_{O_2} should take priority over mPaw reduction (with FI_{O_2} being used as a surrogate measure of alveolar reexpansion).[101]

Recruitment maneuvers are performed by resetting the high-pressure alarm to a higher value (e.g. 50 cm H_2O), eliminating a cuff leak if present, turning off the piston, raising the mPaw slowly to 40 to 45 cm H_2O (maximum 50 cm H_2O) for 40 to 60 seconds, returning the mPaw to the original setting (or 3 cm H_2O higher), and then restarting the piston and restoring cuff leak and alarms to the original levels. Recruitment maneuvers should be considered if desaturation occurs after suctioning, bronchoscopy, circuit disconnects, or patient repositioning.

In the TOOLS trial, one to three recruitment maneuvers were performed immediately on initiating HFOV.[54] This methodology matches protocols used in many animal studies of lung protection using HFOV. With this protocol, an FI_{O_2} of less than 0.6 was achieved in 68% of patients by the end of the initial recruitment cycle, which delivered a mean of 2.4 recruitment maneuvers over 1.5 hours.

With both approaches, the accepted target has been projection of the diaphragm onto the eighth or ninth rib posteriorly on an anteroposterior film. An alternative reference in adults is visualization of the fifth rib above the diaphragm anteriorly or an apical diaphragm distance not greater than 25 cm.[144] Emerging techniques for the evaluation of regional expansion hopefully will soon replace these crude measures.[87] Information on the relative timing, efficacy in terms of achieving the most homogeneous lung expansion pattern, and complication rate of these two approaches is needed before it will be possible to define an "optimal" approach. The potential hazard of the first approach is too little recruitment too slowly. The potential hazard of the second approach is excessive lung distension at a rote value of 30 cm H_2O mPaw if that value is not reduced expeditiously enough in a lung that is very responsive to recruitment. What is becoming clear is the importance of ventilating "on the deflation limb," whether with conventional ventilation or with HFOV.[52,145]

It remains speculative whether the target FI_{O_2} for optimal lung protection should be 0.4 or 0.6. A substantial amount of ongoing atelectasis remains at an FI_{O_2} of 0.6. As one moves toward an earlier transition to HFOV—as in current neonatal and pediatric experience in many centers—lower FI_{O_2} targets become achievable at "reasonable" mean pressures. At high FI_{O_2} requirements, mPaw levels are reduced only when doing so does not increase FI_{O_2} requirement. When the FI_{O_2} is stable at 0.6, some protocols recommend reduction of mPaw before further FI_{O_2} decreases if the mPaw is greater than 35 cm H_2O. Whether this compromise between ongoing atelectasis and the risk of higher pressures is optimal will likely only be resolved when bedside methods of assessing areas of overdistension become available. One protocol that recommends this mPaw/FI_{O_2} compromise also recommends placing the patient in a prone position if the FI_{O_2} requirement remains 0.6 or more in order to potentiate alveolar recruitment in dorsal lung regions.[41]

Carbon Dioxide Elimination

The optimal approach to CO_2 elimination remains controversial. When should the transport advantages of an endotracheal tube cuff leak be introduced? Inasmuch as the lung-protective potential of HFOV lies in its small volume cycles, it would seem logical to introduce it at the time of initiating HFOV in a large patient. With a cuff leak of 5 to 8 cm H_2O, one can eliminate CO_2 at a higher frequency, deliver the smallest possible tidal volumes, and produce the lowest possible ratio of intratracheal to airway opening pressure swings.[84,96] With this approach, even very heavy patients generally can be ventilated at frequencies of 6 Hz or more. If reductions in frequency are required at any stage, the first response to a decrease in Pa_{CO_2} with recovery should be an increase in frequency. Whether the frequency target in adults should be 8 Hz or higher is presently unknown. Detailed protocols differing in their relative weighting of amplitude (ΔP) and frequency are available.[85,101,102]

An alternative approach is progressive reduction of frequency to 3 Hz as needed to achieve target CO_2 levels, with a cuff leak being added only when these much larger stroke volumes prove inadequate.

The advantage of instituting a cuff leak when initiating HFOV is the ability to use higher frequencies and smaller volume cycles. The disadvantages are a need for more nursing care to ensure removal of oral secretions and respiratory therapy involvement to remove and then reset the cuff leak whenever a recruitment maneuver is performed. Endotracheal tubes with infraglottic suction ports may prove useful in this context. In cases of severe upper airway swelling, a pharyngeal airway positioned just above the larynx can be used to provide an exit pathway for a cuff leak, as described by Cartotto et al[66] in a burn patient. Failure of mPaw to drop when instituting a cuff leak indicates swelling around the cuff or upper airway.

Protocols also differ in their approach to setting power or ΔP. Some advocate starting at maximal power so that one can use the highest frequency possible;[101] other algorithms manipulate both ΔP and frequency settings.[41,85] Current protocols favor targeting a relatively high and constant ΔP to enable one to use the highest possible frequency to deliver the lowest tidal volume and smallest intrapulmonary pressure swings that can achieve adequate CO_2 elimination. Transcutaneous P_{CO_2} sensors can provide useful trend information (not absolute values) to guide frequency adjustments during the initiation phase if rapid point-of-care blood-gas analysis is unavailable. Tighter Pa_{CO_2} targets are needed in patients with elevated intracranial pressure, as well as in neonates in whom the risk of retinopathy of prematurity may increase at high Pa_{CO_2}[8] while low Pa_{CO_2} levels produce neurodevelopmental deficits.[146,147]

Patient Positioning

Patients should be placed at 30 degrees head up unless hemodynamically unstable. The prone position also can be used during HFOV to optimize expansion of dorsal lung regions, with appropriate protocols for caring for the prone patient.[148] If the prone position is not feasible but hypoxemia remains severe, switching the patient from side to side in true lateral positions (i.e., 90 degrees to the mattress) may sometimes improve lung recruitability.

TABLE 19-4: Pa_{CO_2} PROBLEMS

Pa_{CO_2} Too Low	Pa_{CO_2} Too High	Acute Increase in Pa_{CO_2}
↑ *f* in increments of 1 to 2 Hz to 8[90] or 12 Hz[89]	↑ ΔP if not already at 90 cm H_2O in increments of 5 cm H_2O	Verify ETT is patent: • Pass suction catheter • Quick bronchoscopy • Can one ventilate adequately with manual bag/mask?
↓ ΔP in 5 cm H_2O increments	Institute a cuff leak if not present	Is there a pneumothorax? • Decreased vibrations unilaterally? • CXR
	Try RM(s) to reverse atelectasis Is a higher maintenance mPaw needed? (CXR or other measure of lung volume) ↓ *f* to a minimum of 3 Hz in 1 to 2 Hz decrements	Progressive Increase Pa_{CO_2} Is chest wall compliance decreasing? • Abdominal compartment syndrome • Burn eschar

Abbreviations: CXR, chest X-ray; *ΔP,* oscillatory pressure amplitude; *ETT,* endotracheal tube; *f,* respiratory frequency; *RM,* recruitment maneuver.

TROUBLESHOOTING

Partial Pressure of Arterial Carbon Dioxide Problems

It is particularly important to troubleshoot Pa_{CO_2} problems appropriately (Table 19-4).

DECREASED PARTIAL PRESSURE OF ARTERIAL CARBON DIOXIDE

As Pa_{CO_2} levels decrease during the course of lung recovery, the first response should be to increase frequency back up to the 8- to 10-Hz range (1- to 2-Hz increments) and then to decrease power (5 to 10 cm H_2O ΔP decrements) in order to minimize volume and pressure swings in the lung. A decrease in ΔP at a constant power setting may be an indicator that lung volume is increasing.

INCREASED PARTIAL PRESSURE OF ARTERIAL CARBON DIOXIDE

An abrupt substantial increase in Pa_{CO_2} in a previously stable patient may reflect plugging of the endotracheal tube, development of a pneumothorax, or atelectasis. One should ensure passage of a suction catheter, check one's ability to manually bag or mask ventilate, and perform a quick bronchoscopy while waiting for a chest X-ray to clarify the etiology. Before decreasing frequency or increasing power in response to a gradual increase in Pa_{CO_2}, one must ensure that the lung is expanded adequately. An abdominal compartment syndrome should be considered. Available oscillators all decrease delivered stroke volume when faced with a greater load.[73,74] Appropriate recruitment procedures often can resolve Pa_{CO_2} problems, while at the same time decreasing the phasic pressure swings within the airways and alveoli. A cuff leak should be considered before lowering frequency.

Oxygenation Problems

As discussed earlier, oxygenation depends on achieving and then maintaining end-expiratory lung volume. A gradual downward drift of O_2 saturation after a recruitment maneuver is indicative of too low a maintenance mPaw. Recruitment should be repeated with a return to an mPaw 2 to 3 cm H_2O higher than the previous level. If the FI_{O_2} requirement remains greater than 0.60 despite recruitment maneuvers, prone positioning should be considered.[16] Inhaled nitric oxide can be added, although whether this improves outcome as well as oxygenation remains unknown.[108] In the severely hypoxemic patient, HFOV is one of a number of recommended techniques (see Fig. 19-10).[16,17]

Air Leaks

Barotrauma occurs at similar frequencies during HFOV as with conventional ventilation, but may be more subtle in its manifestations. Displayed mPaw will remain stable even with a tension pneumothorax. The gradual development of hypotension and desaturation, with or without a unilateral decrease in chest wall motion, should trigger a portable chest X-ray. In an experimental model of pneumothorax during HFOV, air leak was minimized by the use of higher frequency, lower ΔP, lower mPaw, and shorter inspiratory period.[149] Excessive decreases in mPaw will promote atelectasis with a resulting increase in intrapulmonary pressure cost, delaying resolution of the air leak. In general, recruitment maneuvers are not advised in the presence of air leak, but this is not an absolute contraindication. In the presence of severe hypoxemia and unilateral air leak, recruitment

maneuvers performed with the patient in a full lateral position with the leak side down may achieve significant benefit by reexpansion of the nondependent lung.

Hemodynamic Compromise

Inability to tolerate the institution of HFOV or application of recruitment maneuvers may reflect an inadequate intravascular volume. Duval et al[140] reported a need for a transient increase in fluids and inotropic agents in some infants during transition to HFOV. Interpretation of filling pressures (central venous pressure, pulmonary artery occlusion pressure) may be difficult in the setting of high mPaw. A fluid challenge, cardiac echo study, or other assessment of cardiovascular status may be needed in ambiguous situations.[41]

IMPORTANT UNKNOWNS

HFOV protocols are under constant revision through animal experiments and clinical trials that evaluate both the gas exchange and ventilator-induced lung injury impact of ventilator setting decisions. We need criteria that indicate when any given ventilator pattern needs to be replaced by one with a greater potential for lung protection. This is a complex question considering that we do not even know when permissive hypercarbia becomes deleterious for patients.

The optimal frequency or frequencies for minimizing the intrapulmonary pressure and distension "cost" of HFOV in the adult lung with varying pathophysiologies remain unknown. Such information would clarify the risk-to-benefit ratio of early use of a cuff leak. Existing algorithms differ substantially in their management of frequency.[85,101]

Optimal methods of aerosol delivery during HFOV need further evaluation. Better bedside knowledge of which techniques (e.g., recruitment maneuvers, ventilator settings, position changes [prone/supine], and so on) produce the most homogeneous lung expansion across all lung regions would greatly aid decision making. Emerging technologies, such as electrical impedance tomography, show promise.

Neonates often are maintained on HFOV until extubation. Premature transition to conventional ventilation can negate the benefit of HFOV. Currently spontaneous breaths are not augmented during HFOV, so this approach is not feasible in large patients. This may change if demand flow is incorporated into new versions of this device.[150] The "optimal" timing of transition to conventional ventilation may be difficult to determine until this device limitation is resolved. It is well recognized that gross deterioration of oxygenation after transition to conventional ventilation should trigger an immediate reevaluation of the patient and possible return to HFOV.

FUTURE DIRECTIONS

Two large multicenter, randomized, controlled trials are currently underway comparing HFOV to conventional ventilation: OSCILLATE (ISRCTN87124254) and OSCAR (ISRCTN10416500). The OSCILLATE trial (target $N = 1200$) attempts to optimize lung volume "on the deflation limb" of the pressure–volume relationship and is recruiting patients from centers with significant experience with HFOV. The OSCAR trial (target $N = 1006$) employs a more traditional stepwise increase in mPaw (walking up the inflation limb of the pressure–volume curve), and is also assessing the applicability of HFOV as a novel technology in inexperienced centers. Currently, many centers use HFOV rarely and only for severe, refractory oxygenation failure or air-leak syndromes associated with end-stage lung disease. This is not the way to develop a cadre of physicians, nurses, and respiratory therapists who can skillfully troubleshoot interactions between the machinery and the patient's pathophysiology.

Redesigned Machines

Currently, high-frequency oscillators are still classified as class 3 devices by the FDA. This means that any redesign triggers expensive review costs, much in excess of that required for bringing a new conventional ventilator to market. Revision of this classification would greatly facilitate improvements in device design.

Clinical Lung-volume Monitoring

Developments in this area should take a lot of guesswork out of lung-volume optimization during both conventional and high-frequency ventilation. Hopefully, future guidelines for the initiation of HFOV will be able to include some measure of interregional inhomogeneity of alveolar expansion as one of the criteria, not just a plateau pressure, FI_{O_2}, or pH value.

SUMMARY AND CONCLUSION

High-frequency ventilators expand our ability to minimize both atelectrauma and overdistension injury in the vulnerable lung. Evidence of the benefits of early institution rather than late "rescue" use is growing. Optimal use requires constant attention to the interplay between the patient's pathophysiology and machine factors to keep the lung in its "safe zone." The full potential of HFOV will only be clarified when well-controlled randomized clinical trials are done that incorporate both early intervention and lung recruitment protocols that rapidly place the lung on the deflation limb of its pressure–volume relationship. Such trials need to compare HFOV to the lung-protective conventional ventilation protocol considered optimal at the time of study.

EXTRACORPOREAL LIFE SUPPORT FOR CARDIOPULMONARY FAILURE

Heidi J. Dalton
Pamela C. Garcia-Filion

DEFINITION AND HISTORY

Extracorporeal life support (ECLS) is defined as total or partial diversion of a patient's circulating blood volume into a device that can act as a "lung," providing oxygenation and carbon dioxide removal, and a pump, which can act like a "heart," providing circulatory support, or a combination of both functions for patients suffering from both cardiac and pulmonary failure. Adapted from heart-lung machines used for cardiopulmonary bypass, this temporary form of support was termed extracorporeal membrane oxygenation (ECMO) in the past.[1–4] Because of vast changes in the circulatory devices now available and the patient populations being treated, however, the term ECMO is being replaced by ECLS as the designation for extracorporeal life support of a variety of indications and devices. Both are used interchangeably in the chapter. Figure 20-1 shows an example of an early cardiopulmonary bypass circuit.

ECLS was first developed to provide respiratory support in premature infants who had inadequate lung development to support gas exchange compatible with life. Difficulties with intracranial hemorrhage secondary to the heparinization required to prevent clotting of the artificial membrane lung and the circuit, however, caused ECLS to quickly fall out of favor in this population. Work continued, and following the development of the silicone-membrane oxygenator by Kolobow and others, ECLS was successfully applied to term newborns with respiratory failure.[5,6] One of the first of these patients was a newborn named Esperanza (which means hope) by the neonatal intensive care unit nursing staff who were caring for her at the University of California at Irvine in 1976. Esperanza had hypoxemia secondary to what we now would call persistent pulmonary circulation of the newborn. Dr. Robert Bartlett and colleagues were doing research on ECMO at the University of California at Irvine and were contacted for assistance with Esperanza. Their laboratory device was quickly approved by the institutional review board for emergency use, and adapted and applied in an attempt to save Esperanza. The procedure worked well and Esperanza is now a grown woman with children of her own. Following this event, other centers reported success in the use of ECLS in newborns with respiratory failure from diseases such as meconium aspiration syndrome, persistent pulmonary hypertension, and congenital diaphragmatic hernia.[7–10]

This initial success was met with some skepticism, and a randomized controlled trial of ECMO or ECLS versus conventional ventilation was undertaken in newborns with persistent pulmonary hypertension in the late 1980s. This was a two-phase project: if excessive mortality or

FIGURE 20-1 Early cardiopulmonary bypass circuit. (Courtesy of Heidi Dalton MD, with permission.)

benefit was noted in one group, the next twenty patients would be treated with the more successful therapy.[11] The safety monitoring board stopped Phase 1 of the study when four of the ten patients in the conventional arm died while all nine of the patients in the ECMO arm survived. Of the next twenty patients (all receiving ECMO), nineteen patients survived. Thus, 97% (twenty-eight of twenty-nine) of the ECMO patients and 60% (six of ten) of the conventional ventilator patients survived ($p < 0.05$). This trial aroused much controversy, especially regarding the randomization scheme and the fact that only families of patients randomized to ECMO were asked for consent.[12] Another randomized study from the United Kingdom also favored ECLS in neonatal respiratory failure.[13] Today, ECLS is an accepted therapy for neonates with refractory respiratory failure.[14]

At the same time, adults with respiratory failure were also receiving ECLS.[15,16] One of the first case reports, by Hill in 1972, involved a young man who suffered injuries, including a ruptured aorta, as the result of a motorcycle accident. Supported by a cumbersome ECMO circuit for 3 days, the man survived.[17] Further case reports and a historic meeting regarding ECLS held in Copenhagen in the late 1970s led to a National Institutes of Health-sponsored trial of ECMO versus conventional therapy in adult respiratory failure. Published in 1979 in the *Journal of the American Medical Association* (*JAMA*), the ECMO and conventional therapy groups had equivalently poor survival (<10%), and major complications of bleeding.[18] The study also took place during an epidemic of influenza, which may have skewed results. The study, in retrospect, was flawed given lack of consensus definitions of conventional treatment, maintenance of high levels of mechanical ventilator support in both groups with no attempt at lung-protective ventilation in the ECMO patients, and imprecise definitions of organ failure. Of a planned 300-patient enrollment, the study was stopped at ninety-two patients because of the high mortality rates in both groups.

These dismal results dampened enthusiasm for ECLS in the adult patient and it became poorly accepted among adult clinicians in the United States. Across the globe, however, investigators in Italy, Sweden, Germany, Japan, and elsewhere continued work on supporting adult respiratory failure with ECLS techniques.[19] Research by Gattinoni added to the understanding of the pathophysiology of adult respiratory failure, the detrimental impact of mechanical ventilation at high levels on the lung and the potential protective role of ECLS in lung recovery.[20] When Gattinoni published results of a low positive pressure ventilation scheme combined with ECLS, primarily for carbon dioxide removal, which achieved 49% survival in patients with similar entry criteria as the failed National Institutes of Health trial, interest in adult ECLS again began to arise. Further studies with similar results from other centers began to appear and culminated with a conference on ECLS in Marburg, Germany, in 1988.[21,22]

As a means of sharing information regarding patients receiving ECLS, an informal gathering of clinicians, bench researchers, industry representatives, technicians, and survivors was held in 1989. Titled the Extracorporeal Life Support Organization (ELSO), this volunteer consortium has established an international database that contains information on more than 45,000 patients from more than 100 centers. The annual symposium continues to provide dissemination of technology, networking, and discussions of advancements and areas of needed work in the field, and provides an important forum for interaction between clinicians, technicians, and industry and bench researchers.[23,24] ELSO has also established practice guidelines and standards of care for patients receiving ECLS. Membership in ELSO gives access to database information for research or center inquiry for specific patient populations. Quarterly reports on both individual and collective center outcomes, complications, equipment, and other parameters are provided. ELSO also provides small levels of grant support to advance the field of ECLS. Centers providing ECLS who do not report results to the ELSO group weaken the ability to track ECLS changes and outcomes globally. Currently undergoing some revision, to refine severity of illness parameters and other specifics, the ELSO registry continues to provide the most comprehensive information regarding trends in ECLS on an ongoing basis. Further information regarding this group can be found at www.ELSO.med.umich.edu.

As with other groups, use of ECLS in pediatric respiratory failure patients has been controversial. Attempts to establish mortality risks and outcome in pediatric respiratory failure were a prelude to a randomized trial of ECLS versus conventional care.[25] The earlier report of Timmons et al on 470 patients from forty-one pediatric intensive care units with respiratory failure (defined as a fractional inspired oxygen

concentration [$F_{I_{O_2}}$] ≥0.50 and positive end-expiratory pressure [PEEP] ≥6 cm H_2O for ≥12 hours) noted a mortality rate of 43%.[26] Using variables that included age, operative status, Pediatric Risk of Mortality (PRISM) score, $F_{I_{O_2}}$, respiratory rate, peak inspiratory pressure, PEEP, arterial oxygen tension (Pa_{O_2}), and arterial carbon dioxide tension (Pa_{CO_2}), a pediatric respiratory failure score was developed and validated against another patient subset.[27] This led to attempts to perform a randomized controlled trial of ECMO in pediatric respiratory failure patients using pediatric respiratory failure score guidelines. The trial was stopped early when interim analysis revealed a mortality of 18% in the control group (contrasted with a predicted mortality of 36% from earlier evaluations), and the likelihood of achieving statistical significance between ECMO and control groups was deemed futile. This trial was also likely impacted by changes that occurred in the management of respiratory failure: positive inspiratory pressure in the historical group (from which the pediatric respiratory failure score was developed) and peak inspiratory pressure in the control subjects in the randomized controlled trial were quite different (47 ± 15 vs. 34 ± 6 cm H_2O), as were the levels of Pa_{CO_2} (56 ± 17 vs. 66 ± 20 mm Hg). In addition, this trial occurred at the time of rising use of high-frequency ventilation (allowed in the control group), inhaled nitric oxide, prone positioning, and surfactant, and while another clinical trial with liquid ventilation was ongoing.[28–31] Because of the difficulties observed with this and other randomized trials of therapies in respiratory failure, especially with regards to consensus agreement on entry criteria, patient management techniques, and end points, enthusiasm for another randomized controlled trial of ECLS in pediatric respiratory failure has been dim. Despite the absence of any randomized controlled trial, ECLS continues to be used successfully in an ever-expanding population of children.

Perhaps the most successful randomized trial of ECLS is that recently reported from the UK regarding adult respiratory failure: CESAR (*C*onventional versus *E*CMO *S*upport in *A*dult *R*espiratory *F*ailure).[32] This trial involved adults who were randomized to conventional care or transfered to one adult ECMO center (Glenfield Hospital, Leicester, England) if appropriate inclusion criteria (based on a Murray score >3 or refractory hypercapnia with pH < 7.20) were met. Of 180 patients entered into the CESAR trial, equally divided between conventional and ECMO arms, survival at 6 months without disability was significantly higher in the ECMO arm than in the conventional arm (63% vs. 47%, $p = 0.03$); the estimated number to treat to achieve an additional life saved was six. The Data Safety and Monitoring Board stopped the trial for efficacy reasons after 180 patients had been entered. An economic analysis concluded that ECLS patients met "acceptable" cost-adjusted quality per life-year costs of £19,252, comparable to treatment of other conditions such as breast cancer.[33]

Despite the impressive results, the CESAR trial continues to generate controversy, especially regarding the fact that seventeen of the ninety patients randomized to the ECLS arm did not receive ECLS. These seventeen patients were treated at the ECLS center and fourteen survived. In the minds of many clinicians, the finding that patients with severe respiratory failure had improved survival in the ECLS center, whether or not they progressed to the need for ECLS, validated the fact that clinicians in such centers provide optimal care for these patients—and that having ECLS as a tool in the algorithm of care adds a survival benefit.[34–36] To others, this fact makes the trial results "invalid" because if the seventeen patients who did not receive ECLS are removed from the analysis, the survival benefit for ECLS is not significantly different from conventional care.

Another criticism of the CESAR trial is that patients managed in the "conventional" sites did not receive a specific algorithm of care, although use of low-tidal volume, pressure-limited ventilation was advocated. To many, the lack of mandated algorithmic care represents the "true" manner in which clinicians in non-ECLS sites provide care and makes the study even closer to what happens in "real life." To others, the lack of mandated algorithmic care only means that perhaps overall care in the ECLS center was "better," and the use of ECLS had nothing to do with the observed improved outcome. Also of interest (but without further analysis or explanation) is that patients in the ECLS center received corticosteroids more often than other patients. In summary, the CESAR trial provides important, current-era data and shows a positive benefit for use of ECLS in adult respiratory failure, but also raises questions for continued research and discussion.

On the heels of the publication of the CESAR trial came the H1N1 influenza epidemic of 2009–2010. Early reports of survival in patients with severe respiratory or multiple organ failure secondary to H1N1 from Australia and sites where the epidemic hit before moving west to North America revived interest among many clinicians for use of ECLS in adults. The finding that many patients succumbing to H1N1 were previously healthy young adults may also have impacted the willingness of clinicians to try something outside conventional mechanical ventilation.[37–39] Because there are only a few centers in the United States that provide adult ECMO, many ECMO centers were overwhelmed with requests for patient transfer. An H1N1 website developed by the ELSO organization and a U.S. "bed board" map that listed open centers with contact numbers were quickly established to track patients and provide clinicians with needed expertise and assistance. To date, 263 patients have been entered into the ELSO H1N1 database with 63% survival. Two-thirds of patients are older than the age of 18 years.[40]

The use of extracorporeal techniques today continues to rise in every patient age group. New equipment, better understanding of pathophysiology, improved patient management, and increased interest in ECLS in a wider variety of patients makes it an exciting time in this field.

The following focuses on the use of ECLS in, predominantly, the venoarterial mode, because the use of venovenous techniques is discussed in Chapter 21.

CRITERIA FOR EXTRACORPOREAL LIFE SUPPORT

The ability to determine selective criteria for respiratory failure that will separate those patients who will survive with conventional care from those who will not, and thus are most in need of alternative techniques such as ECLS, is a pursuit somewhat similar to the Holy Grail. Despite the creation of multiple severity indices and subsequent evaluation of their efficacy in determining risk of death or morbidity, none have proven sustainable over time or universally correct in predicting outcome.[41–46] Nonetheless, the most commonly used criteria for determination of respiratory failure and candidacy for ECLS are the following:

1. Alveolar-to-arterial oxygen difference ($AaDO_2$), which is calculated using the alveolar gas equation:

$$AaDO_2 = [FI_{O_2} \times (P_B - P_{H_2O}) - Pa_{CO_2}/RQ] - Pa_{O_2}$$

   where P_B represents barometric pressure (760 mm Hg at sea level), P_{H_2O} represents pressure of water vapor (47 mm Hg), and RQ is assumed to be 1. $AaDO_2$ has been historically used in neonatal respiratory failure. An $AaDO_2$ of greater than 610 over 8 hours correlated to 80% mortality in neonatal respiratory failure in historical controls. Among pediatric patients, an $AaDO_2$ of greater than 470 was noted by Timmons to be 81% predictive of death, based on data published in 1991.
2. Oxygenation index (OI), which is calculated as follows:

$$OI = \frac{FI_{O_2} \times \text{mean airway pressure (cm } H_2O) \times 100}{Pa_{O_2} \text{ (mm Hg)}}$$

   An OI greater than 40 predicted mortality of greater than 80% (historically). An OI of 25 to 40 predicted mortality of 50% to 80% (historically). An OI greater than 40 or remaining greater than 25 over several hours continues to be associated with high mortality in neonates, pediatric patients, and adults (especially in those following lung transplantation). In pediatric respiratory failure, high OI even at seemingly short duration of mechanical ventilation of less than 24 hours, is associated with high mortality, as shown in Figure 20-2.[46]
3. Compliance (C), calculated as C = Δvolume/Δpressure, or C = tidal volume/(peak inspiratory pressure* PEEP), although it is preferable to use plateau pressure rather than peak inspiratory pressure. Compliance values of less than 0.5 mL/cm H_2O have been used in the selection of adult patients for ECLS.

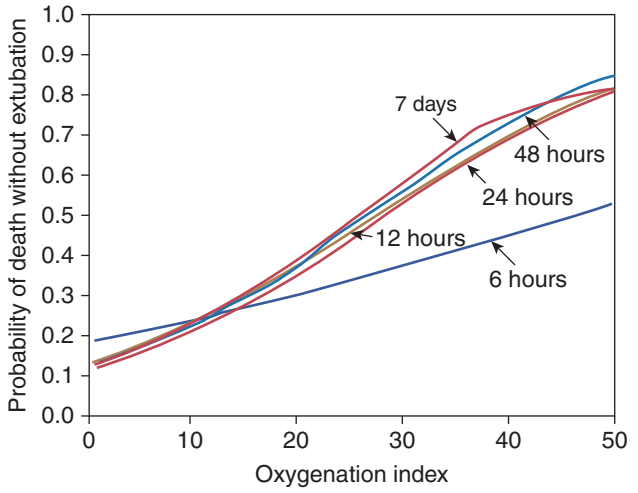

FIGURE 20-2 Oxygenation index and mortality. The presence of a high oxygenation index at any time during mechanical ventilation was associated with increased risk of death without extubation. (Adapted, with permission, from Trachsel et al.[46])

4. Intrapulmonary shunt greater than 30% to 50% on FI_{O_2} greater than 0.6. Shunt has been predominantly used as a selection criterion in adult ECLS.
5. Murray score greater than 3. The score is based on Pa_{O_2}/FI_{O_2}, PEEP, compliance, and number of quadrants exhibiting disease on chest radiograph. The score ranges from 0 to 4, is used in adult ECLS, and was an entry criterion in the CESAR trial.
6. Ventilatory failure. Hypercarbia with persistent pH less than 7 on high ventilator support, such as peak inspiratory pressure greater than 40 cm H_2O.
7. Pa_{O_2}/FI_{O_2}. Calculation is illustrated by the following example: for Pa_{O_2} 50 torr, and FI_{O_2} 100% (1.0), Pa_{O_2}/FI_{O_2} is 50/1, or 50. Pa_{O_2}/FI_{O_2} values of 50 to 100 torr have been described in adult ECLS.

CRITERIA FOR CARDIOPULMONARY FAILURE

If it is difficult to define criteria for respiratory failure, it is equally so when ECLS is considered for cardiac or multiple organ dysfunction. Although no specific criteria have been identified and universally accepted, the following are suggestions from the literature and clinical experts:[47–50]

1. Plasma lactate persistently greater than 5 mM/L.
2. Mixed venous oxygen saturation ($S\bar{V}O_2$) less than 55% at an estimated cardiac index of at least 2 L/min.
3. Severe ventricular dysfunction.
4. Intractable arrhythmia with hemodynamic compromise.
5. Cardiac arrest.
6. Inotrope score greater than 50 for 1 hour or greater than 45 for 8 hours,[50,51] calculated as

Dopamine (mcg/kg/min) + Dobutamine (mcg/kg/min) + 100 × Epinephrine (mcg/kg/min).

A modified inotrope/vasoactive score, calculated as Dopamine (μg/kg/min) + Dobutamine (μg/kg/min) + 100 × Epinephrine (μg/kg/min) + 100 × Norepinephrine (μg/kg/min) + Milrinone (μg/kg/min) × 10 (15 is also used by some clinicians) + 10,000 × vasopressin dose (μg/kg/min).

7. Failure to wean from cardiopulmonary bypass.

VENOARTERIAL CANNULATION MODES

Venoarterial ECLS has been the predominant mode of support in infants and children for many years secondary to lack of adequately sized venous vessels to obtain the amount of blood flow needed to support the patient. Figure 20-3 is an example of a typical venoarterial ECLS circuit with cervical cannulation, a roller head pump, and silicone membrane

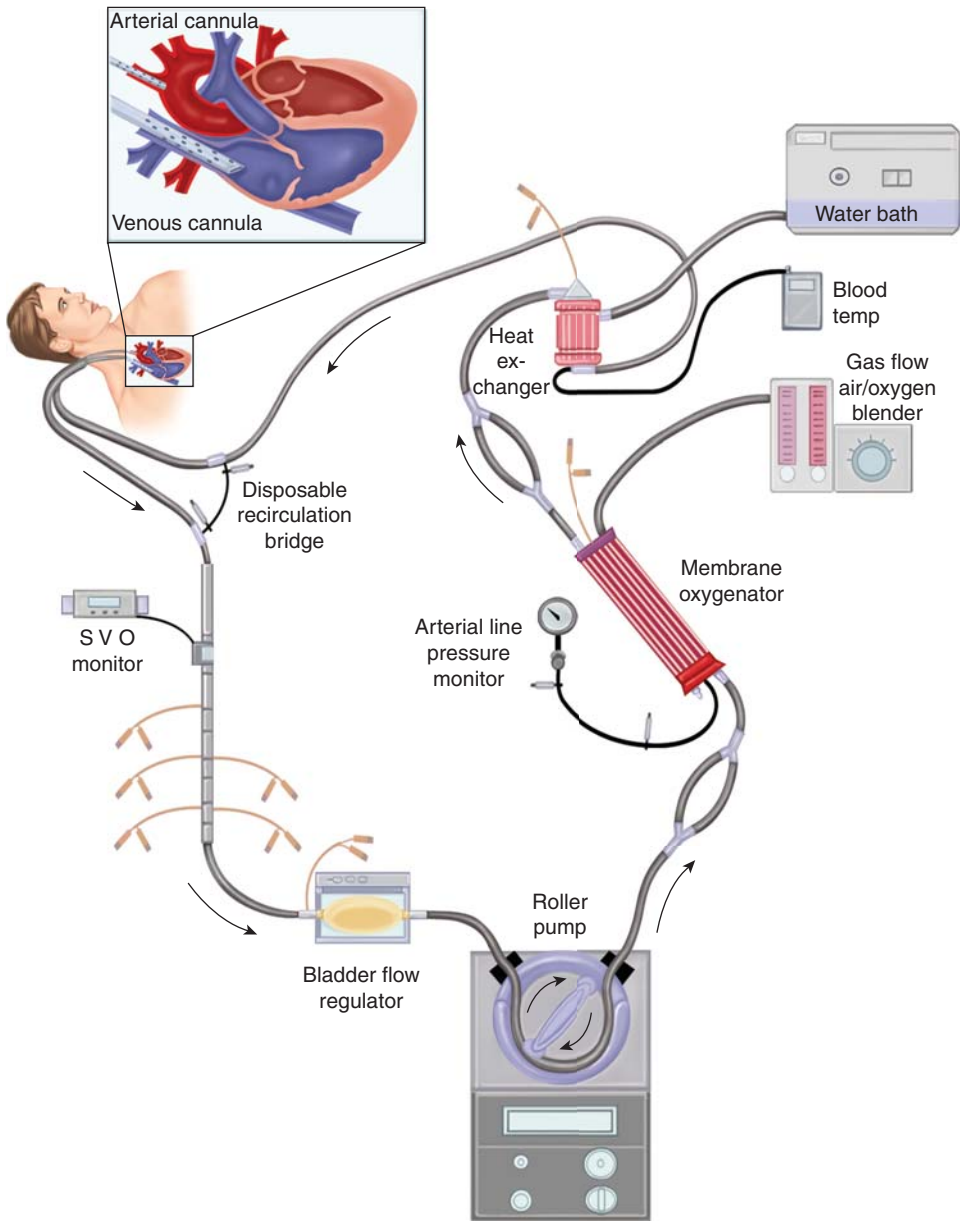

FIGURE 20-3 Venoarterial ECLS circuit with roller-head pump and silicone membrane oxygenator. Note venous saturation device on drainage limb; bladder reservoir device is before pump head. Silicone membrane oxygenator has now been almost totally replaced by new hollow-fiber devices. Heat exchanger device rewarms or cools blood before its return to patient.

FIGURE 20-4 Centrifugal pump and hollow-fiber oxygenator system. These systems often have lower priming volumes, are easier and faster to set up, and do not require gravity drainage. Note that the oxygenator and pump head should be below the level of the patient.

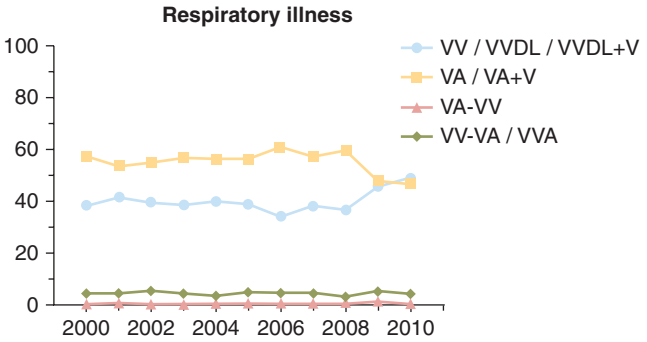

FIGURE 20-5 Cannulation mode for patients with respiratory failure (all ages). *VA*, venoarterial; *VA+V*, additional venous cannula added; *VA-VV*, venoarterial cannulation changed to venovenous during ECLS course; *VV*, venovenous; *VVDL*, venovenous double lumen; *VV-VA*, venovenous cannulation changed to venoarterial during ECLS course.

lung. Figure 20-4 depicts more current equipment with centrifugal pump and hollow-fiber oxygenator. With the advent of double-lumen, single cannulas, and improvements in flow characteristics of available cannulas, venovenous support is now becoming more popular and feasible even among neonates.[51,52] Gone are the days when modifications of thoracostomy or endotracheal tubes provided the "cannulas" for ECLS support; wire-reinforced, thin-walled cannulas now permit excellent flows at smaller internal and external diameters.[53] Venoarterial support, however, remains a mainstay of support in patients with combined cardiopulmonary dysfunction or in those with primary cardiac failure. Figures 20-5 and 20-6 show the changes in mode of cannulation by category and diagnostic group.

Cervical Cannulation

In neonates, use of the internal jugular vein and right common carotid artery is the predominant venoarterial cannulation technique. Figure 20-7 is an example of cannulation through the internal jugular vein and carotid artery for venoarterial extracorporeal support with monitoring parameters that can be used for patient management. While centers may vary somewhat in cervical cannulation technique, most use an open approach to vessel access.[54] Repair of the carotid artery at decannulation is controversial, practiced routinely in some centers and avoided in others.[55–58]

Follow-up studies of repaired vessels has noted patency in 80% to 100% of repaired vessels, but stenosis in repaired vessels also has been noted in several studies, as has the development of aneurysms or pseudoaneurysms of the vessel with need for emergent surgical intervention. In one follow-up report of neurodevelopmental outcome from pediatric patients receiving support for cardiac dysfunction, use of the carotid artery for vascular access was not associated with neurologic dysfunction. Similarly, small comparative studies of neonates, with or without carotid repair at decannulation, did not find neurodevelopmental changes at follow-up between groups and noted good collateral flow in patients where the carotid had been ligated. Despite the lack of evidence in favor of repair of the carotid artery, there is increasing interest, especially in older patients, in avoiding the carotid artery for cannulation because the potential risk for stroke seems higher (anecdotally) despite no proven evidence of this concern. Only long-term outcome studies, up to the ages when stroke becomes more common, will be able to definitely answer whether carotid artery ligation or repair following ECLS is an associated risk factor.

Internal jugular cannulation can be performed with a semi-Seldinger technique or via direct venotomy and insertion of the cannula. Some centers also insert a small retrograde venous drainage cannula to the level of the jugular bulb to obtain more venous drainage from the cerebral circuit and/or to monitor cerebral venous saturation as an indication of adequacy of perfusion to the brain and oxygen delivery and extraction (this is presumably even more important in venovenous support).[59,60] Some clinicians report having been able to increase venous drainage by up to 30% in neonates with this technique, although others have noted clotting difficulties in the retrograde cannula and have abandoned this technique. The effects of ligation of the internal jugular vein on cerebral venous drainage and risk for intracranial hemorrhage from venous stasis or hypertension

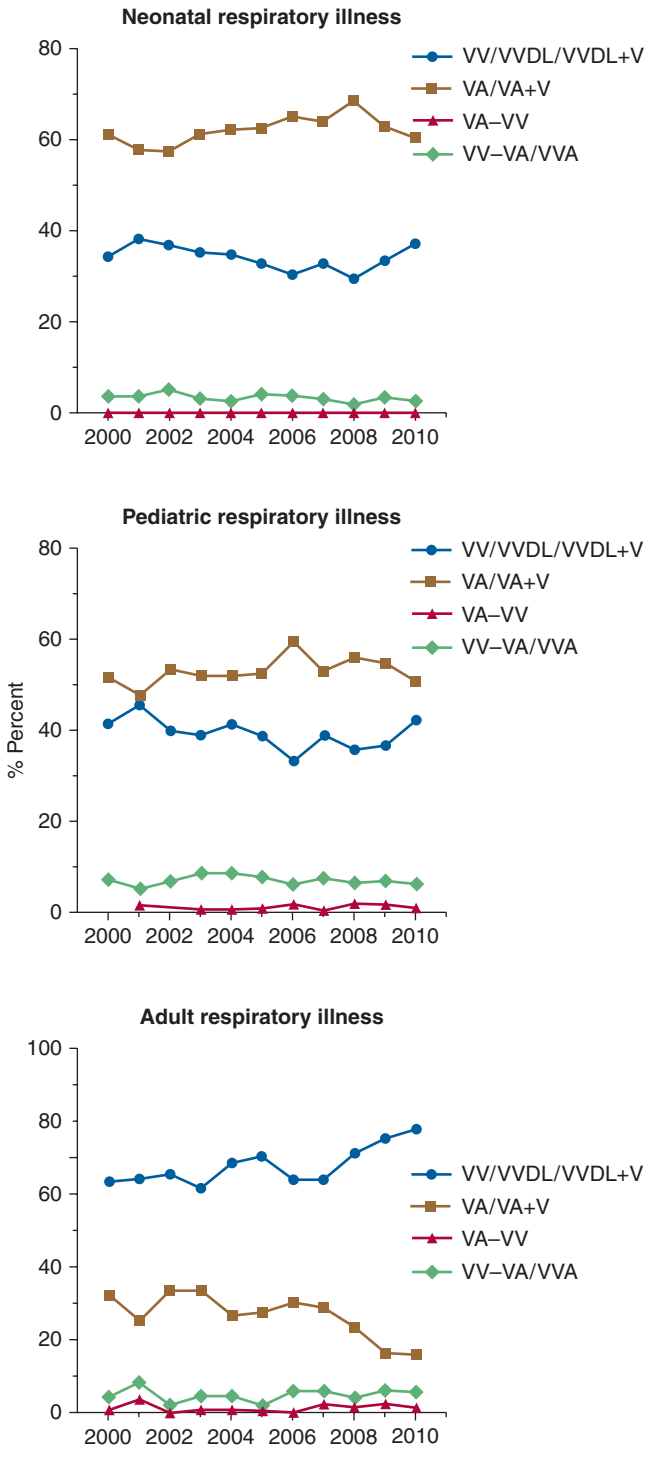

FIGURE 20-6 Cannulation mode by age. Note increase in venovenous support over past several years. *VA*, venoarterial; *VA+V*, additional venous cannula added; *VA-VV*, venoarterial cannulation changed to venovenous during ECLS course; *VV*, venovenous; *VVDL*, venovenous double lumen; *VV-VA*, venovenous cannulation changed to venoarterial during ECLS course.

has not been completely defined. Repair of the vein at decannulation is not practiced routinely, although patency has been described. For cardiac patients in whom future surgeries may involve use of the superior venous system, such as single ventricle patients, judicious use of the internal jugular vein for ECLS and consideration for repair if cannulation occurs should be discussed.

Central Cannulation

ECLS can also be provided through direct insertion of large-bore cannulas into the right atrium and into the aortic arch. This method of cannulation allows the largest volume of blood to be obtained for support. This technique is used predominantly in patients transitioned to ECLS directly from cardiopulmonary bypass or following acute deterioration (including arrest) in the early postoperative period when the sternum can be easily reopened.[61,62] It has also recently been identified as a potential factor in successful support of patients with septic shock and multiple organ failure, who may require high levels of flow to obtain adequate oxygen delivery. In the most cited report, children in septic shock who received central cannulation were unexpectedly found to have improved survival as compared to those in whom other cannulation strategies were used (73% vs. 38% survival, $p = 0.05$, $n = 11$).[63] These patients required sternotomy for cannula insertion after peripheral cannulation proved inadequate for support or vascular access could not be obtained. The major differentiating feature between the groups was the higher flow rates obtained with the central cannulation mode. The authors speculated that this improved flow provided better oxygen delivery and resolution of organ failure with resultant improved survival. A follow-up report of twenty-three children with septic shock supported with ECLS over a 9-year period using central cannulation noted 74% survival to discharge.[64] Although central cannulation in patients without a prior sternotomy is not routine in most centers, the aforementioned reports have led it to be considered in non–cardiac-surgery patients and we have used it successfully in septic patients in whom peripheral cannulation was ineffective. Bleeding from the mediastinal site continues to be a major complication.

Femoral Cannulation

In children older than the age of 2 years or roughly weighing more than 15 kg, femoral vessels may be adequate for venoarterial ECLS. Concern with use of the carotid artery in older patients has already been discussed. Thus, in larger patients (especially adults), femoral cannulation is often preferred. Figure 20-8 is a typical example of femoral/arterial cannulation. Venous cannulation can be performed percutaneously or with open venotomy.[65–67] Optimally, a long, large-bore cannula is passed up the femoral vein to the junction

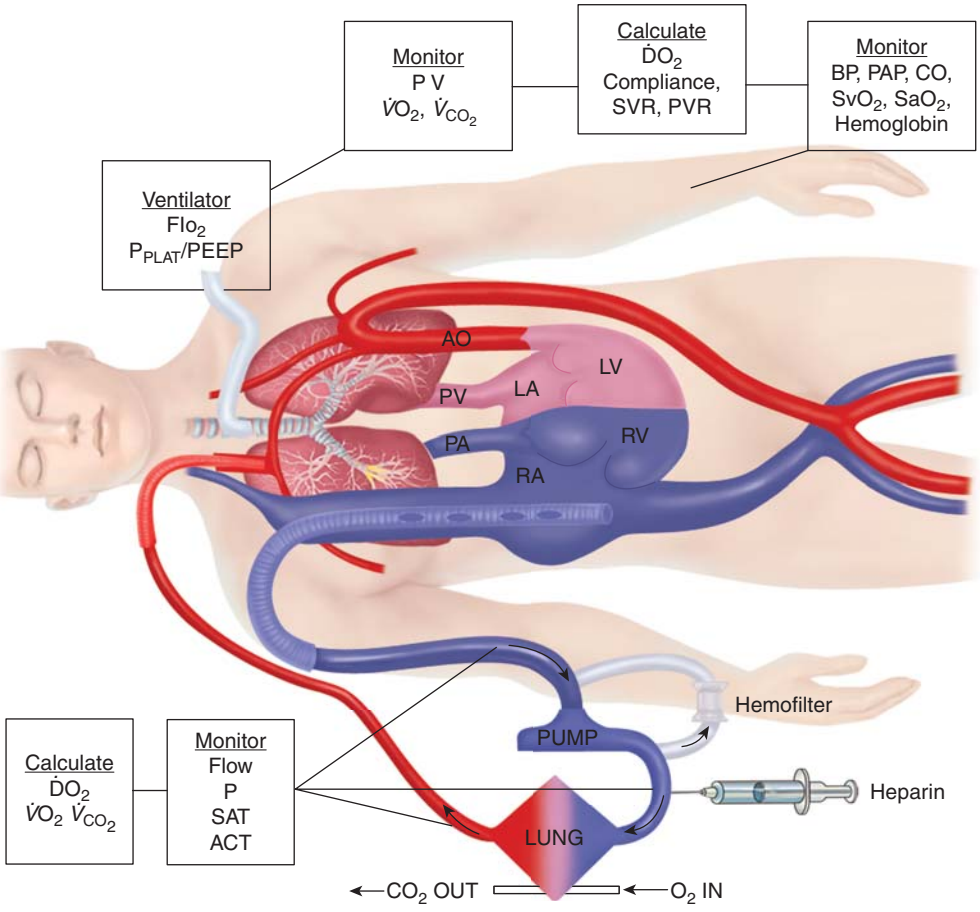

FIGURE 20-7 Venoarterial cannulation. Boxes represent calculations and parameters that can be measured by monitoring site. *ACT*, activated clotting time; *BP*, arterial blood pressure; *CO*, cardiac output (estimated); DO_2, oxygen delivery; *P*, pressure; *PAP*, pulmonary artery pressure (only in patients with a pulmonary artery catheter in place); *PEEP*, positive end-expiratory pressure; P_{PLAT}, plateau pressure; *PVR*, pulmonary vascular resistance; SaO_2, arterial oxygen saturation; *Sat*, saturation of blood; $S\bar{V}O_2$, venous oxygen saturation; *SVR*, systemic vascular resistance; *V*, volume; $\dot{V}_{CO_2}$, carbon dioxide; $\dot{V}O_2$ oxygen consumption. FIGURE 20-8 Modified femoral venoarterial ECMO: For patients usually >15 kg, adequate support can be obtained from femoral venous and femoral arterial cannulation. In this depiction, the patient also has sheaths for cardiac catheterization in the right groin. (Courtesy of Heidi Dalton MD, with permission.)

of the inferior vena cava-right atrium. Figure 20-9 depicts a typical femoral venoarterial cannulation. It should be noted that as the flow characteristics of a cannula are dependent on internal diameter and length, longer cannulas will have higher resistance to flow; however, achieving access near the right atrium allows for the largest pool of venous blood to be obtained, and, thus, short femoral cannulas (while having less resistance) will frequently not result in adequate venous drainage for ECLS support, especially in small patients. Femoral arterial access can be performed by percutaneous or open cannulation. Typically, a short (18 to 25 cm) cannula is used for ECLS return. In access via the femoral vessels, integrity of distal perfusion or venous drainage of the limb is at risk. Measuring vessel size with bedside ultrasound and picking a cannula with an internal diameter slightly less than the vessel can help allow flow around the cannula and prevent blood flow inadequacies to the distal limb.

Placement of small drainage cannulas (for venous engorgement) or distal perfusion cannulas (for distal arterial ischemia) have both been described and used efficiently

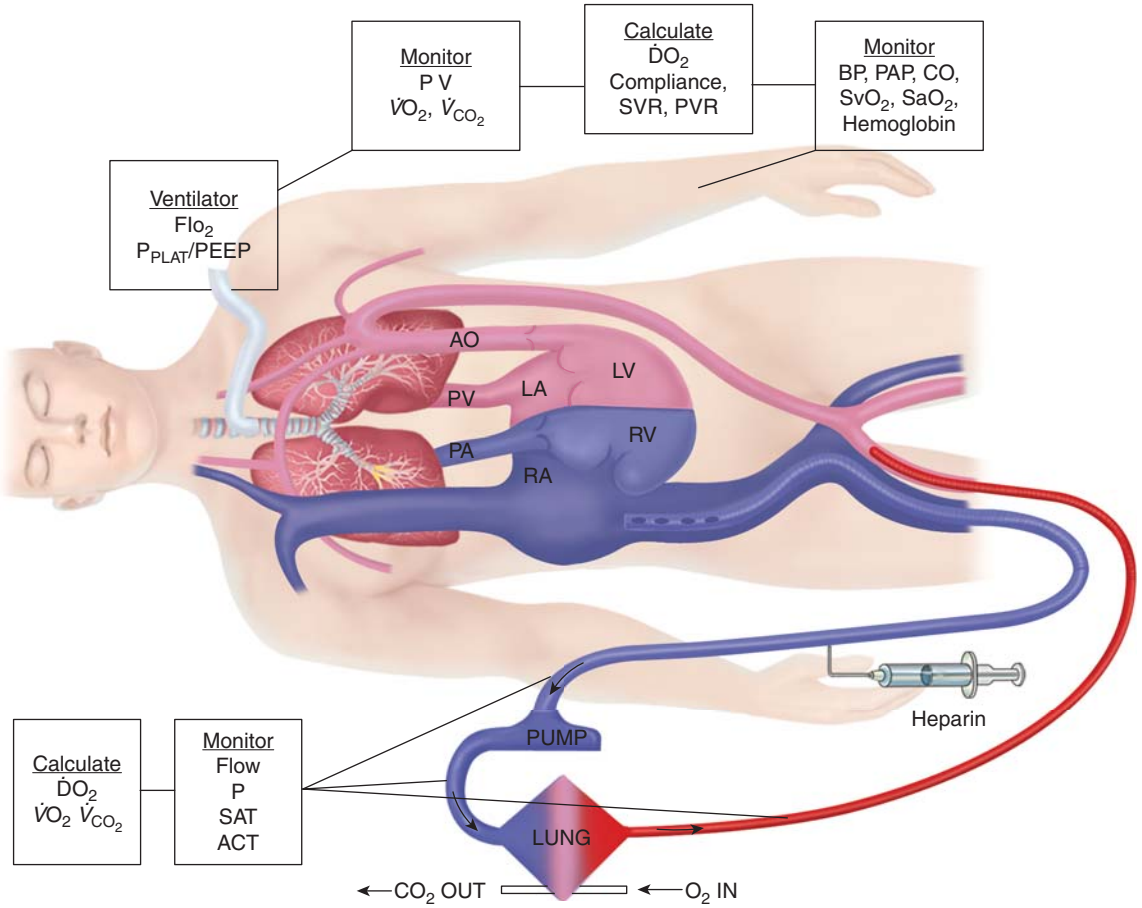

FIGURE 20-9 Femoral venoarterial cannulation. Long femoral drainage cannula to right atrium and short arterial return cannula in femoral artery. Boxes represent calculations and parameters that can be measured by monitoring site. *ACT*, activated clotting time; *BP*, arterial blood pressure; *CO*, cardiac output (estimated); DO_2, oxygen delivery; *P*, pressure; *PAP*, pulmonary artery pressure (only in patients with a pulmonary artery catheter in place); *PEEP*, positive end-expiratory pressure; P_{PLAT}, plateau pressure; *PVR*, pulmonary vascular resistance; SaO_2, arterial oxygen saturation; *Sat*, saturation of blood; $S\bar{V}O_2$, venous oxygen saturation; *SVR*, systemic vascular resistance; *V*, volume; $\dot{V}_{CO_2}$, carbon dioxide; $\dot{V}O_2$, oxygen consumption. (Courtesy of Robert Bartlett, MD, with permission.)

to prevent compartment syndrome or limb loss.[68] Despite these maneuvers, however, limb injury to the extent of amputation has been described several times following femoral access. Thus, close neurovascular monitoring is required.

As venous flow obtained from the femoral route is usually less than that obtained from the internal jugular or central venous sites, the amount of support provided in this mode of venoarterial ECLS is often less than can be obtained with other cannulation techniques. This results in a lower arterial oxygen saturation (SaO_2) secondary to increased mixing of desaturated blood from the patient (assuming the patient has severe respiratory failure and impaired gas exchange) than with other forms of venoarterial cannulation. Oxygen saturation often will be 80% instead of 90% to 100% and will mimic that seen with venovenous support. Another important factor with femoral venoarterial support is that the oxygenated arterial return from the ECLS circuit runs retrograde up the aorta to flow coming out of the native heart. How far up the aorta the oxygenated ECLS blood extends is a product of the amount of bypass performed and the amount being ejected from the left ventricle. One concern with femoral venoarterial bypass is that with severe respiratory failure, blood from the left ventricle will be about the same saturation as that in the right atrium, and this relatively desaturated blood will be what is perfusing the upper body, especially the head and heart. This can result in a "blue upper body and red lower body" phenomenon. Whether this is harmful depends on the extent of desaturation and patient-specific factors. For a patient with evidence of myocardial ischemia, having desaturated blood flowing into the coronary vessels may not be optimal. Similarly, if the patient is exhibiting signs of inadequate cerebral oxygenation (by clinical exam or near-infrared spectroscopy monitoring or some other parameter), then this may be an indication that oxygenation is inadequate. If upper-body oxygen delivery is deemed to be significantly impaired, one technique is to place a venous cannula into the right internal jugular vein or in the femoral vein and direct some of the oxygenated ECLS return into this cannula by means of a Y connector on the return limb of the

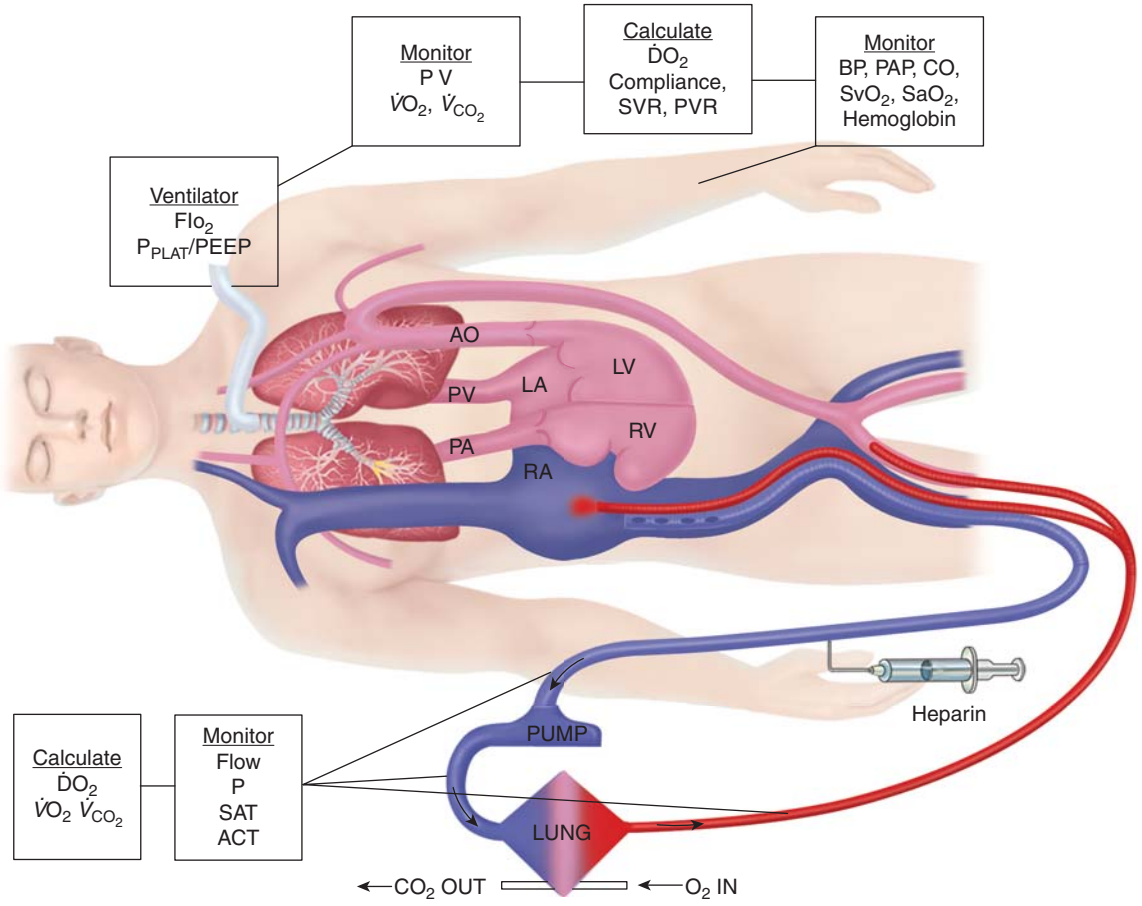

FIGURE 20-10 Hybrid femoral venoarterial cannulation with additional femoral cannula for additional oxygenation to venous circulation. Although the depiction shows additional cannula in same site as venous drainage cannula, it is more common to place additional cannula in the opposite femoral vein or internal jugular vein. Boxes represent calculations and parameters that can be measured by monitoring site. *ACT*, activated clotting time; *BP*, arterial blood pressure; *CO*, cardiac output (estimated); DO_2, oxygen delivery; *P*, pressure; *PAP*, pulmonary artery pressure (only in patients with a pulmonary artery catheter in place); *PEEP*, positive end-expiratory pressure; P_{PLAT}, plateau pressure; *PVR*, pulmonary vascular resistance; SaO_2, arterial oxygen saturation; *Sat*, saturation of blood; $S\bar{V}O_2$, venous oxygen saturation; *SVR*, systemic vascular resistance; *V*, volume; $\dot{V}_{CO_2}$, carbon dioxide; $\dot{V}O_2$, oxygen consumption. (Courtesy of Robert Bartlett, MD, with permission.)

circuit. Figure 20-10 illustrates this method of hybrid femoral venoarterial cannulation with an additional venous cannula providing some oxygenated return. Although the figure depicts two cannulas in one femoral vein, this approach is not common; most clinicians either will place the additional venous cannula in the right internal jugular vein or in the opposite femoral vein. This increases the venous saturation of blood in the right atrium and thus the saturation of blood being ejected out the left ventricle. Careful monitoring of flow in both the venous cannula and the femoral arterial cannula should be performed to prevent one cannula from receiving inadequate flow (as blood will always take the path of least resistance) and clotting. Manipulation of flows to multiple cannulas "Y-ed" into the circuit can be done with a simple screw clamp or other devices. The need for increased venous drainage in femoral venoarterial ECLS can also be achieved by adding another venous cannula (usually in the right internal jugular) and "Y-ing" it into the venous drainage side of the circuit.

Although other vessels, such as the axillary and subclavian, have been used as access for venoarterial ECLS, reports of their use are infrequent. Improved cannula designs with better flow rates and characteristics, may allow improved access to other vessels, even to the point of using umbilical vessels for premature infant support, in the future. Careful attention to neurovascular monitoring is paramount when vessels, especially outside the norm, are cannulated.[69]

PHYSIOLOGY OF VENOARTERIAL EXTRACORPOREAL LIFE SUPPORT

Venoarterial ECLS allows for drainage from the right side of the heart, thus reducing blood flow through the native cardiopulmonary circuit. In patients with impaired pulmonary gas exchange, diversion of venous blood into the ECLS circuit, where it undergoes oxygenation and removal of carbon dioxide, and direct return of oxygenated blood

into the arterial system allows for increased systemic oxygenation. The more blood diverted into the ECLS circuit, the more bypass is performed and the higher the systemic oxygen delivery provided by ECLS. Increasing ECLS flow will decrease the proportion of blood flowing through the diseased lungs, which is ejected out the left ventricle to mix with the oxygenated return from the ECLS circuit. Thus, at higher ECLS flows, systemic oxygen delivery and SaO_2 will increase. This has led to the adage, "If the O's are low, turn up the flow." Similarly, at a constant ECLS flow without manipulations in oxygenation of blood within the membrane oxygenator, a simple herald of improving native respiratory function is an increase in SaO_2, as the patient's lungs become more efficient at gas exchange and the arterial oxygen content (CaO_2) of ejected left-ventricular blood increases. Just as in normal care of a critically ill patient, understanding the role of CaO_2 and oxygen delivery in ECLS is important. As a reminder, CaO_2 is calculated as: (hemoglobin g/dL × % SaO_2 × 1.36 mL/g) + (0.003 mL/dL × Pa_{O_2}) × 10. Thus, the major contributors to CaO_2 are hemoglobin concentration and SaO_2. Pa_{O_2} is of little impact on CaO_2 unless severe anemia exists. Figure 20-7 shows a typical venoarterial circuit with parameters that can be followed or calculated.

To determine the overall oxygen delivered to the patient during ECLS, both the CaO_2 and flow must be considered. The following example illustrates the principles involved:

Assume that perfusate blood is 100% saturated with a Pa_{O_2} of 500 torr, as might be seen with 100% FI_{O_2} applied to the membrane lung. If native respiratory failure is so severe that no oxygenation occurs in the pulmonary circuit, blood returning from the native lungs and being ejected out the left ventricle will have the same saturation as right-atrial venous blood. With normal oxygen delivery and extraction, right-atrial venous saturation is 75% and the partial pressure of oxygen (P_{O_2}) 35 torr. At a hemoglobin of 15 g/dL, the perfusate oxygen content is 22 mL/dL and the right- and left-atrial ventricular oxygen content is 15 mL/dL. If 50% of the native blood flow is diverted into the ECLS circuit and 50% flows through the native cardiopulmonary circuit, the measured systemic oxygen content in the patient will be a combination of these amounts and will result in an oxygen content of 18.5 mL/dL, which corresponds to an SaO_2 of 90% and a Pa_{O_2} of 55 torr. These are the values that will be obtained from the patient's arterial blood, assuming that the blood is being measured past the site where the ECLS return enters the patient so that mixing with native output has occurred.

Thus, an improvement in oxygenation during venoarterial ECLS indicates either (a) improving lung function, (b) decreasing native cardiac output (at constant ECLS flow), or (c) increasing ECLS flow (if native cardiac output is constant). The amount of oxygenation that occurs in the membrane lung, is dependent on gas exchange properties, thickness of the blood film, hemoglobin concentration, the residence time of red blood cells within the membrane lung, and the gradient between inlet venous blood and the oxygen content in the ventilating gas flow.[70,71] Assume that the mixed venous oxygen tension (PvO_2) reaching the membrane lung is 35 to 40 torr and even with room air, the P_{O_2} of ventilating gas is around 100 torr with a saturation of 100%, oxygen will flow into the venous blood and saturation at the outlet of the oxygenator will be optimally 100%. Increasing the FI_{O_2} of the sweep gas may increase the P_{O_2} in outlet blood but will not increase oxygen saturation to greater than 100%; thus, the increase in oxygen content at higher sweep gas FI_{O_2} will be minor unless the patient is severely anemic. If the patient requires more oxygen delivery and blood exiting the membrane lung is 100% saturated, then increasing ECLS flow is needed. For many oxygenators, adequate saturation can be achieved with only room air in the sweep gas. As membrane lung efficiency may decrease over time, an increase in FI_{O_2} of the sweep gas may be required to achieve 100% outlet saturation. Each oxygenator is rated for optimal blood flow (defined as the rate of venous blood flow which results in an increase in SaO_2 from 75% to 95% as blood travels through the device from inlet to outlet). Increasing blood flow rates above the "rated flow" impairs optimal oxygen delivery by the device.

CO_2 removal with venoarterial ECLS is extremely efficient and is dependent on membrane lung surface area, material, geometry, and membrane lung ventilating gas flow (usually termed the "sweep gas flow"), as well as P_{CO_2} content in the patient's blood. Normally, sweep gas flow contains no CO_2 so the gradient for CO_2 exchange across the membrane lung is dependent on the difference between the venous blood reaching the oxygenator and the sweep gas flow. At high sweep gas flows, or with larger membrane surface areas, more CO_2 is removed from the blood, similar to increasing minute ventilation as a means of increasing CO_2 elimination in a normal state. In small patients, CO_2 elimination can be so efficient that the P_{CO_2} returning to the patient is very low and respiratory alkalosis severe. For patients cannulated via the cervical or central arterial route into the arch of the aorta, the ECLS return often reaches the left carotid artery (and thus the brain) first. Because a very low P_{CO_2} in this blood may adversely affect cerebral vascular blood flow, maintaining normal Pa_{CO_2} in the blood returning to the patient is recommended. Some centers regulate P_{CO_2} returning to the patient by manipulating sweep gas flow as a lower sweep will decrease CO_2 removal. Others blend CO_2 gas into the sweep gas mixture to decrease the gradient across the membrane lung between native blood and sweep gas. It should be remembered that CO_2 elimination is better than oxygen uptake across both the silicone membrane and microporous/hollow-fiber oxygenator devices.[72–75]

One important note with venoarterial support is that arterial flow coming from the ECLS circuit *increases* afterload to the left ventricle. This is of paramount importance in situations of left-ventricular dysfunction, because this increase in afterload may result in sudden and complete failure of the left heart. The majority of coronary artery perfusion during venoarterial ECLS has been shown to result from native left-ventricular ejection.[76] Given that venoarterial ECLS never provides complete bypass, because flow from bronchial and thebesian vessels will continue to the left heart,

inability of the left heart to eject can result in impairment of left-ventricular myocardial flow from elevated intracardiac pressure, left-atrial hypertension, pulmonary venous hypertension, and pulmonary hemorrhage. Although a short period of cessation of left-ventricular function can often be tolerated, attempts at afterload reduction with medications such as milrinone or nitroprusside can also be helpful. In patients with prolonged left-ventricular failure, poor aortic ejection, evidence of pulmonary congestion (such as pulmonary edema or hemorrhage), an atrial septostomy can be performed to allow left-atrial blood to be drained via the right-atrial cannula in order to decrease left-atrial pressure.[77,78] In patients with sternotomy, a left-atrial vent can also be placed and "Y-ed" into the venous side of the ECLS circuit to offload the left heart. If the patient's cardiopulmonary function is being "tested" while clamped off ECLS before complete removal of the cannula's to see if adequate recovery has occurred (this process is called "trialing off ECLS"), the left-atrial cannula must be removed or clamped during this process to allow normal filling of the left heart. Echocardiography can be invaluable to follow the extent of left-ventricular dysfunction, overall cardiac function and recovery, adequacy and optimal placement of ECLS cannulas, and assessment for pericardial effusion during ECLS.

Unlike cardiopulmonary bypass, ECLS is intended to provide partial (not *total*) bypass, as animal studies show that complete bypass of the pulmonary circuit is associated with ischemia.[79] The "total" bypass used during cardiac surgery is also thought to be a factor in the reperfusion injury noted in the lung, cytokine generation, and the inflammatory response observed in the post-bypass period. Thus, goals for venous saturation, arterial oxygenation, and hemodynamic support are set for each patient (usually on a daily basis) and ECLS flow adjusted to maintain set parameters. For patients with severely impaired gas exchange, the level of bypass support is set at providing adequate oxygen delivery to support tissue function. In general terms, this often equates to a starting ECLS flow of 100 to 150 mL/kg in neonates, 80 to 100 mL/kg in children, and 50 to 60 mL/kg in adults. The adequacy of support is monitored by establishing normal venous oxygen saturations (>65% to 70%), normalization of lactate levels and base deficit as well as adjunct measures such as clinical exam, vital signs such as blood pressure, neurologic alertness, urine output, near-infrared spectroscopy monitoring, and other measures used by clinicians to identify appropriate organ perfusion.[80] Flow returning from the ECLS circuit is mainly nonpulsatile. One indication of the amount of bypass being performed in a patient with adequate cardiac function is merely following the pulse pressure and systolic pulse contour on the arterial waveform. More bypass will decrease the systolic upswing and give a more narrow pulse pressure.

Several practical points regarding ECLS use in patients with predominant cardiac failure are to maintain intracardiac filling pressures at low levels so as to promote endocardial blood flow and myocardial perfusion. Thus, close attention to central venous pressure and left-atrial pressure (if available) is required. Use of echocardiography to assess cardiac function (how "full" or "empty" the heart is) and aortic outflow is very helpful during ECLS, especially in the cardiac patient and during weaning.[81]

PATIENT POPULATIONS TREATED WITH VENOARTERIAL EXTRACORPOREAL LIFE SUPPORT

Table 20-1 reviews the ELSO registry for patient populations in neonatal (<30 days), pediatric (31 days to 18 years), and adult (>18 years) age groups in terms of major diagnostic categories and outcome. Table 20-2 outlines major diagnostic groups within categories and outcome in the most recent time period of 2000 to 2010. Figures 20-11 and 20-12 show the changes in ventilator settings and blood-gas parameters in age groups and respiratory failure patients. Note that pH has declined and Pa_{CO_2} has increased over time, perhaps indicating adoption of the "permissive hypercapnia" approach to mechanical ventilation. This has not been accompanied, however, by a large change in OI over time, as might be expected if "gentler ventilation" with lower mean airway pressures was occurring. Potential explanations for the lack of change in OI is that mean airway pressure with the high frequency oscillator is often higher (at least initially) than with conventional mechanical ventilation or that clinicians are accepting greater levels of hypoxia as part of "gentler ventilation."

Neonatal

The use of ECLS in neonates has declined over the past 10 years as improved perinatal care and management techniques have advanced.[82,83] Infantile respiratory distress syndrome has largely disappeared with the advent of surfactant and better lung-protective ventilation strategies, as well as changes in ventilator technology, such as the high-frequency oscillator. Meconium aspiration syndrome is also not as prevalent as in the past, and group B streptococcal infection has also declined. These diseases have been replaced with other infections and more complex infant illnesses. Congenital diaphragmatic hernia remains a large group for neonatal ECLS and survival in these patients remains only approximately 50% despite the many different management algorithms and approaches for surgical repair that have been introduced over time.[84–89] The overall survival in neonatal ECLS patients is 69% over the past 10 years, with about 1000 infants receiving ECLS per year.[90] Based on ventilator setting and blood-gas data, there has been little change in severity over time based on oxygenation index (average: 45 to 50) or Pa_{O_2}/FI_{O_2} ratio (average: 50–60 torr) for neonates, although a steady decline in pH and concomitant increase in Pa_{CO_2} have been observed. A recent evaluation of the ELSO registry from 2000 to 2010 revealed a 2.5% decline in survival per year ($p < 0.01$).[91]

Although venoarterial access has been the mainstay in neonates, the fact that many infants with respiratory failure have good cardiac function makes them good candidates for venovenous support. Improved double-lumen, single-site cannulas that can be placed in the internal jugular vein have been developed, which allows for venovenous ECLS to be used in almost half of neonatal respiratory failure patients. Figure 20-13 shows a typical venovenous cannula that is currently widely used in larger children and adults. Figure 20-14 depicts a typical venovenous circuit. One problem that has been encountered with double-lumen cannulas has been difficulty with collapse of the drainage lumen if a high amount of venous "suction" is generated. This is potentially more of an issue with centrifugal pumps than with the older style semiocclusive, rollerhead devices.[92] Development of wire-reinforced double-lumen, single cannulas has been spurred by the many centers that are changing to centrifugal equipment for its ease of use and ability to use shorter circuits with less priming volume. Although these cannulas have been very successful in larger patients, smaller sizes have encountered some difficulty with accurate placement, and clinical reports of unexplained tamponade occurring days after placement without well-identified myocardial perforations have surfaced. Newer models are expected in clinical trials soon. Current management is to try venovenous ECLS support in almost any neonate without known complete cardiac collapse before implementing cardiac cannulation for venoarterial support. Successful use of venovenous support even in infants with primary respiratory failure and pre-ECLS need for vasoactive support has been well described.[93]

Pediatric

As experience with ECLS has grown, the expansion to patient populations avoided in the past is nowhere as clearly seen as with pediatric patients. The "old days" when a healthy child would contract overwhelming pneumonia and be rescued with ECLS support are now a memory, as most pediatric ECLS patients today have underlying comorbidities in addition to their acute critical illness.[94–101] The latest review of pediatric respiratory failure patients entered into the ELSO database was recently published.[102] This report compared patients who received ECMO from 1993 to 2007. Survivors were noted to have a lower median body weight (9 vs. 9.9 kg), with a similar median age in survivors and nonsurvivors. Older children (ages 10 to 18 years) had lower survival (50%) compared to infants (57%), toddlers (61%), and children (55%). Although there was little change in survival over time, patients with comorbidities increased from 19% in 1993 to 47% in 2007. Renal failure, chronic lung disease, and congenital heart disease (two ventricles) formed the bulk of underlying comorbid conditions. Other conditions, which represent the changes in exclusion criteria

TABLE 20-2: OUTCOME ACCORDING TO MAJOR DIAGNOSTIC GROUP (2000 TO 2010)

Primary Diagnosis	n (%)	Survival
Neonatal	9086	68.6
MAS	2239 (24.6)	92.9

ARDS, acute respiratory distress syndrome; *CDH*, congenital diaphragmatic hernia; *MAS*, meconium aspiration syndrome; *post-op*, postoperative; *PPHN/PFC*, persistent pulmonary hypertension of the newborn, or persistent fetal circulation; *RDS*, respiratory distress syndrome.

Data analyzed from ELSO registry years 2000 to 2010. Survival is to hospital discharge. (Unpublished data, Dalton HJ and Garcia-Filion P, with permission.)

over time, note that patients with cancer, solid-organ transplantation, immunodeficiencies, and even stem cell transplantation patients have received ECLS and survived. All these conditions would have been excluded as candidates for ECLS in the past. Nonetheless, children with no comorbidities have experienced improved survival with ECLS over time: 57% in 1993 to 72% in 2007. Another important factor in this summary of more than 3000 pediatric ECLS patients is that a significant decline in survival was not noted until patients reached a ventilator duration of longer than 14 days before ECMO. This is a large change from prior reports, which found that a ventilator duration of longer than 7 days was associated with worsening outcome. The use of high-frequency ventilation did not change over the period 1993 to 2007, and survival was not different between modes of ventilation. Patients who received high-frequency oscillation, however, did have a longer period of ventilation before ECMO than did those who received conventional mechanical ventilation (4.6 vs. 3 days). Nonsurvivors had a higher oxygenation index (48 vs. 42) and lower pH (7.27 vs. 7.31). Of note, pre-ECMO pH was progressively lower in both survivors and nonsurvivors as the years progressed. A trend in increased use of venovenous ECMO over years was also observed, and venovenous ECMO was associated with improved outcome. As the ELSO registry gives little detail on severity of illness before ECMO, however, interpretations of outcome comparisons between venoarterial and venovenous ECMO can be difficult.

Table 20-2 shows the major categories of pediatric respiratory failure who have received ECLS. One difficulty in interpreting ELSO data is that many patients who are currently receiving ECLS have a combination of respiratory and cardiac failure, making assigning them to one of the three major groups in the ELSO registry (respiratory, cardiac, or emergency cardiopulmonary resuscitation) difficult. This skews the ability to accurately report results and is one major area where the ELSO registry is being renovated. Without data on severity of illness beyond the respiratory indices previously discussed, identifying risk factors for outcome or complications is difficult. A growing population where this is easily represented is patients in septic shock: these patients often have both respiratory and cardiac dysfunction, as well as injury to other organs.[103] Outcome of patients in septic shock is believed to be lower than in patients with single-organ failure, although good comparisons on a large scale have not been conducted. Better refinement of organ failure and severity of illness by the ELSO registry may allow more sophisticated analyses of these complex patients in the future. Debate (without resolution) continues as to the efficacy of ECLS in high-output failure versus low-cardiac output states, where it seems more intuitive that the additional oxygen delivery provided by ECLS may be of greater benefit to tissue oxygenation. In the Australian series of children with sepsis, central cannulation achieved significantly greater flow rates than did peripheral cannulation.[63] This observation requires confirmation in a larger series. As with neonates, lower pH and higher Pa_{CO_2} values have been observed over time, with oxygenation index and Pa_{O_2}/FI_{O_2} remaining fairly constant (see Fig. 20-4). Despite the push for more venovenous support and better cannula availability, there does not seem to have been much of a change in the mode of ECLS support for respiratory failure patients. Although not statistically significant, an overview of data from the ELSO registry between 2000 and 2010 noted a slight increase in survival, 1.9% per year, despite the complexity of patients receiving ECLS.[104]

Adult

An increase in the use of ECLS in adults is occurring with the advent of new technology, the CESAR trial, the H1N1 epidemic, and reports of successful use around the globe.[15,105] Although most adult patients with respiratory support may be appropriate candidates for venovenous support, about one-third are managed with venoarterial cannulation. There has been an increase in venovenous support, however, over the past 2 years probably as a consequence of improved double-lumen cannulas and simpler, easier-to-use pumps

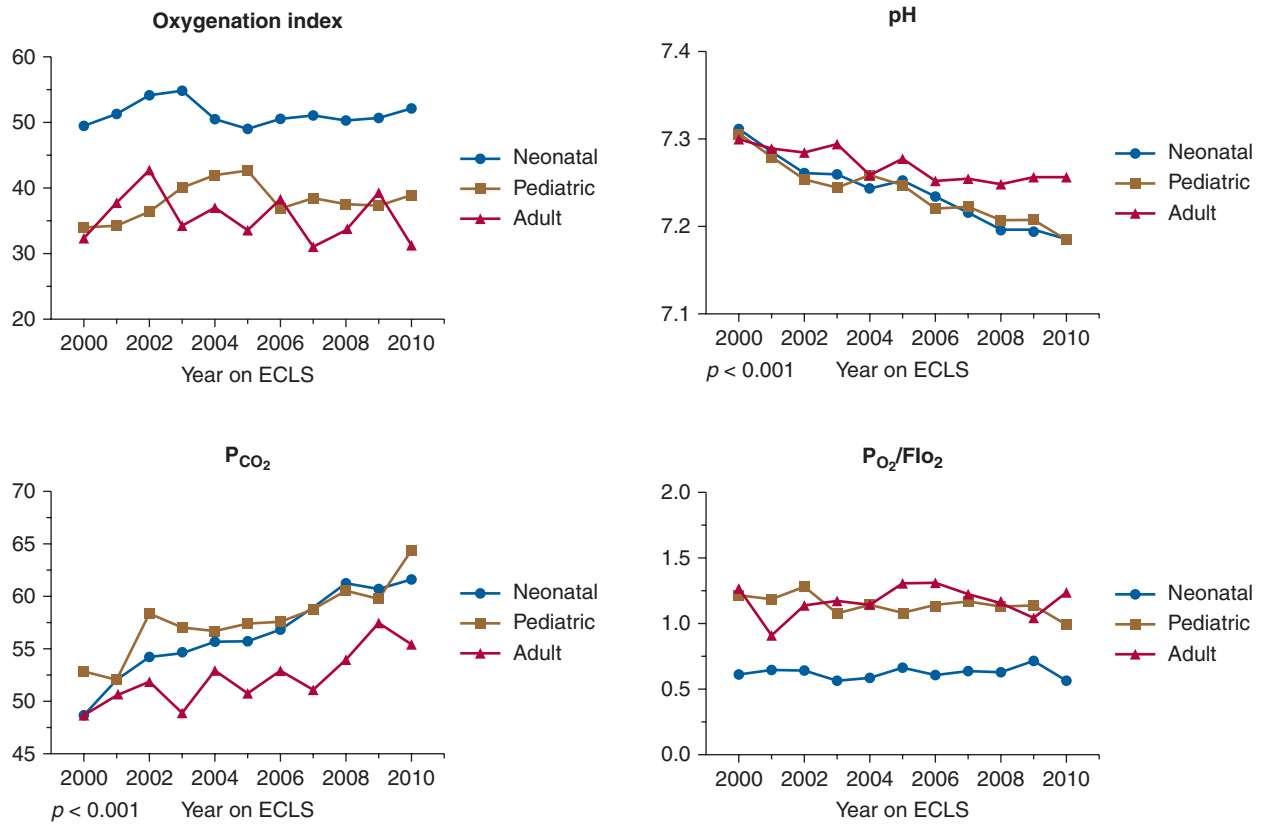

FIGURE 20-11 Severity indices and blood-gas parameters over time by age group (2000 to 2010). Oxygenation index and P_{O_2}/FI_{O_2} have decreased slightly in adults over time; pH has decreased and Pa_{CO_2} has increased, possibly reflecting greater use of "lung-protective" ventilation. Increased use of high-frequency oscillation ventilation (HFOV) in neonates and pediatric patients versus adults may influence the oxygenation index because mean airway pressure is often higher with HFOV.

and oxygenators.[106,107] Over the past year, three-quarters of adult patients received venovenous ECLS via multiple sites or use of a double-lumen cannula. Chapter 21 discusses the use of venovenous support and the various devices that focus on gas exchange. Within the ELSO registry, overall survival in adult respiratory failure is similar to that in pediatric patients at 56%. One difficulty with both pediatric and adult patients is that the largest category reported to ELSO is "other," which is obviously ill-defined and makes it difficult to identify exactly what type of disease these patients have. Similar to pediatric ECLS patients, adult survival between 2000 and 2010 has noted a slight (nonsignificant) increase in survival of 2.5% per year.

Cardiac

Although not the focus of this chapter, most patients requiring venoarterial support have cardiac failure, as a result of congenital heart defects, myocarditis, cardiomyopathy, cardiogenic shock, or before or after heart transplantation.[77,106–120] Patients who receive ECLS emergently as a rescue mode of resuscitation from cardiac arrest (external cardiopulmonary resuscitation [ECPR]) are now an increasing population within the ELSO registry. Up to July 2011, 694 neonatal ECPR patients were reported, with 39% surviving to discharge; 1347 pediatric EPCR patients, with 40% survival; and 591 adult ECPR patients, with 29% surviving to discharge. The acceptance of advanced cardiac life support as a resuscitative tool is highlighted by recent statements from groups such as the American Heart Association: "To consider extracorporeal cardiopulmonary resuscitation [cardiopulmonary resuscitation] for in-hospital cardiac arrest refractory to initial resuscitation attempts if the condition leading to cardiac arrest is reversible or amenable to heart transplantation, if excellent conventional cardiopulmonary resuscitation has been performed after no more than several minutes of no-flow cardiac arrest, and if the institution is able to rapidly perform extracorporeal membrane oxygenation."[121–123]

PATIENT MANAGEMENT DURING VENOARTERIAL EXTRACORPOREAL LIFE SUPPORT

Supporting patients who are receiving ECLS involves a mixture of providing adequate gas exchange, hemodynamic support, and minimizing risks of major complications such as

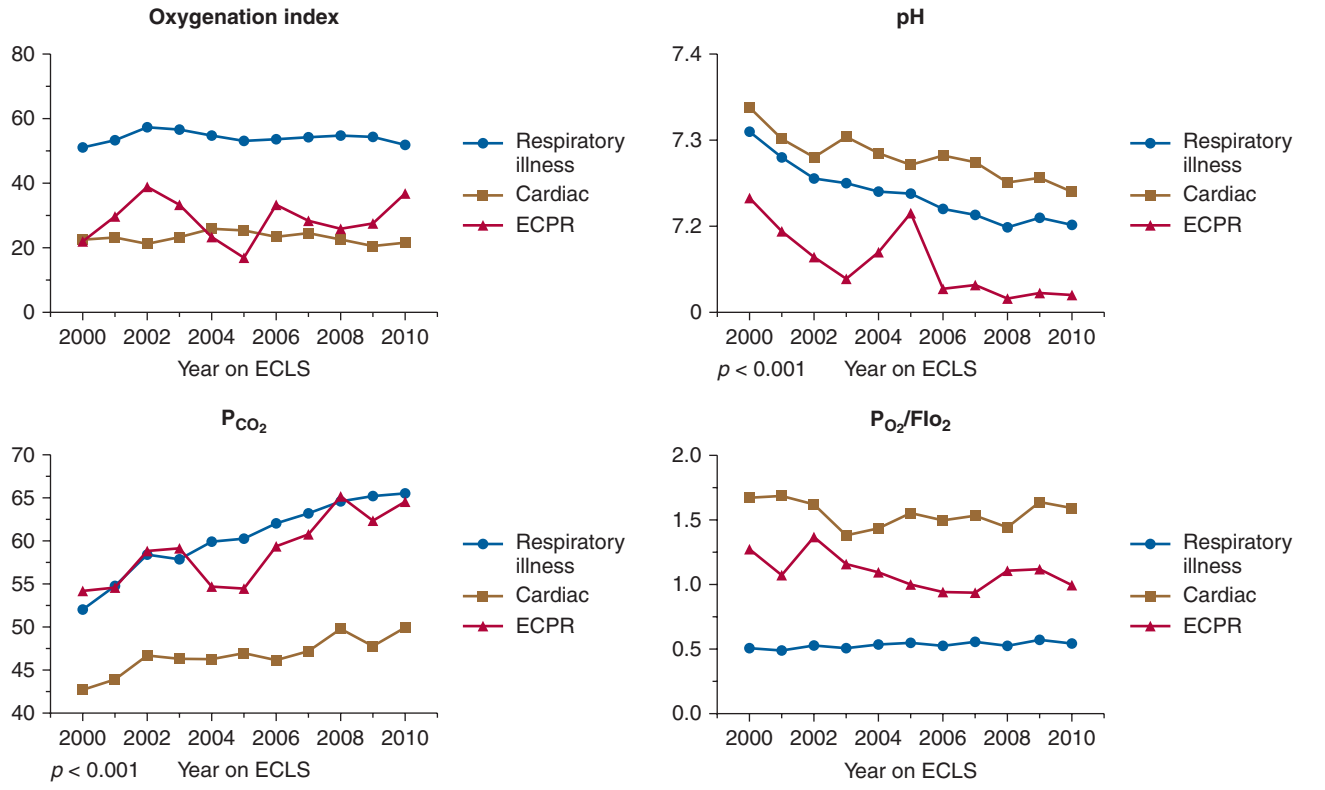

FIGURE 20-12 Severity indices and blood-gas parameters over time by diagnostic category (2000 to 2010). Oxygenation index and P_{O_2}/FI_{O_2} have decreased slightly in adults over time; pH has decreased and Pa_{CO_2} has increased, possibly reflecting greater use of "lung protective" ventilation. Increased use of high-frequency oscillation ventilation (HFOV) in neonates and pediatric patients versus adults may influence oxygenation index because mean airway pressure is often higher with HFOV.

bleeding and infection. As already discussed, gas exchange is controlled by a combination of blood flow to the oxygenator, surface area of the oxygenator, and sweep gas mixture. Oxygenation is predominantly influenced by the amount of blood flow to the oxygenator and carbon dioxide by the amount of sweep gas and surface area provided by the membrane in relation to the blood flow through the oxygenator. The measured oxygen saturation and carbon dioxide in the patient is a combination of the blood returning from the oxygenator and that being ejected by the patient's left ventricle. The extent of hemodynamic support is provided by the amount of blood returning from the oxygenator to the patient, as well as the systemic vascular resistance, oxygen delivery, and extraction rates in the patient. Patients with poor cardiac function require more support from the ECLS circuit, and oxygen delivery can also be increased by provision of well-oxygenated blood returning from the ECLS as compared to that poorly oxygenated blood ejected from the left ventricle in patients with severe respiratory failure. Careful monitoring of the adequacy of ECLS support over time is important, because failure to reverse lactic or metabolic acidosis in the first 24 hours after ECLS is associated with poor outcome.[124,125] As centrifugal pump systems are becoming more widely used in ECLS, it is important to recognize that these systems are especially reliant on adequate preload in the patient for venous drainage and sensitive to afterload for arterial return. When a patient's systemic vascular resistance (SVR) increases, flow from the centrifugal circuit to the patient can be reduced unless the revolutions per minute are increased to maintain forward flow and overcome the added resistance being generated in the patient. Thus, an unexpected decrease in flow in the ECLS circuit may be the result of agitation, temperature decrease, or other factors that can increase SVR. Afterload reduction or other measures that reduce SVR may augment forward flow from the circuit. Likewise, reduction in SVR, as in sepsis, may indicate a need for increased flow to provide adequate oxygen delivery. There are some patients in whom tissue oxygenation is inadequate no matter what the flow provided; these patients are the most difficult to treat and have high mortality.

To maintain consistent patient support, most centers set daily goals for bedside personnel to follow with regards to the levels of oxygen, carbon dioxide, blood pressure, hemoglobin, and anticoagulation to be maintained.

Exposure to the ECLS circuit causes destruction of red blood cells and adherence of platelets, necessitating intermittent administration of blood products.[126] The underlying illness may also affect blood product production or increased consumption. It is conventional wisdom to maintain hemoglobin close to 15 g/dL to optimize oxygen content, although no studies have definitively shown that maintaining a high hematocrit enhances survival.[127–129] The current debate regarding the risks and benefits of blood

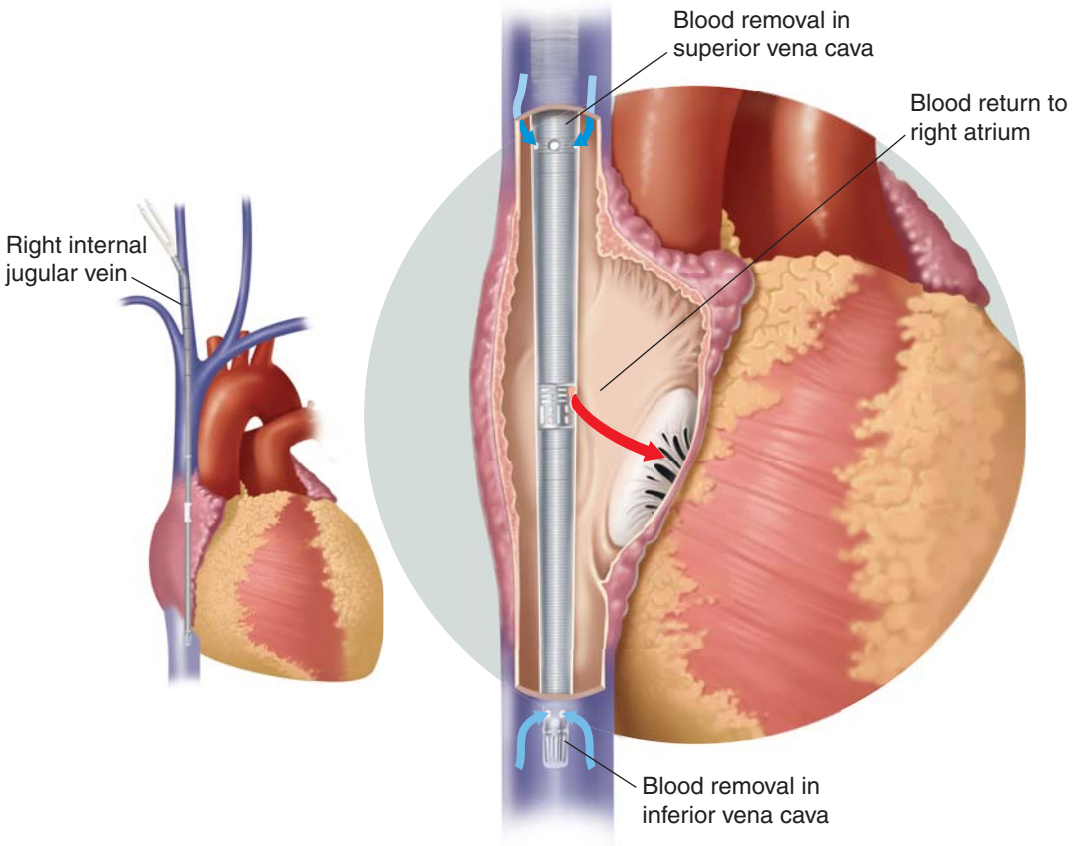

FIGURE 20-13 Venovenous double-lumen cannula. To be properly positioned, the distal drainage port must sit in the inferior vena cava at the right-atrial junction and proximal drainage port in the superior vena cava/right-atrial junction. The inflow port will be directed at the tricuspid valve. (Photo courtesy of Avalon Laboratories, LLC, Rancho Dominguez CA.)

transfusion in critically ill patients holds true for ECLS: some clinicians limit blood exposure by maintaining hematocrit levels closer to 30%, whereas others maintain levels greater than 40%.[130,131] The rheology of blood flowing through newly available cannulas, tubings, and oxygenators make this question a needed focus for future research to determine what is the "best" hematocrit during ECLS.

In a similar fashion, platelets levels have traditionally been maintained at more than 100,000, although there are numerous reports where patients have platelet levels of 20,000 or less without excessive bleeding. When bleeding does occur, attempts to increase platelet levels is a common practice, although, again, no definitive study shows that this step improves outcome.[132] Other coagulation indices (prothrombin time, partial thromboplastin time, fibrinogen) are followed, and corrected with administration of replacement factors with plasma or cryoprecipitate.

As anticoagulation with heparin is standard practice to avoid clotting of the extracorporeal circuit, maintaining adequate heparinization while avoiding bleeding is a delicate balance. The activated clotting time, determined by a bedside test, is the standard measurement used for adjusting heparin dosage with ECLS.[133] Usually maintained at levels of 180 to 220 seconds, recent studies show that this test correlates poorly with measured heparin levels and indices of anticoagulation measured by other means. There is a continued need to develop more effective methods to assess how the level of anticoagulation relates to observed bleeding. The best method to reverse bleeding that is poorly controlled by simple administration of blood products or surgical intervention to establish hemostasis remains the most perplexing problem with ECLS today. Use of factor concentrates, such as VIIa and antithrombin, as well as monitoring of antithrombin, factor Xa, and thromboelastograph data are the current methods used by clinicians in an attempt to address bleeding and anticoagulation concerns.[134–140] Bleeding remains one of the most common complications during ECLS. Lowering the heparin dose, even to the point of stopping heparin for 12 to 24 hours, has been successfully reported.[141] Heparin-induced thrombocytopenia is another problem, leading to use of alternative agents such as argatroban or lepirudin.[142] Bleeding has also been treated with agents that help stabilize clot, such as aminocaproic acid or aprotinin (which is no longer available in the United States).[143]

Maintaining adequate fluid balance is another goal during ECLS. While diuretics remain the mainstay of fluid removal, many patients have renal insufficiency requiring hemofiltration or dialysis.[144–148] The association between renal insufficiency and outcome has produced both reduced survival and unchanged outcomes in various reports.

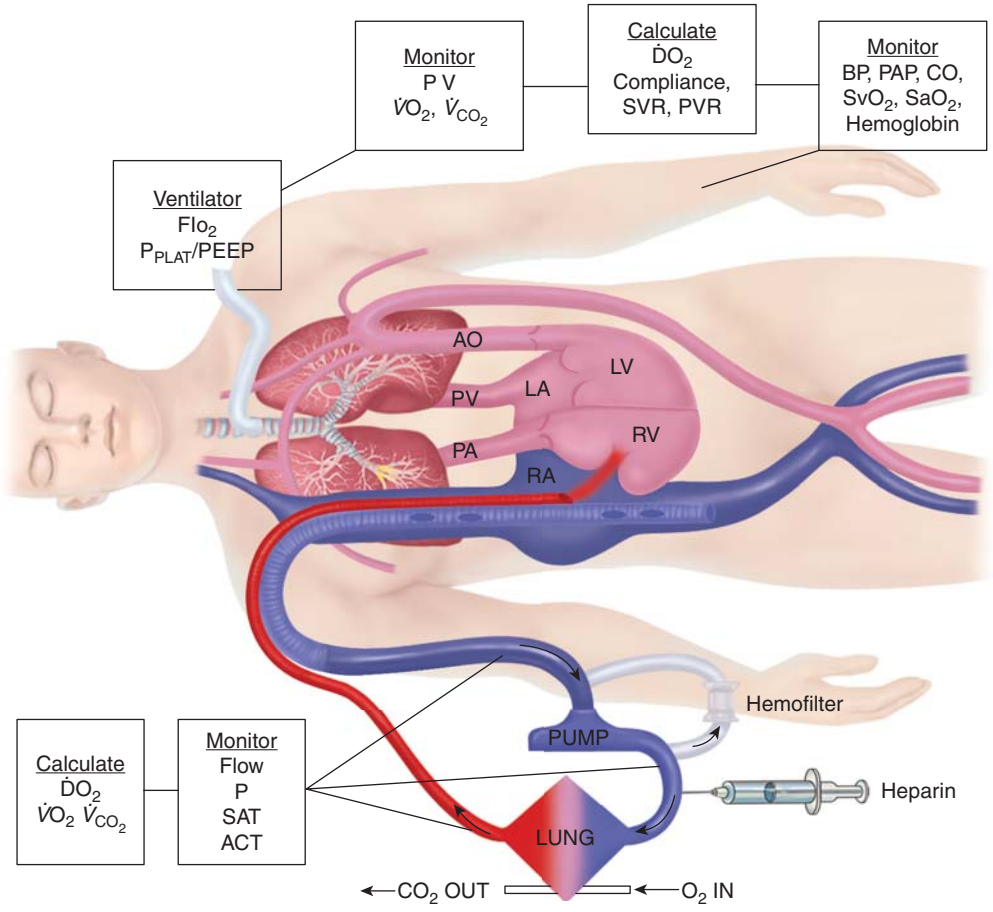

FIGURE 20-14 Venovenous ECLS circuit. Boxes represent calculations and parameters that can be measured by monitoring site. *ACT*, activated clotting time; *BP*, arterial blood pressure; *CO*, cardiac output (estimated); DO_2, oxygen delivery; *P*, pressure; *PAP*, pulmonary artery pressure (only in patients with a pulmonary artery catheter in place); *PEEP*, positive end-expiratory pressure; P_{PLAT}, plateau pressure; *PVR*, pulmonary vascular resistance; SaO_2, arterial oxygen saturation; *Sat*, saturation of blood; $S\bar{V}O_2$, venous oxygen saturation; *SVR*, systemic vascular resistance; *V*, volume; $\dot{V}_{CO_2}$, carbon dioxide; $\dot{V}O_2$, oxygen consumption. Patients on ECLS are at risk for infection from changes in leukocyte function, nosocomial contamination of indwelling cannulas, and underlying critical illness.[149–151] Although infection during ECLS has been reported, and may be associated with worsened survival, the early practice of "prophylactic" antibiotics has been fairly well abandoned. Periodic monitoring and treatment of documented infection is important, and successful recovery, even after nosocomial infection with organisms such as fungus, has been reported.

Satisfactory nutrition is important to promote healing during ECLS. Enteral nutrition is preferred, although parenteral support may be required if a patient cannot tolerate full enteral calories.[152,153] The ability to tolerate feedings can be adversely affected by medications that reduce gut motility. Chief among these are narcotics.

One major difference in patient management between centers is the use of sedation.[154,155] The growing movement to lessen sedation and keep patients more awake on ECLS produces benefit beyond the ability to monitor neurologic function. It also promotes the ability to adequately feed the patient, and maintain normal body movement to reduce peripheral edema and promote skin integrity. Minimizing sedation decreases the inherent risks of using increasing doses of sedative and analgesic agents secondary to toxicity or withdrawal. The new, more miniaturized circuits and improved cannulas are one reason that more patients are being maintained wide-awake on ECLS, riding exercise bikes, or reading or eating ice cream (Fig. 20-15). Hopefully, this trend will continue.

The optimal ventilator management during ECLS is debatable, although all agree that minimizing ventilator-induced lung injury is a goal.[156–158] For the patient who is awake on venoarterial ECLS, because most gas exchange needs can be performed by the oxygenator, ventilator weaning to the point of extubation or minimal settings is a possibility. Some patients exhibit air-hunger or distress despite adequate oxygenation and ventilation provided by ECLS, and may require some pressure support or breathing assistance. Use of PEEP to maintain lung expansion may prevent atelectasis. Keeping inspiratory pressure of less than 30 cm H_2O is recommended. Promoting spontaneous breathing is important and recommended. Although use of high frequency ventilation is

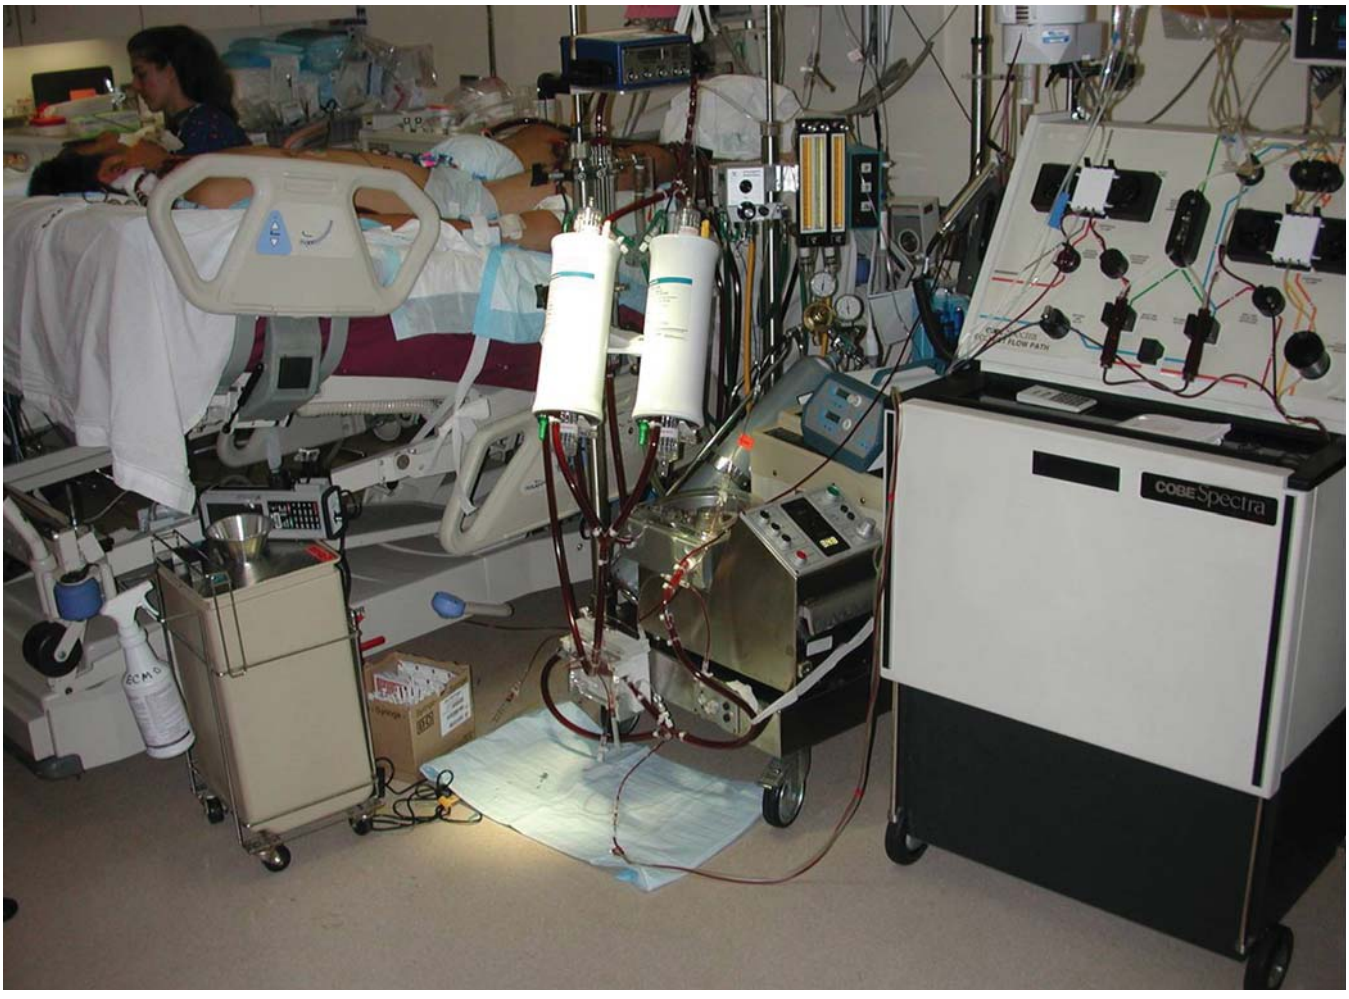

FIGURE 20-15 Ambulatory ECLS is becoming more common. (Photo courtesy of Ira Cheifetz MD, with permission.)

also described, this mode makes it difficult to keep patients awake and interpret actual tidal volumes. It is not commonly used unless attempts are being made to "push" the patient off ECLS secondary to complications.

Determining when a patient is ready for weaning is relatively simple during venoarterial ECLS. For patients with respiratory failure, improving oxygenation, clearing of the chest radiograph and improved tidal volumes at low pressure ventilation often herald recovery.[156–158] For patients with hemodynamic compromise, the ability to maintain adequate blood pressure and tissue perfusion on lowered flows of ECLS may indicate time to wean.[159] Use of low-dose vasoactive agents may be needed to assist cardiac function and facilitate weaning. To truly assess the ability to wean off venoarterial support, most centers clamp the patient off support and observe gas exchange and hemodynamics with the patient separated from ECLS support. Echocardiography to evaluate cardiac performance may also be useful during this period.[160] If weaning is not tolerated, the cannulas can be unclamped and the patient continued on ECLS. During clamping, it is important to remember that a patient needs to remain heparinized and the cannulas "flashed" by releasing the clamps every few minutes to prevent clotting. Patience is required while awaiting organ recovery. A recent report noted no difference in survival for patients who required ECLS for less than 10 days compared to those maintained for more than 21 days. The impact of ventilation days before ECLS has also shown that survival can be obtained with durations thought "too long" in the past.[161,162]

OUTCOME

Tables 20-1 and 20-2 list the overall survival for different patient groups. The greatest need is for long-term studies to assess neurodevelopmental outcome. Although short-term reports have found reasonable outcome, the impact of ECLS on school performance, risk for stroke later in life, and quality of life is not well known.[163,164] Older children and adults seem to have global neurologic function that matches that observed when they are discharged. The most in-depth reports of outcome have been in neonates with respiratory or

cardiac failure.[165–168] In the ELSO registry, neonates placed on ECLS for respiratory failure have an incidence of seizures of approximately 10%, although there is poor correlation with seizures noted during ECLS and overall neurologic outcome. Approximately 7% of neonates with respiratory failure are noted to have abnormal imaging studies (either hemorrhage or stroke). Two-thirds of neonatal respiratory failure survivors appear to have a normal neurodevelopmental outcome. Severe chronic respiratory disease in patients treated with ECMO is uncommon. Most authors report an incidence of bronchopulmonary dysplasia (defined as the need for oxygen beyond the first month of life) of 4% to 27%.[169] Most cases occurred in patients who had required extreme ventilator settings for more than 7 days before ECMO rescue. A follow-up report of neonates treated with ECMO and evaluated at 10 to 15 years post-ECMO found that although the ECMO patients had some impairment on pulmonary function testing, they had similar aerobic capacity and were able to reach similar anaerobic exercise goals as age-matched healthy controls.[170]

Of 5000 pediatric respiratory ECMO patients listed in the Registry through July 2011, 9% had intracranial infarct or hemorrhage on computed tomography examination. Brain death occurred in 6% of the patients and another 6% had seizures. Long-term neurologic outcome data are sorely missing in the pediatric population. In one review of fifteen pediatric and four adult patients, 58% survived to discharge. Patients were evaluated by use of the pediatric cerebral performance category, which measures cognitive impairment, and the pediatric overall performance category, which measures functional morbidity. Overall, 64% of survivors had normal pediatric cerebral performance category scores, 27% had mild disabilities, and 9% had moderate cognitive disability. Functional morbidity was normal in 27%, while 45% had mild disability, 18% moderate disability, and 9% were severely disabled.[171] In another small series of twenty-six patients followed 1 to 3 years after ECMO, 38% of pre–school-age children were described as normal and 31% exhibited abnormalities. Four patients (31%) who had prior neurologic dysfunction remained at baseline following ECMO. Among school-age children, 77% were described as normal by parental report. More specific neurologic follow-up in the pediatric age groups is needed.[172,173]

Neurologic complications in cardiac patients who receive ECMO parallel that of respiratory failure patients: 49% developed brain death, 3% had intracranial infarct, and 6% had intracranial hemorrhage. Because many cardiac patients are in a state of prolonged low cardiac output or sudden cardiac arrest before ECMO, the ability to assess neurologic function once ECMO is instituted is vitally important. Paralysis and sedation should be minimized until neurologic examination can be performed. This information is especially important in patients who are being listed for transplantation, so as to avoid transplanting a viable organ into an inappropriate recipient. Among neonatal patients placed on ECLS for cardiac dysfunction, most have congenital heart disease. Outcome of survivors reveals that approximately 50% have normal neurodevelopmental outcome. New reports of neurodevelopmental outcome in patients with congenital heart disease reveal abnormalities, which were previously unsuspected. How many of the post-ECLS abnormalities are the result of the underlying condition, pre-ECLS events, or the result of ECLS itself, cannot be ascertained.[172] In a recent 2-year follow-up study of ECLS performed in patients younger than 5 years of age, 46% survived to discharge and 41% were alive at the 2-year assessment.[174] Neurodevelopmental concerns were identified in most survivors, with a mean mental score of 73 ± 16, mental delay in 50% of survivors, and motor or sensory disability in 12%.

In an evaluation of patients who had undergone ECLS for resuscitation during cardiopulmonary resuscitation, 22% of patients had acute neurologic injury, defined as brain death, brain infarction, or intracranial hemorrhage identified by ultrasound or computerized tomography imaging. Brain death occurred in 11%, cerebral infarction in 7%, and intracranial hemorrhage in 7%. The in-hospital mortality rate in patients with acute neurologic injury was 89%. During ECMO, neurologic injury was associated with ECMO complications such as pulmonary hemorrhage, dialysis use, and cardiopulmonary resuscitation. Pre-ECMO factors, including cardiac disease and pH greater than 6.8, were associated with decreased odds of neurologic injuries. In a review of adults resuscitated from cardiac arrest with ECLS, overall survival was 27%, with brain death occurring in 28% of nonsurvivors. Pre-ECLS factors, such as higher Pa_{O_2}, lower Pa_{CO_2}, ECLS finding of pH less than 7.2, need for renal replacement therapy, and development of hyperbilirubinemia or central nervous system injury on ECLS, were associated with poor outcome.[175,176]

Among adult patients who received venovenous ECLS for respiratory compromise, a follow-up study of twenty-one patients noted that pulmonary function was at least 80% of normal. Quality-of-life measurements revealed that patients were adversely affected as compared to normal, although most had returned to work. Several other studies also note good recovery after ECLS survival.[177] Follow-up studies of patients from the CESAR trial will add much in terms of neurodevelopmental function in adult ECLS survivors.

Longer-term evaluation of patients surviving ECLS and comparison to patients with similar disease severity and diagnosis is imperative to adequately interpret neurologic outcome.[178–183]

THE FUTURE

The current extension of ECLS systems to older pediatric and adult patients in various clinical settings highlights the changes that have occurred in this environment. Progress in renal replacement, liver support, and plasmapheresis, and the development of new cardiac support devices applicable to pediatrics, may further expand the use of ECLS

techniques. Additionally, the development of small, portable systems for cardiopulmonary resuscitation may herald a new age of ECLS and make interhospital transport easier, safer, and more available.[184–186] Single-site, double-lumen catheters for venovenous ECMO may obviate the risks of arterial cannulation and offer the benefit of requiring only one surgical site for venous access. Heparin-bonded circuits may decrease the need for systemic anticoagulation and the risk of hemorrhagic complications.[92,184,187] Given the myriad adverse events associated with mechanical ventilation, the thought that extracorporeal gas exchange may obviate the need for intubation in respiratory failure has been suggested. Until the day when medical science may make the need for ECLS obsolete, research into ways to make it safer and more efficient should continue.[188]

EXTRACORPOREAL CARBON DIOXIDE REMOVAL

Antonio Pesenti

Michela Bombino

ARTIFICIAL ORGANS FOR RESPIRATORY FAILURE

Extracorporeal carbon dioxide removal ($ECCO_2R$) refers to a technique of life support focused on the removal of CO_2 from blood rather than improving blood oxygenation.[1] This chapter introduces the concept of $ECCO_2R$ and discusses some of the experience and future on this exciting topic. $ECCO_2R$ has been developed mainly with a view to applying it in patients with the most severe form of acute respiratory distress (ARDS).[2] We will try, however, to widen the perspective to cover also the possible role of $ECCO_2R$ in the prevention of hyaline membrane disease[3] and in the treatment of severe asthma,[4–8] multiple bronchopleural fistulas,[9–10] and severe chronic obstructive pulmonary disease.[11]

The mainstay of supportive treatment in ARDS is mechanical ventilation, a lifesaving procedure introduced in the management of patients with bulbar polio in the great epidemic that struck Copenhagen in 1952. These patients, paralyzed by polio, required long-term artificial ventilation;[12] they became the first critical care patients. The use of mechanical ventilators later was extended to all patients with severe acute respiratory failure, whose main problem often was altered gas exchange and not respiratory muscle weakness or paralysis. The critical care profession witnessed both the pros and cons of optimizing gas exchange through use of the ventilator: The focus shifted from high to low tidal volumes, from high to low airway pressures, and from high to lower inspired oxygen fractions (FI_{O_2}). It is provocative to consider how we support the failing lung. In ARDS, we use an artificial organ (the ventilator), which is designed to substitute for the respiratory muscles rather than to act as a gas exchanger. Technology has been the limiting factor for a widespread application of artificial gas exchange,[13] but research and development continues at a promising pace.

Membrane Oxygenators, Membrane Gas Exchange, and Membrane Lungs

Extracorporeal oxygenation was first provided as a heart–lung machine to render major cardiovascular surgery feasible and safe.[14] The first oxygenators were based on bubbling of oxygen through the blood or filming of blood in an oxygen atmosphere. To avoid the problems caused by the direct contact between blood and gas,[15,16] Kolff designed a membrane oxygenator,[17] which Clowes[18] and Kolobow[19] developed further into clinically applicable membrane gas exchangers.[20–22] Attention was focused on extracorporeal oxygenation, and the term *extracorporeal membrane oxygenation* (ECMO) was coined. Very little attention was paid to concurrent CO_2 removal: Hypocapnia was recognized as a common annoyance to be prevented by adding CO_2 to the gas ventilating the oxygenator.

Pioneers

In 1967, Ashbaugh et al[23] described ARDS. Soon this became a very common diagnosis in critical care, and mechanical ventilation moved to center stage as the main supportive therapy.[24] To optimize oxygenation, tidal volumes of 10 to 15 mL/kg were recommended, levels of positive end-expiratory pressure (PEEP) ranged from 5 to 60 cm H_2O.[25,26] With these ventilator settings, patients with ARDS experienced high inspiratory pressures and gross disruption of lung parenchyma. Barotrauma was common.[27–29] In 1972, Hill et al[30] published the first successful ECMO application in a patient with ARDS. Over the next few years, 217 patients with acute respiratory failure were supported with ECMO.[31] In 1973, a group of pioneers initiated a National Institutes of Health (NIH)-sponsored randomized trial of ECMO in severe ARDS. The entry criteria (Table 21-1) were intended to enroll a population with a 70% mortality rate. In fact, final mortality was 90% in both the control and ECMO groups.[32] The NIH-ECMO study proved that long-term extracorporeal life support was feasible, but it did not show any benefit on survival. Consequently, adult ECMO almost stopped,[33] with the exception of a few centers, such as the one where Bartlett conducted innovative studies on extracorporeal life support in infants and adults.

Meanwhile, astute observers pondered the question: Why did the NIH-ECMO study fail?[34]

Why Did the National Institutes of Health Extracorporeal Membrane Oxygenation Study Fail?

ECMO was aimed at buying time for the lung to rest and heal.[35] This could not be achieved under the persisting damage caused by high tidal volumes and pressures, however. Lung management in the ECMO group was not much different from that in the control group; this fact could explain the similarities in survival.[34] The choice of a venoarterial bypass, aimed in part at lowering pulmonary blood flow and pulmonary artery pressure, might have contributed to severe

TABLE 21-1: EXTRACORPOREAL MEMBRANE OXYGENATION ENTRY CRITERIA: $Pa_{O_2} \leq 50$ mm Hg (REPEATED THREE TIMES)

Study Entry Speed	Entry Testing Period (hours)	FI_{O_2}	PEEP, cm H_2O	Qs/Qt	Pa_{CO_2} mm Hg	ICU Care Duration Before Entry Testing (hours)
Rapid	2	1.0	≥5	—	30 to 45	—
Slow	12	≥0.6	≥5	≥0.3	30 to 45	≥48

ECMO EXCLUSIONS

Contraindication to anticoagulation (e.g., gastrointestinal bleeding, recent cerebrovascular accident, chronic bleeding disorder)
Pulmonary artery wedge pressure >25 mm Hg
Mechanical ventilation >21 days
Severe chronic systemic disease or another clinical condition that in itself greatly limits survival, for example,
- Irreversible central nervous system disease
- Severe chronic pulmonary disease (FEV_1 < 1 L, FEV_1/FVC < 30% of predicted, chronic Pa_{CO_2} > 45 mm Hg, chest X-ray evidence of overinflation or interstitial infiltration, previous hospitalization for chronic respiratory insufficiency)
- Total body surface burns >40%
- Rapidly fatal malignancy
- Chronic left-ventricular failure
- Chronic renal failure
- Chronic liver failure

maldistribution of pulmonary blood flow. In turn, this might have deprived the lungs of enough blood flow to defend against the damage of high-tidal-volume, high-pressure ventilation.[36]

THE CONCEPT OF EXTRACORPOREAL CARBON DIOXIDE REMOVAL

In 1976, Kolobow et al[1] noted that membrane oxygenators more appropriately constituted membrane lungs than just oxygenators. They observed that a membrane lung can exchange CO_2 much more easily than it can oxygenate blood. They explored the potential of $ECCO_2R$ in a series of innovative experiments.

DISSOCIATING RESPIRATORY FUNCTIONS

Blood oxygenation and CO_2 removal take place through different mechanisms.[37] When normal venous blood reaches the lungs, its mixed venous oxygen tension (Pv_{O_2}) is typically 47 mm Hg, and mixed venous carbon dioxide tension (Pv_{CO_2}) is 43 mm Hg (Fig. 21-1). Let us assume that oxygen consumption and CO_2 production amount to 250 and 200 mL/min, respectively. The hemoglobin carried in venous blood (150 g/L) is normally 70% to 85% saturated; the lungs therefore can add just 40 to 60 mL of oxygen per liter of venous blood. Thus, to fulfill the requirements for oxygenation, we need a blood flow of at least 4 to 7 L/min. Note that ventilation is not required to oxygenate blood, whereas what is strictly needed is enough oxygen to compensate for its consumption and maintain a constant alveolar concentration. In summary, oxygenation requires a high blood flow (4 to 7 L/min) and a small supply of oxygen (250 mL/min). The opposite applies to CO_2 removal. Pv_{CO_2} content is at least double the maximum O_2 content (Fig. 21-2). Consequently, the normal CO_2 production per minute can be removed easily from less than 1 L of blood, provided that ventilation is high enough.

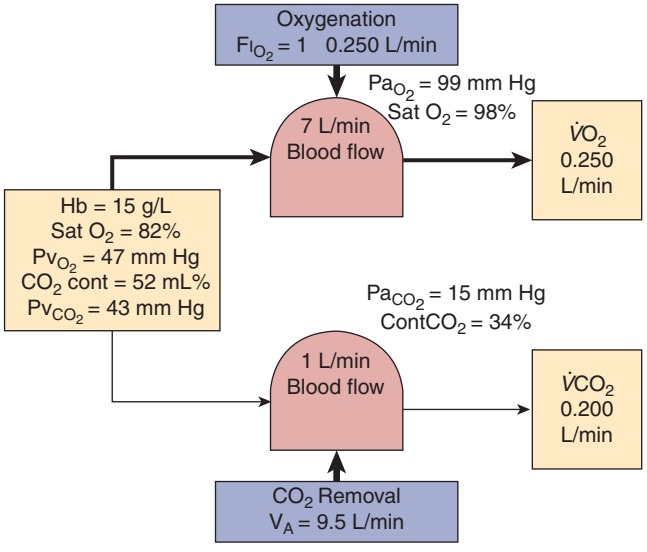

FIGURE 21-1 Dissociation of oxygenation and CO_2 removal. For normal mixed venous blood (v), oxygenation requires normal pulmonary blood flow and a continuous O_2 supply equal to O_2 consumption (250 mL/min in this example) without any ventilation. Removal of CO_2 can be accomplished by a reduced pulmonary blood flow if this is matched by a sufficiently high alveolar ventilation. (Reproduced, with permission, from Gattinoni L, Pesenti A, Kolobow T, Damia G. A new look at therapy of the adult respiratory distress syndrome: motionless lungs. *Int Anesthesiol Clin.* 1983;21:97–117.)

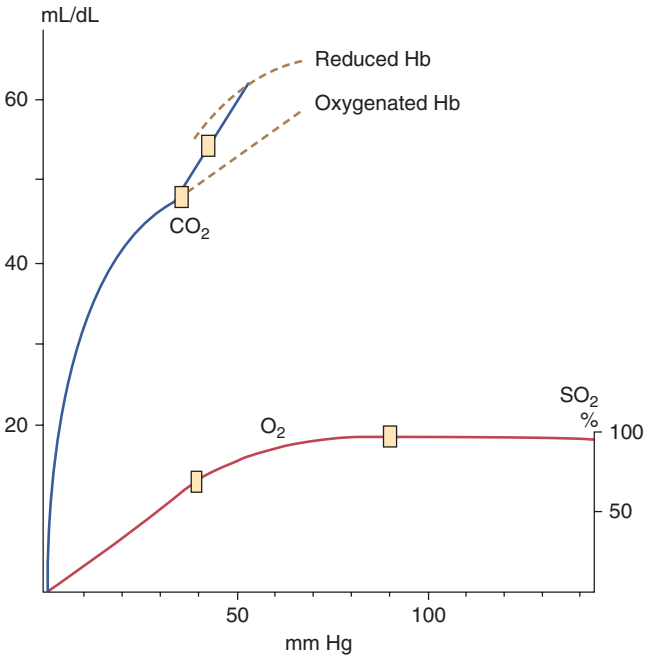

FIGURE 21-2 Gas dissociation curves for O_2 and CO_2 in blood. The *solid rectangles* represent arterial and mixed venous blood points. The line connecting the CO_2 dissociation curves for reduced and oxygenated hemoglobin (*Hb*) represents the nominal in vivo CO_2 dissociation curve as mixed venous blood becomes oxygenated in the lung (Haldane effect).

In conclusion, oxygenation requires a high blood flow, whereas CO_2 removal can be achieved at low blood flows. Kolobow et al[38] exploited the concept that if CO_2 is removed by a membrane lung through a low-flow, high-ventilation venovenous bypass, then oxygenation can be maintained by the natural lung without any ventilatory constraint. Physicians now had an opportunity to adjust the ventilator settings free of the constraints of tidal ventilation.

EXTRACORPOREAL CARBON DIOXIDE REMOVAL AND THE CONTROL OF SPONTANEOUS BREATHING

When CO_2 was removed by the membrane lung, unsedated lambs decreased their spontaneous ventilation, reducing both respiratory frequency and tidal volume.[39] Changes in

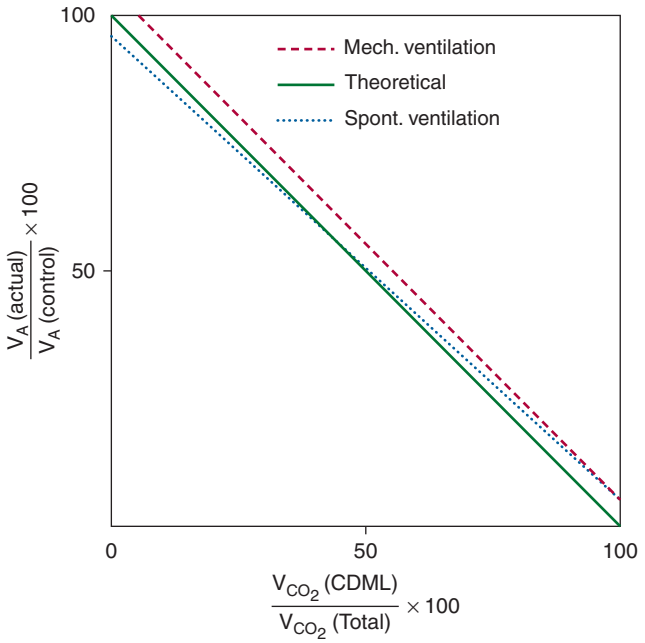

FIGURE 21-3 Alveolar ventilation (percent of control values) as a function of extracorporeal CO_2 removal (percent of total CO_2 production, i.e., V_{CO_2} of carbon dioxide membrane lung [CDML] plus natural lung). The theoretical values are computed assuming that Pa_{CO_2} and total V_{CO_2} are constant throughout the procedure. (Reproduced, with permission, from Gattinoni L, Pesenti A, Kolobow T, Damia G. A new look at therapy of the adult respiratory distress syndrome: motionless lungs. *Int Anesthesiol Clin.* 1983;21:97–117.)

alveolar ventilation were highly predictable, targeted toward a constant pH and Pa_{CO_2}. The greater the removal of CO_2 by the membrane lung, the greater was the decrease in alveolar ventilation (Fig. 21-3). The amount of CO_2 excreted by the natural lung decreased to maintain the total CO_2 removal (sum of membrane lung plus natural lung) constant and equal to the rate of CO_2 production by the body.

We can postulate that the control of spontaneous breathing in chronic obstructive pulmonary disease patients, while resetting the CO_2 balance with extracorporeal removal. Could be easy to achieve and predictable. We have experience about the control of respiratory drive in patients with ARDS during their recovery phase, when extracorporeal CO_2 removal can be titrated to the needs of the patient until weaning is completed.[40] Unfortunately, very little is known about the impact of $ECCO_2R$ upon the respiratory drive in the acute phase of ARDS.

Apneic Oxygenation

When CO_2 production is entirely removed by a membrane lung, then ventilation is no longer needed. The lung can be kept motionless, provided the alveolar oxygen concentration is kept constant by continuously supplying oxygen to match the body's O_2 consumption.[38] This process, known as *apneic oxygenation,*[41] is otherwise normally limited by the CO_2 rise. In this case, the membrane lung avoids an increase in CO_2. Apneic oxygenation therefore can be maintained at will by $ECCO_2R$: The lung can be kept completely motionless, the ultimate goal being lung rest and recovery.

Low-Frequency Positive-Pressure Ventilation

A decrease in respiratory compliance and functional residual capacity was noticed during apneic oxygenation. This led to the introduction of low-frequency positive-pressure ventilation (LFPPV). LFPPV with $ECCO_2R$[42] is simply apneic oxygenation to which a few (deep) breaths (sighs) per minute are added. With LFPPV-$ECCO_2R$, respiratory compliance and functional residual capacity can be maintained at baseline for days or weeks.

Alveolar Partial Pressure of Oxygen Control during $ECCO_2R$

During $ECCO_2R$, the respiratory quotient (R), that is, the ratio of CO_2 removal from the natural lung to oxygen uptake, changes according to the amount of CO_2 removed by the membrane lung. If baseline R equals 1, when we remove 50% of the body's CO_2 production by $ECCO_2R$, the new R of the natural lung will be 0.5. This affects alveolar oxygen tension (PA_{O_2}), which follows Riley's alveolar gas equation: At any given FI_{O_2}, when R decreases, PA_{O_2} decreases. Figure 21-4 shows the changes in FI_{O_2} required to maintain a constant PA_{O_2} at varying R values. Note that Pa_{CO_2} is held constant through the effect of $ECCO_2R$.[37]

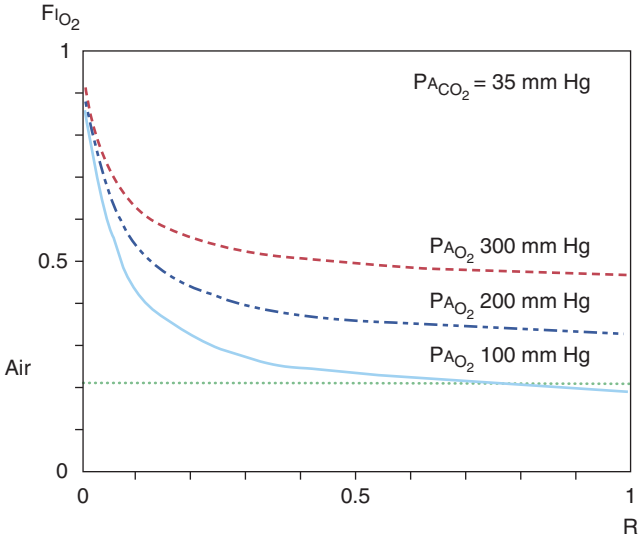

FIGURE 21-4 FI_{O_2} required to maintain a PA_{O_2} of 100, 200, and 300 mm Hg at constant Pa_{CO_2} as function of pulmonary respiratory quotient (R) according to Riley's alveolar air equation. (Reproduced, with permission, from Gattinoni L, Pesenti A, Kolobow T, Damia G. A new look at therapy of the adult respiratory distress syndrome: motionless lungs. *Int Anesthesiol Clin.* 1983;21:97–117.)

When $ECCO_2R$ equals 100% of the CO_2 produced by the body, then alveolar ventilation is nil, and FI_{O_2} must be raised to 1 to compensate for oxygen consumption. This does not at all mean that the alveolar oxygen concentration must be 100%. At this extreme of physiology, the gas mixture ventilating the membrane lung is of the utmost importance. At a steady state and during apneic oxygenation, the only gas exchange taking place in the lung is oxygen consumption. No nitrogen, CO_2, or water exits or enters the alveolar gas. If the gas ventilating the membrane lung is 100% humidified oxygen, then alveolar gas will be 100% oxygen minus CO_2 and water. If nitrogen (N_2) is added to the gas ventilating the membrane lung, then mixed venous blood P_{N_2} will equilibrate with P_{N_2} of the gas in the membrane lung, causing a corresponding change in PA_{O_2}.[38] During apneic oxygenation, despite the need to keep FI_{O_2} at 1, PA_{O_2} will be determined by the P_{N_2} of gas in the membrane lung. The role of membrane lung P_{N_2} in preventing reabsorption atelectasis during $ECCO_2R$ is entirely speculative but based on accepted physiology.[43]

Because of the Haldane effect, Pa_{CO_2} (and Pa_{CO_2}) will be higher than Pv_{CO_2} secondary to changes in the CO_2 dissociation curve related to the oxygenation of hemoglobin. During $LFPPV\text{-}ECCO_2R$, PA_{O_2} is mostly regulated by FI_{O_2}. If a continuous oxygen flow is added to compensate for oxygen consumption taking place between breaths, then many factors come into play. Experimental data exemplify the complexity of these mechanisms.[44]

RATIONALE FOR EXTRACORPOREAL CARBON DIOXIDE REMOVAL USE IN ACUTE RESPIRATORY DISTRESS SYNDROME

The goals of $ECCO_2R$ are different from those of the 1974 to 1977 ECMO trial[32] (Table 21-2). The reasons for these differences are rooted in ARDS pathophysiology. As already outlined, mechanical ventilation was developed by many workers[45–52] who pointed out how positive pressure and tidal volume interact in optimizing oxygenation. At the same time, however, the dangers and drawbacks of mechanical ventilation became apparent.[27] This was no surprise. Teplitz, a U.S. Army pathologist during the Vietnam War, described ARDS as "an end-stage pathologic picture which ... is not a new disease process ... but a result of iatrogenic modification of the pathology of noncardiogenic pulmonary edema." This view underlined the interaction between the original insult and the evolution and damages caused by treatment.[53]

Pontoppidan[50] suggested a tidal volume of 12 to 15 mL/kg as ideal for patients with ARDS. He also issued warnings[27–29] about the side effects of continuous positive-pressure ventilation and the appearance of lung damage related to high FI_{O_2}, high pressure, and high volumes.

In the late 1970s and early 1980s, the deleterious effects of mechanical ventilation were elucidated, and the concept of barotrauma evolved to that of volutrauma.[54,55] A third mechanism of damage was proposed later: the release of inflammatory mediators from the ventilated lung, leading eventually to multiple-organ failure and possibly death.[56–60] The term *ventilator-induced lung injury* became popular. In the meantime, a revolutionary idea was gathering momentum: Why strive to maintain a normal Pa_{CO_2} in patients with ARDS? Trying to achieve this goal can damage the lung severely, whereas accepting a higher than normal Pa_{CO_2} may induce only minor side effects. In 1990, Hickling et al[61] reported a better outcome by lowering tidal ventilation and tolerating high Pa_{CO_2} levels. They proposed the term *permissive hypercapnia,* indicating the price to be paid for limiting barotrauma. The targets of gas exchange in ARDS changed quickly.[62] A similar approach had been suggested previously for severe asthma.[63]

Several studies were performed to investigate the effects of lung-protective (low-pressure, low-tidal-volume) ventilation.[64–69] Only two studies[64,66] demonstrated benefit, but their effect has been striking. For the first time, the mode of ventilation was shown to affect outcome. One limitation with lung-protective ventilation, however, is hypercapnia. In selected patients, low-flow $ECCO_2R$ offers a very powerful tool for overcoming these limitations while offering total lung rest.

Hypoxemia, however, is the main characteristic of ARDS. Supportive therapy in ARDS is directed to its relief because hypoxemia is a major determinant of organ dysfunction and even may be the direct cause of death. Mechanical ventilation can be tailored to correct hypoxemia primarily by increasing FI_{O_2} and airway pressures.[70] Use of high airway pressure, however, is limited by several factors mainly related to hemodynamics and barotrauma. The solution is often to decrease tidal volume and increase frequency; this solution culminates in the use of high-frequency ventilation or oscillation.

TABLE 21-2: NATURAL (PATIENT) LUNG TREATMENT AND GOALS: ECMO VERSUS $LFPPV\text{-}ECCO_2R$

	ECMO[32]	$LFPPV\text{-}ECCO_2R$
GOALS		
Ventilation	Minimize FI_{O_2}, TRADITIONAL V_T	Minimize FI_{O_2}, LUNG REST
Extracorporeal circulation	Arterial Oxygenation	CO_2 removal (to rest the lung)
TREATMENT		
Lung ventilation	$V_T = 0.6$ L $P_{PEAK} = 50$ cm H_2O PEEP = 10 cm H_2O VR = 15/min	V_T low $P_{PEAK} = 35$ to 40 cm H_2O PEEP = 17 cm H_2O VR = 2 to 4/min
Lung perfusion	Low (0.1 Q_t)	High (all Q_t)

P_{PEAK}, peak airway pressure; Q_t, cardiac output; *VR*, ventilator rate; V_T, tidal volume.

With high-frequency oscillation, the mean airway pressure is in principle much higher than during positive-pressure ventilation. High-frequency ventilation has proven safe and effective in the treatment of adult patients with ARDS.[71–73] Use of high airway pressures, however, combined with inspiratory pressure limitation may lead to insufficient carbon dioxide removal.

In summary, the major aims of $ECCO_2R$ are to prevent ventilator-induced lung injury and barotrauma by limiting the ventilation in a nonhomogeneous lung, to put the lung to rest, and to foster healing while maintaining a selected Pa_{CO_2}. In addition, $ECCO_2R$ enables the application of a constant mean airway pressure targeted to optimal oxygenation and free of the constraints dictated by tidal ventilation.

CLINICAL APPLICATIONS: VENOVENOUS BYPASS

To the present time, the main indication for $ECCO_2R$ is severe ARDS secondary to a potentially reversible cause.[74,75] Generally accepted contraindications to extracorporeal life support and $ECCO_2R$ include the presence of significant bleeding, surgery in the preceding 72 hours, severe brain damage, uncontrolled severe sepsis, unresolved malignancies, severe chronic systemic disease, and ARDS of a known irreversible origin.

Bypass Technique

In 1979, Gattinoni et al[2] reported the use of LFPPV-$ECCO_2R$ in an adult patient with ARDS. The technique involved venovenous bypass: The common femoral and jugular veins were cannulated both distally and centrally through surgical cutdowns. The wounds and the multiple cannulation involved continuous oozing of blood and limitations in nursing care and patient mobility.[76] Subsequently, we developed a double-lumen cannulation of the femoral vein that allowed a single cutdown.[77] With saphenosaphenous bypass,[78] surgery became very superficial and distal drainage was unnecessary. The number of cannulas therefore was reduced to two. The most significant improvement in cannulation, however, came with the springwire-reinforced percutaneous cannulas,[9,79] which are placed by a modified Seldinger technique,[80] with a shorter procedure time, practically no bleeding, a reduced risk of cannulation-site infection, and very simple decannulation.

Blood flow is normally kept at 15% to 30% of the patient's cardiac output. The system must have a capability of running at 50 to 60 mL/kg/min should we need to substitute for the natural lung oxygenation (Fig. 21-5).

Our current standard includes the use of two springwire-reinforced percutaneous femoral cannulas (20F to 28F), a centrifugal pump, and a plasma tight hollow-fiber polymethylpentene oxygenator. The entire circuit is surface heparinized to minimize the need for systemic anticoagulation.[81–83]

Anticoagulation

Following an initial 50 to 100 IU/kg intravenous heparin bolus at the time of cannulation, heparin infusion is started, aiming at the selected activated clotting time (150 to 200 seconds in the case of Jostra Bioline surfaces). Surface-heparinized circuits can even be run without any systemic anticoagulation[84] for at least 12 to 48 hours as needed to stop or prevent incidental bleeding. Antithrombin III activity is maintained around 100% to promote surface-bonded and intravenous heparin function. Platelets are transfused when lower than 50,000/μL. When heparinized surfaces are not in use, activated clotting time and/or partial thromboplastin times of 1.5 to 2 times normal must be maintained at all times.

Clinical Management

$ECCO_2R$ normally is started in a sedated, paralyzed patient. After the initial adjustments (which normally take 1 to 2 hours), the ventilator is set to provide a low-frequency sigh over a baseline constant PEEP (e.g., using intermittent mandatory ventilation or biphasic positive airway pressure). PEEP is adjusted to maintain mean airway pressure at the prebypass level and to prevent acute worsening of lung edema. A catheter inserted into the inspiratory line provides a constant oxygen supply and constant PEEP during the long expiratory pause. As soon as possible, attempts are made to reestablish spontaneous respiratory activity, most often in the form of pressure supported breathing with an intermittent sigh (e.g., biphasic positive airway pressure plus assisted breathing or intermittent mandatory ventilation plus pressure support).

Hemodynamics are not affected by the venovenous bypass. Changes in lung function can be followed with venous admixture measurements. Very high values of mixed venous saturation and arterial O_2 saturation suggest decreased cardiac output with an increased proportion of extracorporeal blood flow/total cardiac output. When lung function improves, weaning is attempted by decreasing FI_{O_2} and PEEP and by decreasing the CO_2 removal from the membrane lung.[40] When necessary, the extracorporeal circuit setup allows low-flow venovenous $ECCO_2R$ to be converted into high-flow venovenous ECMO, and management then is focused on achieving a viable oxygenation despite an extremely reduced or even absent natural-lung oxygen transfer.

Complications of Venovenous $ECCO_2R$

We have never stopped $ECCO_2R$ because of a technical accident. From day to day, however, various changes of circuit elements may be required, mainly involving the membrane lung and/or the centrifugal pump(s).

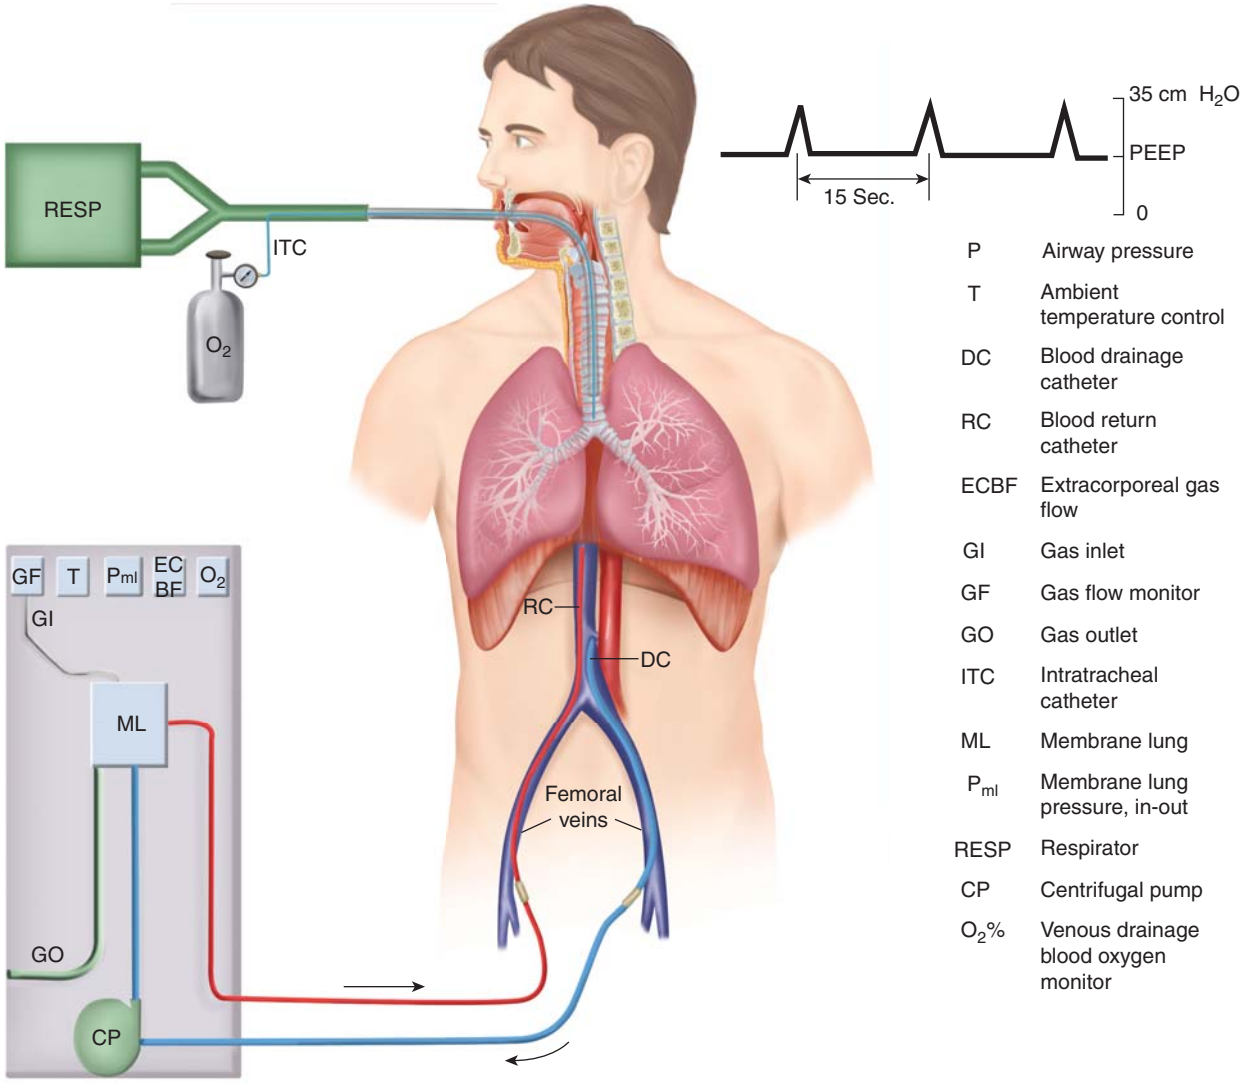

FIGURE 21-5 LFPPV-ECCO$_2$R circuit. (Reproduced, with permission, from Gattinoni, et al. *JAMA*. 1986;256:881–886,. Copyright © 1986 American Medical Association. All rights reserved.)

Bleeding always has been the major complication with extracorporeal life-support techniques. The NIH-ECMO study reported an average blood-product transfusion of 3575 mL/day.[85] In 1986, we reported[86] an average blood-product requirement of 1.8 L/day in our first forty-three patients. The use of percutaneous cannulation coupled with heparinized surfaces decreased the packed-red-cell requirement to 200 to 300 mL/day.[75] Bleeding from the chest drainage tubes is a major complication that often demands a surgical approach.[87] The major threat posed by extracorporeal support remains intracranial hemorrhage. We reported that a prebypass Pa_{CO_2} of greater than 75 mm Hg, disseminated intravascular coagulation, or a positive brain computed tomographic scan before bypass increase the risk of fatal intracranial hemorrhage during bypass.[75]

Clinical Results in Acute Respiratory Distress Syndrome Patients

It is difficult to isolate from the literature the experience with venovenous ECCO$_2$R because of undefined boundaries between venovenous ECCO$_2$R, venovenous ECMO, and partial extracorporeal CO_2 removal (PECO$_2$R).[40] ECCO$_2$R refers more to a way of managing the diseased lung rather than to technical details, and the flexible handling of the circuitry is one of the advantages of ECCO$_2$R. The technique can shuttle back and forth between venovenous ECCO$_2$R, venovenous ECMO, and PECO$_2$R in the same patient.

Table 21-3 is an attempt to collect the available experience on ECCO$_2$R, defined as such by authors, including our own data (see also Table 21-4). At the time of writing, patients

TABLE 21-3: VENOVENOUS $ECCO_2R$ FOR ARDS: INTERNATIONAL EXPERIENCE

Author (Ref.)	Year	Center	No. Patients	Survivors	% Survival
Wagner (87)	1990	Marburg (Germany)	76	38	50%
Bindslev (82)	1991	Stockolm (Sweden)	14	6	43%
Brunet (121)	1993	Paris (France)	23	12	52%
Morris (88)	1994	Salt Lake City (USA)	21	7	33%
Guinard (122)	1997	Paris (France)	10	4	40%
Gattinoni, Pesenti	2008	Milan, Monza (Italy)	124	49	40%
Total			268	116	43%

with severe ARDS are still starting on $ECCO_2R$ later and later in their illness. Whether this is wise, we have our doubts. Moreover, the time spent on bypass gets increasingly longer (139 days for our longest survival run), probably indicating increases in unmeasured elements of disease severity at the time of connection. Despite these considerations, many patients with ARDS suffer from complications related to ventilator-induced lung injury and are doomed to an unfavorable outcome. ARDS carries a substantial mortality, 31% to 39.8% in the ARDS Network studies.[66]

Only one controlled, randomized trial has been conducted on the effect of LFPPV-$ECCO_2R$ in patients with severe ARDS.[88] The investigators enrolled forty patients meeting the original NIH-ECMO entry criteria. Nineteen patients were randomized to LFPPV-$ECCO_2R$ and twenty-one to control mechanical ventilation. Survival was equivalent in the two groups: seven survivors in the $ECCO_2R$ and eight in the control group. The investigators and accompanying editorialists[89] concluded that extracorporeal support is not recommended in ARDS.

A more balanced interpretation of this study, however, must take into account several considerations.[90–92] The incidence of uncontrollable bleeding, leading to premature interruption of the treatment in seven of nineteen patients, was extremely high. More surprisingly, of seven $ECCO_2R$ survivors, five had been disconnected as an emergency because of severe bleeding. Average transfused blood products (packed red cells plus fresh-frozen plasma) was 3.39 L/day (4.79 L/day in the survivors). A problem in the management of blood clotting or the surgical procedure to control bleeding appears obvious when related to contemporary published experience. This study suggests that despite a high rate of catastrophic bleeding in the $ECCO_2R$ group, the net outcome was not worse in the $ECCO_2R$ group. As such, $ECCO_2R$ may prove beneficial, provided that the associated bleeding problems are handled effectively.

TABLE 21-4: OUTCOME WITH $ECCO_2R$ IN MILAN-MONZA (1979 TO 2008; ADULT PATIENTS)

	Survivors	Nonsurvivors	p

RECENT CLINICAL DEVELOPMENTS: ARTERIOVENOUS BYPASS

Venovenous $ECCO_2R$ still remains a complex procedure, reserved for centers with experience and capabilities to run it safely in very diseased patients. In an effort to simplify extracorporeal respiratory assist, Barthelemy et al[93] reported that an animal could be supported for up to 24 hours by a pumpless artery-to-vein extracorporeal system in combination with apneic oxygenation. Subsequently, Awad et al[94] demonstrated the feasibility of arteriovenous CO_2 removal ($AVCO_2R$) for up to 7 days in sheep. Young et al[95] evaluated $AVCO_2R$ in a femorofemoral arteriovenous (AV) model, both with and without a blood pump. A step forward in pumpless $AVCO_2R$ came with the design of very-low-resistance membrane lungs.[96] A pumpless system is expected to minimize the foreign-surface interactions and blood-element shear stress.

$AVCO_2R$ (also termed *interventional lung assist* [iLA] or *pumpless extracorporeal lung assist*) was studied in normal animals and in experimental lung-injury models.[97–100] Short-term feasibility and safety phase I trials were performed successfully in patients,[101] showing that an AV shunt coupled with a low-resistance membrane lung can achieve

an $ECCO_2R$ between 70% and 100% of the total CO_2 production. Reng et al[102] published a collection of ten patients treated by what they named "pumpless ECLA." In 2006, a paper from the same institution reported ninety patients with ARDS treated with $AVCO_2R$, with a survival rate of 41%.[103] The authors pointed out that the contribution of the bypass to oxygenation was moderate, while the removal of CO_2 averaged 140 mL/min allowing a consistent decrease in ventilation. The paper also reported a high rate of complications, up to 24%, mainly related to the arterial cannulation. More recently Zimmerman et al[104] reported a higher survival rate (50.9%) and fewer complications (11%) with a reduction of arterial cannula size, allowing a residual lumen equal to or greater than 30% of the vessel diameter. The iLA Registry,[105] updated to 500 cases by July 2010, mostly ARDS (268 cases, 53.6%) and chronic obstructive pulmonary disease exacerbations (125 cases, 25%), points out that early institution of iLA produces a 42% higher survival rate. We are now awaiting the results from the prospective randomized Extrapulmonary Interventional Ventilatory Support for Lung Protection in Severe Acute Respiratory Distress (Xtravent) trial that completed enrollment on January 2011.[106]

AV bypass can be established quickly, it is simple and does not require specialized personnel. The clinical application is limited to patients whose cardiovascular system can tolerate the increased cardiac output and whose arterial blood pressure can drive enough blood to achieve a sufficiently high CO_2 removal (shunt flows are 1 to 2.5 L/min). Although vasopressors can be added to increase shunt blood flow, no direct intervention is possible to otherwise regulate it. Lastly, $AVCO_2R$ consists of pure CO_2 removal: with the exception of extremely severe hypoxemia, the amount of oxygen that can be transferred to arterial blood can influence the systemic oxygenation only marginally.[107] In contrast to venovenous $ECCO_2R$, no simple conversion to ECMO is possible. The technique is fascinating and promising in its extreme simplicity, however. Very-low-resistance, surface-heparinized membrane lungs are now available for clinical use.[97]

Pumpless devices have been recently used as bridge to lung transplantation[108–110] with interesting results. The rapid implementation and extreme simplicity of the iLA system makes it suitable for the aerial transportation of critically ill patients with respiratory failure.[111,112]

NEW TRENDS: LOW FLOW PARTIAL CARBON DIOXIDE REMOVAL

The clinical application of $PECO_2R$, originally described by Marcolin et al,[40] was successfully implemented in a patient with severe and persisting bilateral bronchopleural fistulas.[9] The technique consisted of a very low flow (0.4 to 0.6 L/min) venovenous bypass, allowing a rapid liberation from mechanical ventilation to spontaneous breathing and healing of the fistulas.

More recently, Livigni[1] et al[13] described the application of a modified continuous venovenous hemofiltration circuit comprising ultrafiltrate recirculation and a membrane lung to achieve partial CO_2 removal in sheep. In 2009, Terragni et al[114] reported on the successful application of the same device to decrease tidal volume to levels lower than the standard 6 mL/kg predicted body weight (Fig. 21-6) in patients

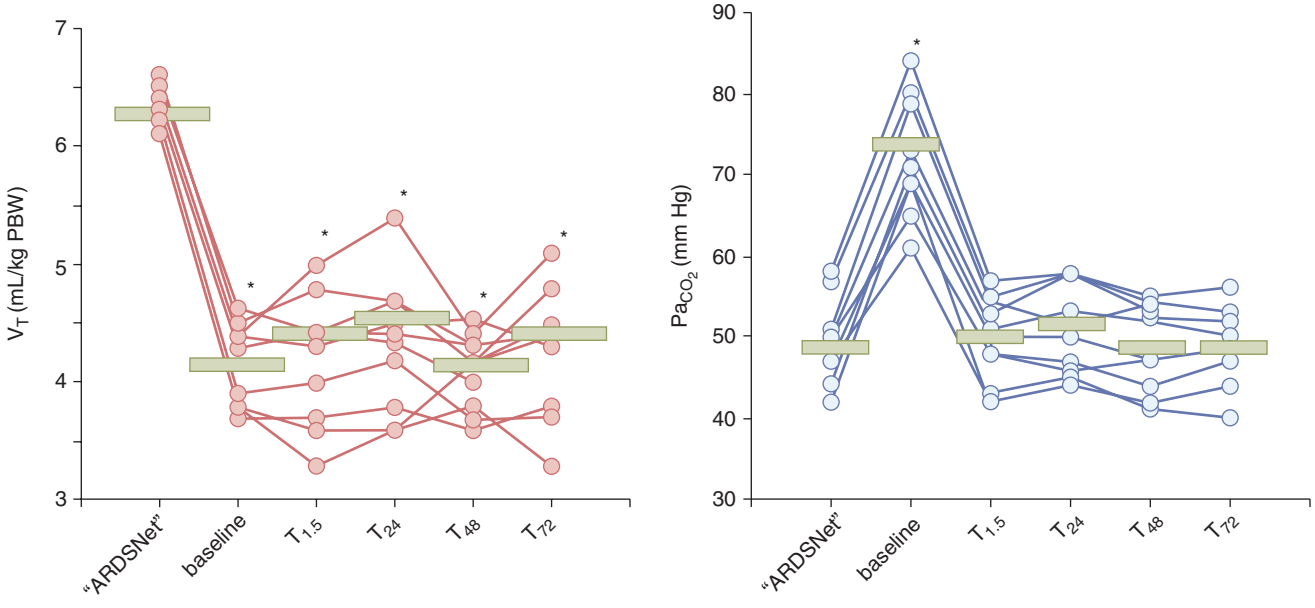

FIGURE 21-6 Individual and average (*horizontal bar*) values of tidal volume (V_T) and Pa_{CO_2} during Acute Respiratory Distress Syndrome Network ("*ARDSNet*") strategy, after lowering V_T and before initiating carbon dioxide removal (*baseline*), and 60 to 90 minutes (T1.5), 24 hours (T24), 48 hours (T48), and 72 hours (T72) after initiation of carbon dioxide removal. * P versus ARDSNet strategy. The data show how CO_2 removal is able to maintain normocapnia despite a reduced, noninjurious tidal volume. (Reproduced, with permission, from Terragni PP, Del Sorbo L, Mascia L, et al. Tidal volume lower than 6 ml/kg enhance lung protection: role of extracorporeal carbon dioxide removal. *Anesthesiology*. 2009;111:826–835.)

suffering lung hyperinflation in spite of lung-protective ventilation. The same investigator group[115] reported that at least 30% of patients with ARDS undergo lung hyperinflation despite limiting tidal volume to 6 mL/kg.

Batchinsky et al[116] successfully applied a new device (Hemolung) in swine that was able to remove a substantial proportion (72 mL/min) of an animal's CO_2 production at blood flows comparable to those used in dialysis or hemofiltration (400 to 500 mL/min). Preliminary clinical experience in five spontaneously breathing patients with chronic obstructive pulmonary disease has been recently reported.[117]

Zanella et al[118] achieved the remarkable result of a CO_2 removal of more than 150 mL/min from a blood flow of 500 mL/min in pigs. The technique includes the administration of a metabolizable acid (lactic acid) to convert blood bicarbonate to gaseous CO_2 before the membrane lung.

CONCLUSIONS

$ECCO_2R$ is a fascinating approach to the management of respiratory failure and is a powerful tool for overcoming any ventilatory problem. For patients with the most severe form of ARDS, a venovenous circuit with the possibility of shifting to modern full venovenous ECMO (if needed) may be a better solution. Venovenous $ECCO_2R$ should be limited to centers where appropriate technical skills, motivations, personnel, and experience are available.

In its purest conceptual application, $ECCO_2R$ is achieved by an arteriovenous pumpless shunt. Exciting perspectives are offered by the development of low or very low blood flow extracorporeal CO_2 removal techniques.[113–118] Their applications open up the possibility of substantially limiting the invasiveness of mechanical ventilation, to decrease the rate of failure of noninvasive ventilation, to limit the use of endotracheal intubation, and therefore substantially limit the incidence of ventilator associated pneumonia (actually an intubation-related disease). The need for increased airway pressure could be essentially covered by invasive or noninvasive continuous positive airway pressure, and sedation needs might as well be markedly decreased.

The dream of a fully awake, nonintubated, eating, drinking, and communicating patient connected to something like a hemodialysis machine, rather than a fully sedated, intubated, mechanically ventilated patient might finally have a chance of becoming true.[119,120]

TRANSTRACHEAL GAS INSUFFLATION, TRANSTRACHEAL OXYGEN THERAPY, EMERGENCY TRANSTRACHEAL VENTILATION

Umberto Lucangelo
Avi Nahum
Lluis Blanch

Clinical evidence highlights the importance of limiting airway pressure during mechanical ventilation. In addition, experimental results suggest the importance of avoiding lung overdistension and cyclic end-expiratory airspace collapse and reexpansion, indicating that both phenomena promote mechanical damage and release of inflammatory mediators.[1–3] Unfortunately, interventions that can attenuate the structural insult caused by mechanical ventilation, such as the use of low tidal volume, high positive end-expiratory pressure, and reduced respiratory rate, can limit total minute ventilation.[4,5] In this context, transtracheal oxygen therapy and tracheal gas insufflation (TGI) could have a role as adjuncts to mechanical ventilation.[6–10]

BASIC PRINCIPLES

Mechanism of Action

TGI attempts to minimize dead space by delivering fresh gas through an intratracheal catheter to flush the anatomic dead space free of CO_2. During TGI, low-to-moderate flows of fresh gas introduced near the carina, either continuously or in phases, dilute the CO_2 in the anatomic dead space proximal to the catheter tip. Because CO_2 is washed out during expiration, less CO_2 is recycled back into the alveoli during the subsequent inspiration. Any catheter flow during inspiration contributes to the inspired tidal volume (V_T) but bypasses the anatomic dead space proximal (mouthward) to

the catheter tip. At higher catheter flow rates, turbulence generated at the tip of the catheter by the jet stream can enhance gas mixing in regions distal to the catheter tip, thereby contributing to CO_2 removal.[11–14] The fresh gas stream exiting the catheter tip rapidly establishes an expiratory front beyond the catheter tip between CO_2-rich alveolar gas and CO_2-free fresh catheter gas.[13] This front is practically abolished by inverting the catheter tip and directing the catheter jet mouthward, thus eliminating the distal effect of TGI.[12] These observations indicate that the primary mechanism of CO_2 elimination during TGI is expiratory washout, and the forward-directed TGI penetrates a substantial distance into the central airways, extending the compartment susceptible to CO_2 washout with a smaller contribution of turbulence beyond the straight catheter tip. Consequently, partial pressure of arterial carbon dioxide (Pa_{CO_2}) during TGI falls as a nonlinear function of catheter flow rate. Initially, modest flow rates achieve large decrements in Pa_{CO_2}, but once the anatomic dead space is flushed free of CO_2, the effect on Pa_{CO_2} diminishes as catheter flow rate increases.[6,11]

Modes of Operation

During TGI, fresh gas can be delivered continuously, or delivery can be timed to occur in phases during a specific portion of the respiratory cycle by gating a solenoid valve that either directs the flow to the catheter or diverts it to the atmosphere.[15,16] During continuous TGI, closure of the expiratory valve during inspiration causes catheter flow to deliver variable portions of the inspired V_T.[17,18] Phasic inspiratory TGI can be used as the only source of fresh gas, thereby bypassing the anatomic dead space proximal to the catheter tip.[16] It can also be combined with a conventional ventilator to augment alveolar ventilation. During continuous or phasic inspiratory TGI, the catheter-delivered portion of the inspired V_T is a function of catheter flow rate and inspiratory time. During phasic expiratory TGI, catheter flow is timed to occur during all or part of expiration and does not contribute appreciably to the inspired V_T.

The effect of insufflating fresh gas during specific phases of the respiratory cycle has been examined under different catheter-flow conditions. Catheter flow only during inspiration (inspiratory bypass) effectively avoids the "anatomic" dead space proximal to the catheter tip (extending from the ventilator's Y piece). Insufflation during late expiration (expiratory washout) washes the proximal dead space free of CO_2. Limiting TGI to the final 60% of expiration effectively reduces Pa_{CO_2} (not different from panexpiratory TGI) while limiting exposure of the trachea to TGI gas and reducing the potential for TGI-induced hyperinflation (Fig. 22-1).[16,19,20] Although experimental studies suggest that restricting the flow of TGI gas to some portion of the expiratory phase preserves effectiveness, a rigorous engineering analysis showed that applying TGI flow solely within the final 50% of the expiratory phase yields a near maximal effect of expiratory TGI (Fig. 22-2), and this approach could simplify implementation and decrease adverse consequences.[21]

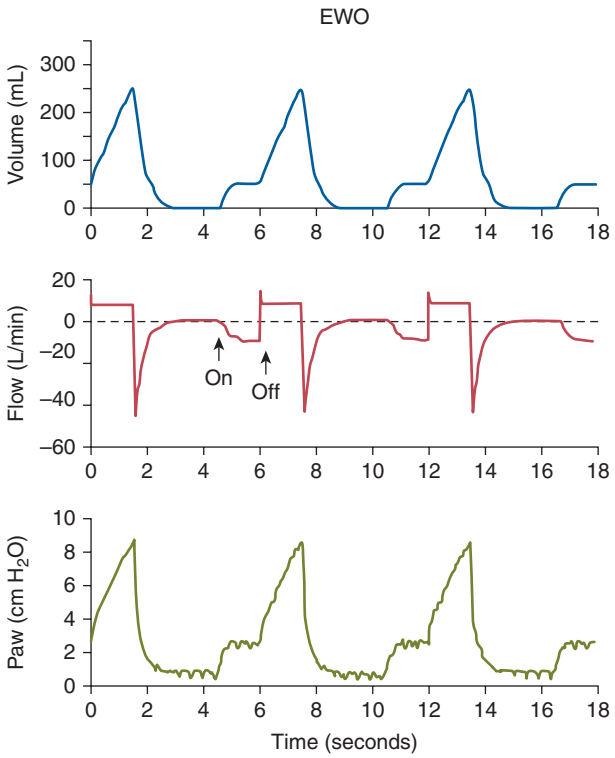

FIGURE 22-1 Simultaneous tracings during expiratory washout (EWO) at 10 L/min catheter flow. (*Above*) Plethysmographic lung volume relative to the end-expiratory lung volume measured without catheter flow. (*Center*) Flow tracing measured in the inspiratory and expiratory limbs of the external circuit. (*Below*) Proximal airway pressure. Note that lung volume and proximal airway pressure tracings show preinspiratory step changes. These deflections indicate that gas flows both antegrade (volume tracing) and retrograde (flow tracing) from the catheter tip during this period. (Used, with permission, Burke WC, Nahum A, Ravenscraft SA, et al. Modes of tracheal gas insufflation: comparison of continuous and phase-specific gas injection in normal dogs. *Am Rev Respir Dis.* 1993;148:561–568.)

Continuous TGI increases alveolar ventilation more than inspiratory bypass or late-expiratory washout.[16] Bidirectional continuous TGI delivery produces less hyperinflation than antegrade delivery, even with small diameter endotracheal tubes (ETT).[22]

PHYSIOLOGIC EFFECTS

TGI reduces anatomic dead space and increases alveolar ventilation for a given frequency and V_T combination. TGI's main effect is to enhance CO_2 removal by flushing the dead space from the carina to the Y of the ventilator circuit. The catheter and the TGI jet effect, however, oppose expiratory flow and favor air trapping at end-expiration and auto–positive end-expiratory pressure (auto-PEEP).[6,11,23–28]

TGI reduces Pa_{CO_2} during hypoventilation[16,29–32] although TGI's efficacy in lowering Pa_{CO_2} diminishes when an increased alveolar component dominates the total physiologic dead space.[18,32,33] An inverse correlation between

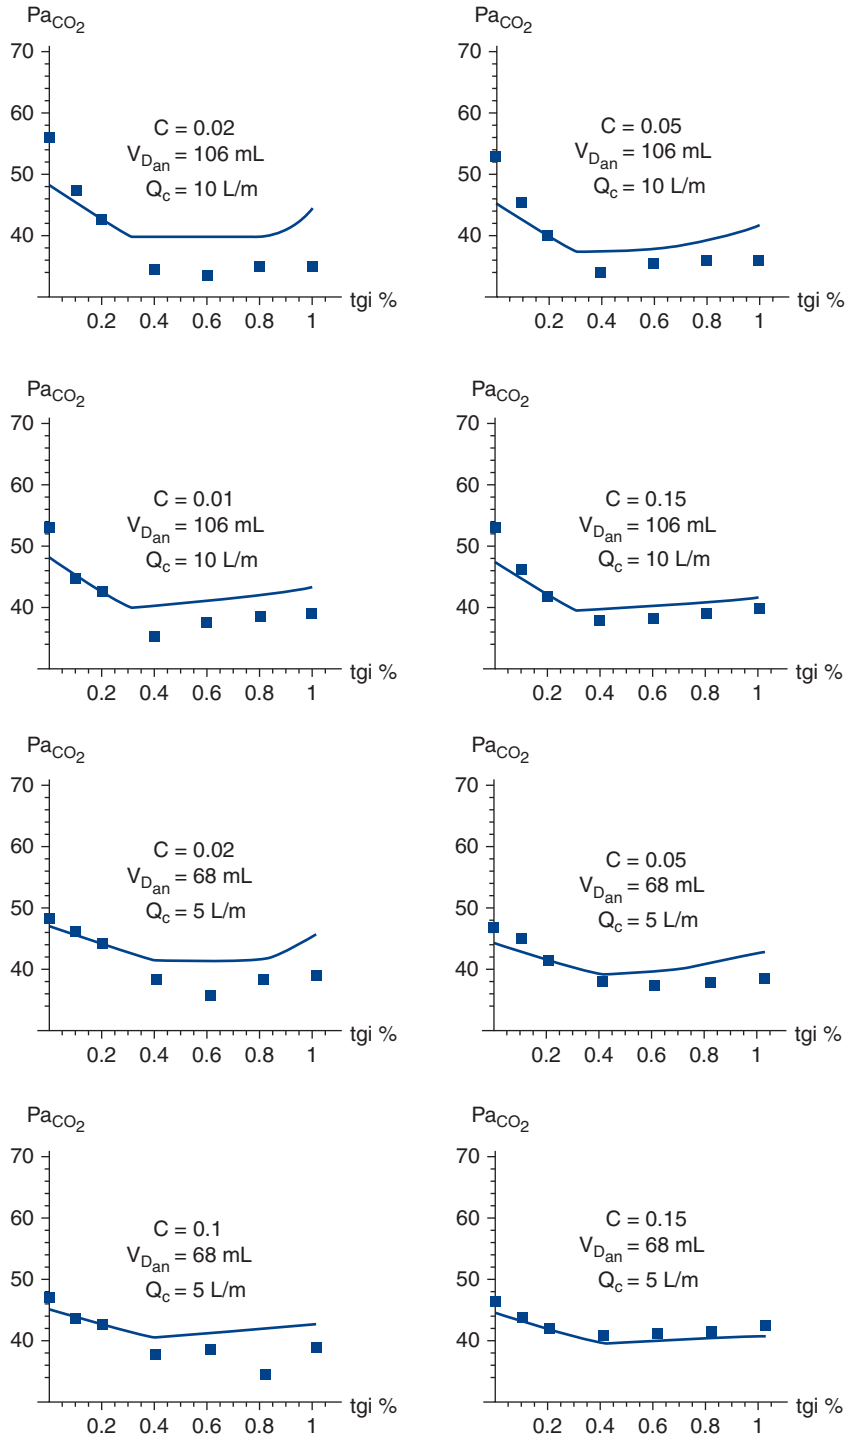

FIGURE 22-2 Partial pressure of CO_2 in alveolar gas (Pa_{CO_2}) vs. duration of tracheal gas insufflation (*TGI*) as a percentage of expiratory time. Comparison of experimental data (*boxes*) with mathematical model (*line*). V_T = 500 mL, Re = 5 cm $H_2O \cdot L^{-1} \cdot sec^{-1}$, and D = 0.33. *VT*, tidal volume; *Re*, compartmental resistance during expiration. Decreasing compliance (*C*), elevated dead space ($V_{D_{an}}$), and higher catheter flow (*Qc*) all magnify the effect of TGI on CO_2 clearance. Of particular note is that, with rare exception, the maximal decrease in Pa_{CO_2} is observed at catheter flow durations between 40% and 60% of the expiratory phase, suggesting that more prolonged application of TGI accrues little additional benefit with regards to CO_2 clearance over a broad range of impedance variables. (Used, with permission, Hota S, Crooke PS, Adams AB, Hotchkiss JR. Optimal phasic tracheal gas insufflation timing: an experimental and mathematical analysis. *Crit Care Med.* 2006;34:1408–1414.)

respiratory rate and Pa_{CO_2}[34] indicates that lower breathing frequencies (or longer expiratory times) favor TGI efficiency (reductions in Pa_{CO_2} and physiologic dead space).

Increase in lung volume is a serious limitation of TGI and should be avoided. Solutions to minimize expiratory TGI-induced auto-PEEP include using lower TGI flows, delivering TGI during pressure-controlled ventilation (PCV), and optimizing mechanical ventilation during TGI. During PCV, a TGI-induced increase in airway pressure automatically results in decreased V_T, and the lack of expiratory TGI-induced auto-PEEP is associated with less efficient CO_2 elimination. Likewise, reducing TGI flow reduces CO_2 clearance.[27,35–37]

INDICATIONS AND CONTRAINDICATIONS

Transtracheal Oxygen Therapy

Transtracheal oxygen therapy (TTO) administers gas directly into the trachea in nonintubated patients (Fig. 22-3). Long-term oxygen therapy is an established treatment for chronic lung disease with hypoxemia. Oxygen is usually delivered via a nasal cannula, irritating the nasal mucosa and the skin of the upper lip and ears. In 1982, Heimlich described a method for delivering oxygen directly into the trachea, bypassing the anatomic dead space and using the main airways as a reservoir.[38] Numerous studies have since found clear clinical benefits for TTO, including reductions in hematocrit,[39] pulmonary vascular resistance,[40] work of breathing,[41] dyspnea,[42] and incidence of cor pulmonale.[39] Other advantages are decreased oxygen cost and air pollution, decreased frequency of hospitalization, and improved exercise tolerance with better physical, psychological, and social function.[43]

FIGURE 22-3 Level of insertion and position of the indwelling tracheal catheter. (Used, with permission, Christopher KL, Schwartz MD. Transtracheal oxygen therapy. *Clin Chest Med.* 2003;24:489–510.)

THE TECHNIQUE

The Spofford-Christopher Oxygen Optimizing Program is a four-step protocol for TTO:[44]

1. Patient evaluation, selection, and procedure preparation. Refractory hypoxemia and discomfort during maximal nasal cannula therapy are specific indications. Patients with chronic obstructive pulmonary disease (COPD) must also guarantee adequate bronchial hygiene and good pharmacologic control of airway activity throughout the program.
2. A tracheocutaneous fistula is created by a modified Seldinger technique or a surgical Lipkin procedure. Low predicted compliance with treatment (as in anxious patients) and neck anatomic alterations (as in severely obese patients) are strong contraindications to the tracheocutaneous fistula. The Lipkin method has fewer complications than modified Seldinger technique.[45]
3. Tract maturation management. Patients must learn to clean the catheter and prevent inadvertent catheter displacement.
4. Mature tract management. This phase aims to prevent complications and educate the patient.

HOW TO VENTILATE THE PATIENT

The choice of equipment for oxygen supply and delivery depends on the setting (hospital or home) and on the patient's ability to move; choices for home treatment include compressed gas cylinders, liquid oxygen, and molecular sieve oxygen concentrators. TTO usually requires an oxygen flow rate ranging from 0.25 to 1.5 L/min, but flow rates up to 2.9 L/min can be delivered through larger catheters to guarantee adequate oxygenation in severe refractory hypoxemia.[46]

Oxygen flow requirements with TTO are 25-50% lower than with continuous flow therapy via a nasal cannula; 0.5 L/min of oxygen by the catheter is equivalent to 4 L/min by nasal prongs, because the tracheal effect acts as an anatomic reservoir that stores oxygen during the last part of exhalation. Oxygen flow requirements during exercise are also reduced by approximately 30% with concomitant reduction in patient sense of dyspnea. Moreover, the equipment is lighter and mobility may be improved.

COMPLICATIONS

The main complications are subcutaneous emphysema, barotrauma, and bleeding from catheter misplacement. Patients

receiving long-term TTO are at risk for catheter lumen occlusion by inspissated secretions, inadvertent catheter removal (particularly dangerous during the maturation phase), and chronic tract problems like infections and keloids.[43]

Emergency Transtracheal Ventilation

In the rare emergency situation in which it is impossible to guarantee adequate ventilation by facial mask, supraglottic device, or endotracheal intubation,[47] usually because of laryngeal stenosis, foreign bodies, tumors, or facial trauma, transtracheal ventilation is recommended.[48]

THE TECHNIQUE

Since the first report by Jacobs et al of a series of patients who were successfully ventilated in emergency conditions using a catheter placed through the cricothyroid membrane,[49] many transtracheal emergency ventilation strategies have been reported.[50] Current techniques consist of directly inserting a 14- to 18-gauge intravenous catheter between the tracheal rings or through the cricoid membrane. The device is connected to a syringe and advanced through the skin until the airway lumen is punctured. After air aspiration confirms placement, the cannula is connected to the oxygen delivery system. Percutaneous transtracheal emergency ventilation is performed; dedicated kits[51] or self-made devices can also be used.[52]

HOW TO VENTILATE THE PATIENT

Although manual or automatic jet ventilation is the reference standard for oxygen administration during transtracheal emergency ventilation, many techniques have been proposed to deliver oxygen with or without the aid of a jet valve. Commercially available resuscitation bags require great effort to ventilate through a 14-gauge catheter and make it impossible to guarantee adequate V_T.[50] Tubing that supplies oxygen can be coupled with a three-way stopcock, effectively creating a manual jet valve; however, tank and wall oxygen using flow regulators do not provide sufficient flow rates and, consequently, despite acceptable oxygenation, lead to hypercapnia. Only when the flow regulator is placed in the "wide open" position, an estimated flow of 65 L/min can be generated and physiologic V_T can be delivered.[50] Experimentally, both bidirectional manual respiration valves and active expiration using ejector-based expiratory ventilation assistance have proved useful in conditions of high expiratory resistance and occluded upper airway.[53–55]

COMPLICATIONS

Complications of transtracheal emergency ventilation mainly result from the need to operate under emergency conditions and ensure ventilation as soon as possible.[56] Bleeding and posterior tracheal wall lesions are the most common, although kinking and inability to ventilate patients have also been reported when standard intravenous catheters are used.[57] Moreover, catheters equipped with safety systems sometimes do not allow a syringe to be connected. Other complications can arise with chronic therapy (e.g., infection and tracheal stenosis).[43]

In conclusion, TTO can be an effective and safe alternative to nasal prongs for long-term home oxygen administration, and transtracheal ventilation using commercially available intravenous catheters and manual jet ventilation valves or wall oxygen supply can ensure emergency lung ventilation.

Chronic Respiratory Failure

In patients with end-stage pulmonary disease and chronic CO_2 retention, continuous insufflation of fresh gas (oxygen and/or air) through an intratracheal catheter has been used to provide continuous oxygen therapy, decrease oxygen flow requirements,[7–9,58] provide a method for oxygen delivery, decrease dyspnea, and increase exercise tolerance.[59] A continuous low flow (4 to 5 L/min) delivered to the tracheostomy tube reduces dead space, V_T, and minute ventilation without affecting Pa_{CO_2} in the acute state and maintains or reduces Pa_{CO_2} in the chronic state, presumably by reducing dead space. In patients with the most severe forms of COPD, TGI resulted in oxygen consumption and CO_2 production, as well as a less-demanding respiratory pattern.[9]

Patients with chronic respiratory failure may experience dynamic hyperinflation that may be relieved when minute ventilation decreases and expiratory time increases during high-flow insufflation. Brack et al[60] found an almost immediate decrease in end-expiratory lung volume during high-flow insufflation compared to low-flow oxygen insufflation. To investigate whether this drop in end-expiratory lung volume was caused by active expiration, they performed a Konno-Mead analysis of rib cage-abdominal volume loops. The absence of a systematic change in loop configuration and the unaffected inspiratory and expiratory asynchrony indices did not suggest increased abdominal expiratory muscle recruitment during high-flow insufflation. Therefore, the drop in end-expiratory lung volume coinciding with the reduction in minute ventilation, respiratory rate, and prolongation of expiratory time after transition to high-flow insufflation was most likely caused by the reversal of dynamic hyperinflation (Fig. 22-4).

Acute Lung Injury and Acute Respiratory Distress Syndrome

One of the most important features of TGI is that it can maintain normocapnia or a given level of Pa_{CO_2} while V_T is decreased, allowing a reduction in minute ventilation. Therefore, TGI can be used to decrease the forces acting on the lung and thereby minimize ventilator-induced lung injury in patients with acute respiratory distress syndrome (ARDS).[36,61–63]

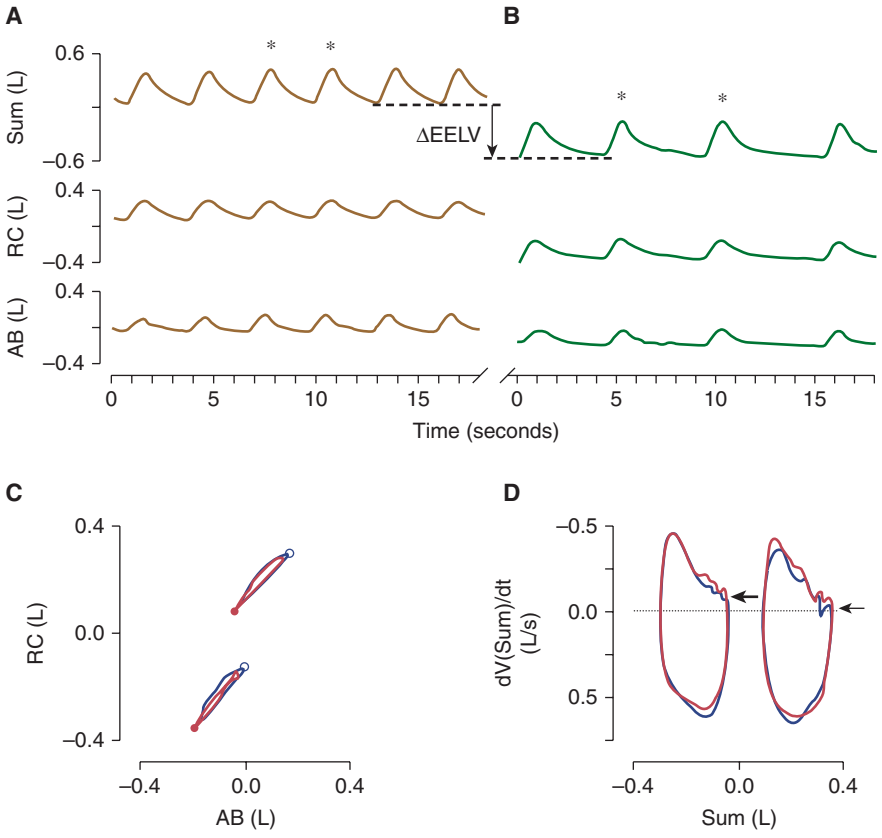

FIGURE 22-4 Time series of inductive plethysmographic rib cage (*RC*), and abdominal (*AB*) signals along with instantaneous lung volume (*Sum*) during transtracheal insufflation of oxygen at 1.5 L/min (low-flow insufflation, *top left*, *A*) and with an oxygen-air mixture at a rate of 15 L/min (high-flow insufflation; *top right*, *B*). Note the marked reduction of respiratory rate and end-expiratory lung volume (*vertical line with arrow*) during high-flow insufflation. For two breaths during low-flow insufflation and high-flow insufflation (marked with *asterisks*, respectively) rib cage versus abdominal volume loops (*bottom left*, *C*), and flow-volume loops (i.e., time derivative of the sum volume vs. the sum volume loops) (*bottom right*, *D*) are plotted. The loops at lower volumes in *bottom left*, *C*, and *bottom right*, *D*, correspond to high-flow insufflation. In *bottom left*, *C*, the major downward and minor leftward displacement of the loops with high-flow insufflation indicates that the drop in lung volume was predominantly related to deflation of the rib cage. The closed and open circles in *bottom left*, *C*, correspond to end-expiration and end-inspiration, respectively. During high-flow insufflation (*top right*, *B*), the expiratory flow approaches zero at end-expiration, as indicated by the *small, horizontal arrow* in *bottom right*, *D*. In contrast, during low-flow insufflation (*top left*, *A*), inspirations commence before expiratory flow has ceased (*large arrow*, *bottom right*, *D*), suggesting dynamic hyperinflation. (Used, with permission, Brack T, Senn O, Russi EW, Bloch KE. Transtracheal high-flow insufflation supports spontaneous respiration in chronic respiratory failure. *Chest.* 2005;127:98–104.)

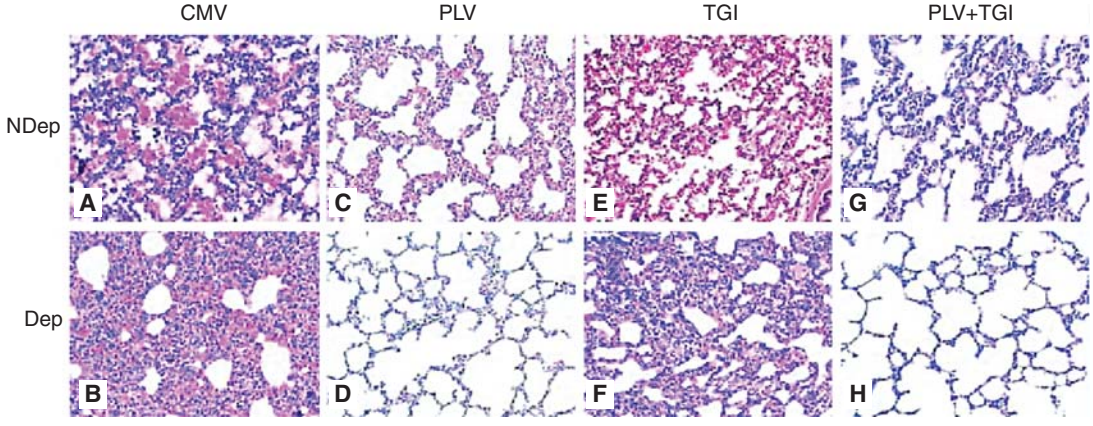

FIGURE 22-5 Representative photomicrographs (×100) of lung sections obtained at 4 hours after lung injury and stained with hematoxylin and eosin. The samples were from nondependent (*NDep*) and dependent (*Dep*) regions for mechanical ventilation (*CMV*, *A* and *B*), partial liquid ventilation (*PLV*, *C* and *D*), continuous tracheal gas insufflation (*TGI*, *E* and *F*), and combination (*PLV + TGI*, *G* and *H*) groups. Intraalveolar and interstitial inflammation and hemorrhage, atelectasis, edema, and exudation were severe, especially in the dependent regions in CMV group. Dependent region damage was significantly less in the PLV and in PLV+TGI groups. (Used, with permission, Guo ZL, Liang YJ, Lu GP, Wang JC, Ren T, Zheng YH, Gong JY, Yu J. Tracheal gas insufflation with partial liquid ventilation to treat LPS-induced acute lung injury in juvenile piglets. *Pediatr Pulmonol.* 2010;45:700–707.)

Experimental studies on lung injury show that TGI results in lower ventilator requirements (airway pressures, V_T, and dead space), more favorable alveolar surfactant composition, and a more favorable histologic trend than conventional mechanical ventilation.[64,65] Similarly, in experimental bilateral or unilateral lung injury, the combination of TGI and partial liquid ventilation is more effective than conventional mechanical ventilation or either modality alone (Fig. 22-5).[66–69] In this regard, TGI helps partial liquid ventilation to offset diffusional issues, remove partial pressure of arterial carbon dioxide (Pa_{CO_2}), and decrease the demands for ventilator gas pressures and V_T. Perfluorocarbon liquids provide cytoprotection and low-pressure mechanical support to the atelectatic lung, and these combined effects may offset lung inflammation associated with higher V_T. The combined application of TGI and partial liquid ventilation, however, is still in the early experimental stages.

In patients with ARDS who are ventilated with a permissive hypercapnia strategy,[63] the combination of increasing respiratory rate to the limit of inducing auto-PEEP, elimination of unnecessary instrumental dead space, and reduction in external PEEP when TGI-induced auto-PEEP increases (to maintain the total PEEP constant) seems a suitable pressure-limited ventilator strategy in combination with TGI[36,70] (Fig. 22-6).

In ARDS, high-frequency oscillation (HFO) improves oxygenation relative to conventional mechanical ventilation. Mentzelopoulos et al recently examined whether the combination of HFO and TGI (HFO-TGI) results in better gas exchange than standard HFO and conventional mechanical ventilation.[71] In fourteen patients with ARDS, the combination of HFO-TGI substantially improved oxygenation relative to both standard HFO and conventional mechanical ventilation according to the ARDS Network protocol. HFO-TGI also reduced shunt fraction and oxygenation index relative to conventional mechanical ventilation and HFO, respectively, but failed to improve Pa_{CO_2}. This study demonstrated the short-term feasibility of HFO-TGI, although its clinical utility in ventilator-induced lung injury remained uncertain. In subsequent studies, these authors compared standard HFO and HFO-TGI matched for tracheal pressure to determine whether TGI affects gas exchange independently from tracheal pressure. Compared to HFO alone, HFO-TGI resulted in a higher partial-pressure-of-arterial-oxygen-to-fractional-inspired-oxygen-concentration ratio at similar tracheal pressures, lower Pa_{CO_2} (at the higher tracheal pressure level),[72] and less nonaerated lung tissue below the carina.[73] These results imply enhanced lung recruitment and/or gas transport and alveolar ventilation during HFO-TGI in ARDS (Fig. 22-7).

TGI-associated reduction in Pa_{CO_2} is a potentially important maneuver in patients with cerebrovascular injury with intracranial hypertension and concomitant acute lung injury and/or ARDS, who need lung-protective ventilation and aggressive treatment to maintain intracranial pressure as low as possible. Both anecdotal case reports[74,75] and case series[76] show that TGI in patients with acute lung injury and/or ARDS and severe head trauma allows a more protective ventilator strategy while Pa_{CO_2} is reduced or remains constant; more importantly, no short-term deleterious effects on hemodynamics or cerebral parameters occurs (Fig. 22-8).

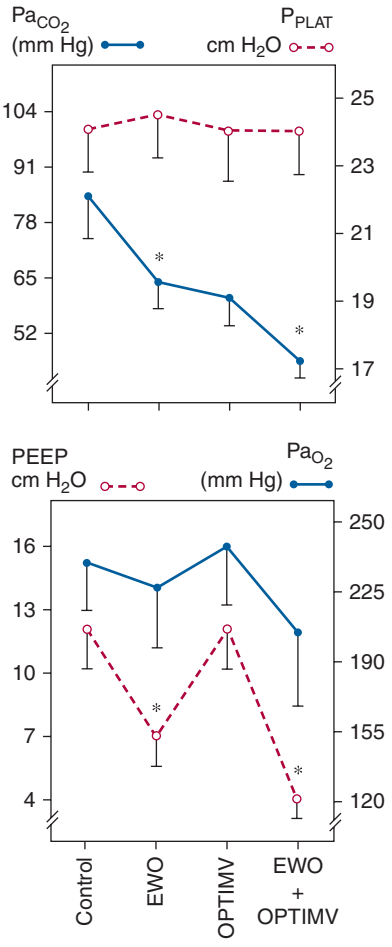

FIGURE 22-6 Changes in Pa_{CO_2}, inspiratory plateau airway pressure (P_{PLAT}), PEEP, and Pa_{O_2} induced by optimized mechanical ventilation (*OPTIMV*), expiratory washout (*EWO*), and the combination of *OPTIMV* and *EWO* in six patients with severe acute respiratory distress syndrome. Extrinsic PEEP had to be reduced by 5.3 ± 2.1 cm H_2O during EWO and by 7.3 ± 1.3 cm H_2O during the combination of OPTIMV and EWO, whereas it remained unchanged during OPTIMV alone. Plateau pressure did not change significantly, suggesting that lung hyperinflation was not produced. In patients with severe ARDS, the combination of OPTIMV and EWO has additive effects and resulted in partial pressure of arterial carbon dioxide (Pa_{CO_2}) levels close to normal values. (Used, with permission, from Richecoeur J, Lu Q, Vieira SRR, et al. Expiratory washout versus optimization of mechanical ventilation during permissive hypercapnia in patients with severe acute respiratory distress syndrome. *Am J Respir Crit Care Med.* 1999;160:77–85.)

Liberation from Mechanical Ventilation

Failure of the respiratory muscle pump is the most common cause of unsuccessful weaning from mechanical ventilation. Indeed, patients with COPD who fail weaning trials exhibit not only an almost immediate rapid and shallow breathing pattern but also progressive worsening of pulmonary mechanics with inefficient CO_2 clearance. Worsened pulmonary mechanics in these patients is characterized by

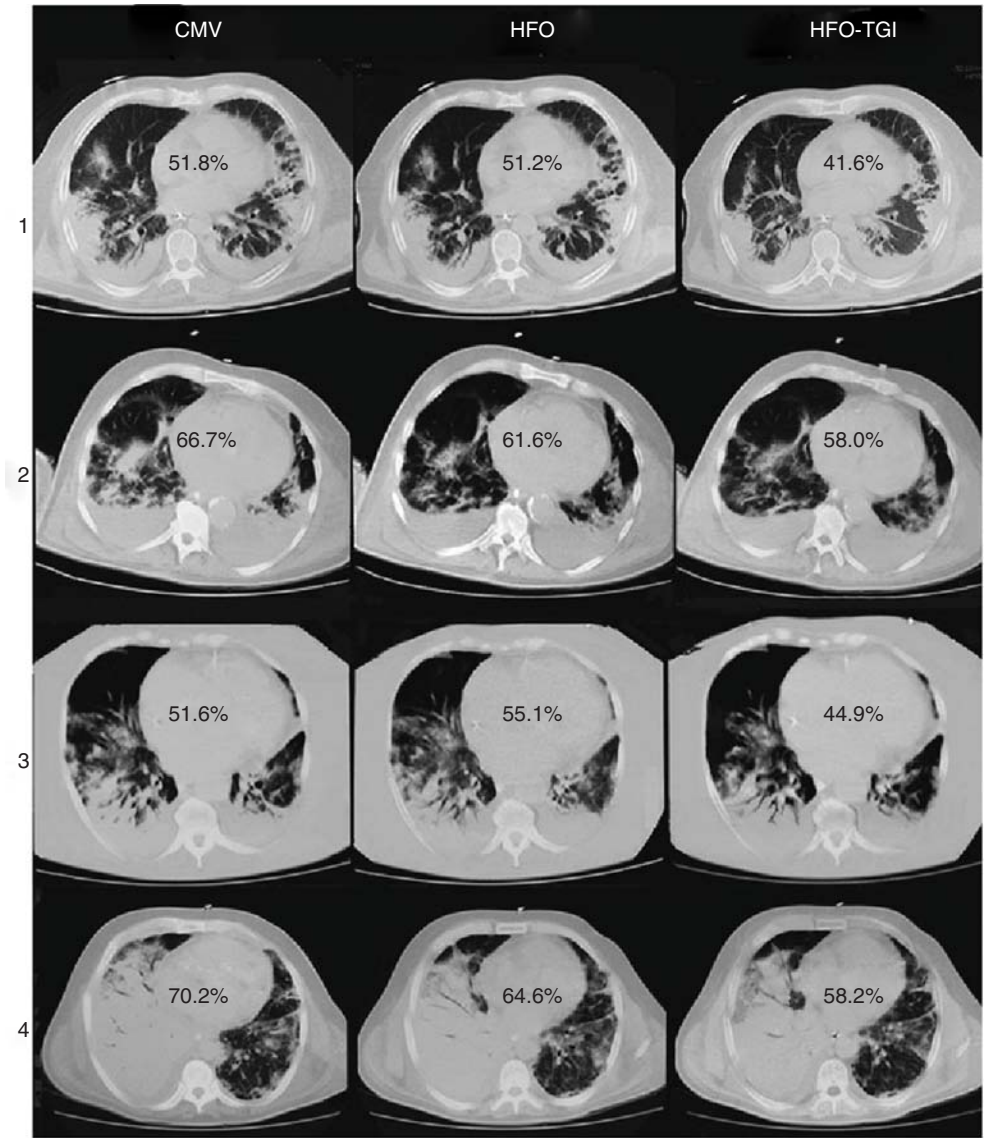

FIGURE 22-7 Computed tomography (CT) sections of the lower lung from four representative patients (*1* to *4*). CT sections correspond to 7 cm below the carina. In patients 1 and 3, HFO preceded HFO-TGI. In patients 2 and 4, HFO-TGI preceded HFO. Percentages reflect proportions of nonaerated lung-tissue weight in lower-lung CT sections. Regional gas volume was higher during HFO-TGI versus CMV and HFO. In the nondependent lower lung, there was a HFO-TGI–related decrease in the percentage of nonaerated parenchyma versus CMV and HFO. The corresponding regional lung volume and tissue weight were higher during HFO-TGI versus CMV and HFO; HFO-TGI resulted in a higher gas volume versus CMV, and a trend toward higher gas volume versus HFO. *CMV*, conventional mechanical ventilation; *HFO*, high-frequency oscillation; *TGI*, tracheal gas insufflation. (Used, with permission, from Mentzelopoulos SD, Theodoridou M, Malachias S, et al. Scanographic comparison of high frequency oscillation with versus without tracheal gas insufflation in acute respiratory distress syndrome. *Intensive Care Med.* 2011;37:990–999.)

increased auto-PEEP and inspiratory resistance, together with decreased dynamic lung compliance.[77] Therefore, TGI could facilitate liberation from ventilator support by enhancing CO_2 clearance.

In spontaneously breathing sheep with acute lung injury,[78] the combination of continuous positive airway pressure (CPAP) and TGI reduced the inspiratory work of breathing. The beneficial effect of TGI with CPAP on the work of breathing was attributed to a favorable balance between decreased ventilatory requirements and low workload superimposed by the apparatus and TGI. TGI may increase the work needed to open the demand valve and trigger the ventilator; this problem may be surmounted by a system that stops TGI flow before end-expiration.[79]

Case series[34,80] on the effects of TGI on lung function in patients undergoing weaning from mechanical ventilation have reported a flow-dependent reduction in V_T, minute ventilation, Pa_{CO_2}, and physiologic dead space when gas is delivered through an orotracheal tube. Moreover, distal positioning of the TGI catheter is more effective than proximal positioning, and the effects are less pronounced in patients with tracheostomies. Interestingly, the improvement

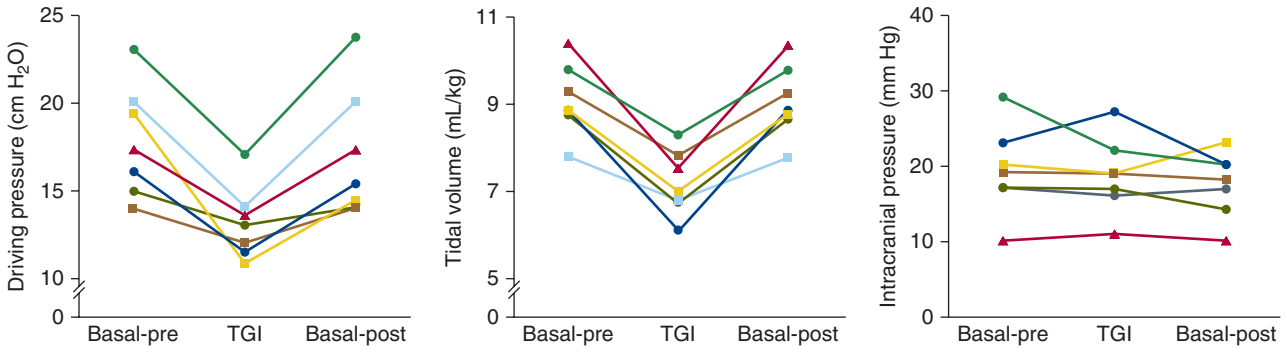

FIGURE 22-8 Individual values of driving airway pressure (difference between plateau pressure and PEEP) (*left*), tidal volume (*center*), and intracranial pressure before (*basal-pre*), during (TGI), and after (*basal-post*) application of expiratory TGI in patients with severe head trauma and acute lung injury. Expiratory TGI allowed the targeted Pa_{CO_2} level to be maintained, together with substantial reductions in tidal volume and driving pressure, without deleterious effects on cerebral parameters. (Used, with permission, from Martinez M, Bernabe F, Peña R, et al. Effects of expiratory tracheal gas insufflation in patients with severe head trauma and acute lung injury. *Intensive Care Med.* 2004;30:2021–2027.)

in ventilatory efficiency from the reduction of dead space yielded a decrease in Pa_{CO_2} at the same respiratory rate and at lower V_T.[81]

OPERATIONAL CHARACTERISTICS OF TRANSTRACHEAL GAS INSUFFLATION

Catheter Position

In TGI, a single catheter is usually placed above the main carina, making this technique simple to use. Nonetheless, more distal catheter placement may improve the efficiency of TGI in two ways.[31] First, with more distal placement, a greater volume lies proximal to the catheter tip, permitting additional expiratory flushing of CO_2-laden dead space. Moving the catheter toward the carina also advances the jet-generated turbulence zone closer to the lung periphery, thereby improving TGI efficacy. The clinical benefit, however, of introducing TGI catheters deeper than the main carina is doubtful. In a series of animal studies, the effect of TGI on Pa_{CO_2} was strongly dependent on catheter flow rate, but catheter tip position was not crucial provided it was within a few centimeters below or above the main carina.[13,26,31] Similar findings have been reported in critically ill patients.[82] Bronchoscopic guidance may not be necessary for TGI catheter placement because the position of the catheter can be verified on a chest radiograph by estimating the distance from the tip of the ETT to the main carina.

Catheter Flow Rate

TGI usually employs modest catheter flow rates. Most animal and human studies of TGI have used a flow rates of 4 to 10 L/min. CO_2 elimination during TGI depends primarily on catheter flow rate,[31,61,82,83] with turbulence generated at higher flows enhancing distal gas mixing and CO_2 elimination.[12] Once fresh gas sweeps the proximal anatomic dead-space free of CO_2, further increases in flow rate are unlikely to wash out more CO_2. Because expiratory washout of the proximal anatomic dead space is the primary mechanism of action of TGI, both curtailing expiratory time and prolonging lung deflation may diminish the efficacy of TGI unless catheter flow rate is very high. Decreasing expiratory time would decrease the volume of fresh gas delivered to the central airways per respiratory cycle (Fig. 22-9). In situations of short expiratory times, higher flow rates are required to preserve TGI efficacy. At high catheter flow rates, the high impact pressure and shear of the inflow jet can damage the bronchial mucosa.[84,85]

The optimal flow rate in terms of the decrement in Pa_{CO_2} afforded by TGI is a complex function of the volume of anatomic dead space proximal to the catheter tip, the volume of fresh gas delivered per expiration, the pattern of CO_2 exhalation from the lungs, and the CO_2 exchange characteristics of the respiratory system before TGI. Once dead space proximal to the catheter tip has been almost completely flushed by the fresh gas during expiration, any catheter-flow dependence of Pa_{CO_2} is likely to be secondary to enhanced turbulent mixing in the airways distal to the catheter tip. Consequently, Pa_{CO_2} continues to decrease with increasing flow rate as catheter flow rate rises but at a slower pace.[12,31] In most TGI systems, the effect of increasing flow rate diminishes considerably when flow rate exceeds 10 L/min.

Catheter Shape

To benefit from the distal turbulence produced by TGI, the catheter must direct the jet stream toward the periphery of the lung.[14] Inverting the catheter mouthward eliminates the distal effects and decreases CO_2 removal. Inverting the catheter within the ETT, however, avoids directing the jet stream onto the bronchial mucosa, which may cause bronchial injury.[84–86] Alternatively, the catheter tip can

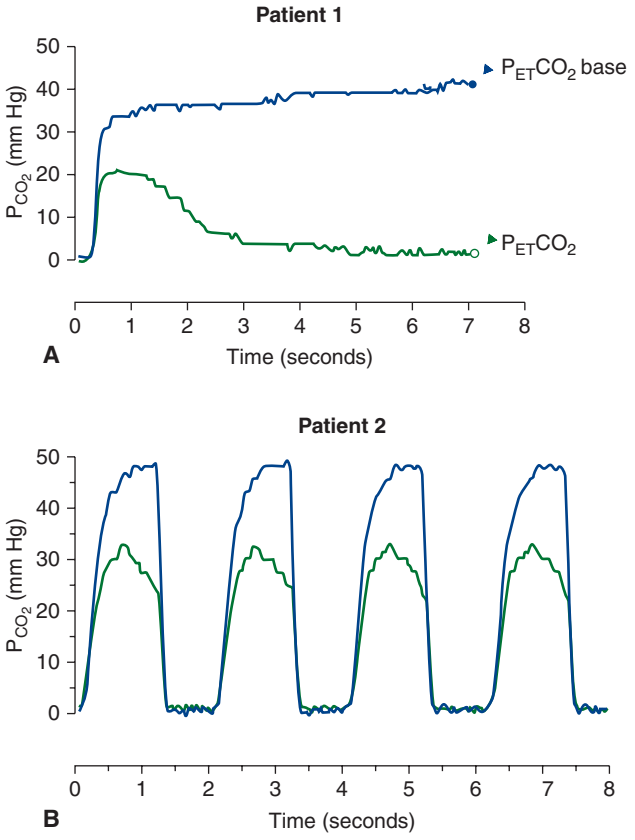

FIGURE 22-9 Representative exhaled capnograms in two patients without TGI and with TGI at 6 L/min insufflation flow. A greater reduction in end-tidal CO_2 ($P_{ET}CO_2$) from the $P_{ET}CO_2$ base value corresponded with a larger reduction in Pa_{CO_2}. At a given insufflation flow, efficiency to clear CO_2 is a function of the time available to flush proximal dead space. (Used, with permission, from Ravenscraft SA, Burke WC, Nahum A, et al. Tracheal gas insufflation augments CO_2 clearance during mechanical ventilation. *Am Rev Respir Dis.* 1993;148: 345–351.)

be positioned within the ETT so that the jet hits the ETT wall. The orientation of the ETT holes with respect to the catheter (end or side) appears to have little impact on catheter efficiency.[31] Nevertheless, catheter shape directly influences the extent (or lack of) dynamic hyperinflation caused by TGI.[87]

Humidification

The fresh gas delivered by TGI should be heated and humidified to prevent mucous plug formation and to prevent TGI gas from causing bronchial injury via cooling and dehydration of the bronchial mucosa. Few studies have systematically examined the occurrence of bronchial mucosal injury during TGI. Similarly, few studies have examined the effect of conditioning TGI gas on the extent of injury to bronchial mucosa. TGI can cool tracheal gas significantly. The extent of cooling is greatest at high flow rates with continuous TGI and can be compensated only partially by conditioning the ventilator-delivered inspired gas during panexpiratory TGI.[88,89] Case series have reported either no damage or no encrustation,[86] whereas other investigators found intratracheal catheter obstruction after 2 days of continuous use.[62]

Endotracheal Tube Design

In most human studies, a small-caliber catheter is introduced through an angled sidearm adapter attached to the ETT and positioned just above the main carina.[61,62,82,90] Placing a catheter through the ETT interferes with suctioning and can increase airway resistance by partially occluding the airway. Moreover, the catheter is not fixed in space and may cause injury to bronchial mucosae if it whips within the trachea at high flows. Alternatively, the catheter can be placed outside the ETT along the trachea. This technique requires visualization of the vocal cords and deflation of the ETT cuff and risks puncturing the cuff.

Designs incorporating channels within the ETT wall would solve these problems and simplify TGI application. Boussignac et al[91,92] embedded small capillaries in the walls of an ETT for TGI, and also used this modified ETT to deliver high-velocity jets of O_2 at the carinal orifice to prevent arterial O_2 desaturation during suctioning.[93] The modified ETT can be used to make mechanical ventilation less aggressive in different clinical scenarios.[94,95] Future clinical applications of TGI will probably use a modified ETT that incorporates the catheter in its wall attached to a standardized circuit for gas delivery. In any case, TGI should never require reintubation.[96]

Other systems allow aspiration of anatomic and instrumental dead space in the late part of expiration, and replacing the aspirated volume with fresh gas through the inspiratory line of the ventilator improves CO_2 clearance.[97] This aspiration system has allowed reductions in airway pressure and V_T while keeping Pa_{CO_2} constant in healthy humans,[98] as well as in patients with ARDS [99] and COPD.[100] This aspiration system might avoid the problems associated with jet streams of gas or with gas humidification without developing auto-PEEP.

ADJUSTMENTS AT THE BEDSIDE

Inspired Oxygen Fraction

The actual fraction of inspired carbon dioxide (FI_{O_2}) during TGI depends on two factors: the contribution of TGI to total inspired V_T and the FI_{O_2} of the catheter gas. If, however, the FI_{O_2} of the catheter gas is matched to ventilator FI_{O_2}, the actual inspired FI_{O_2} will always be identical to that delivered by the ventilator.

Airway Opening Pressure

During TGI, the jet stream increases flow through the ventilator circuit during expiration and creates a region where bidirectional flows exist. Both effects change the resistance characteristics of the respiratory system and modify the relationship between airway opening (Pao) and alveolar (Palv) pressures observed at baseline (catheter flow rate, 0 L/min). Because expiratory resistance increases during TGI, Pao tends to underestimate Palv (and functional residual capacity [FRC]) when the system is switched from baseline to TGI conditions. During panexpiratory TGI, catheter flow ceases during inspiration, and inspiratory Pao provides as much useful information regarding Palv as during conventional mechanical ventilation. In contrast, during continuous TGI, inspiratory Pao (measured at the tip of the ETT) differs from the tracheal pressure (Fig. 22-10). During expiration under both continuous and expiratory TGI conditions, however, catheter flow pressurizes the respiratory system, so Pao underestimates tracheal pressure.[84] During expiration, the extent that Pao underestimates tracheal pressure increases with catheter flow rate and depends on the geometry of the system and the orientation of the catheter with respect to the trachea.

Effect of Transtracheal Gas Insufflation on Lung Volume

Catheter flow delivered during inspiration contributes to total inspired V_T. This contribution is eliminated if TGI is timed to occur only during expiration.[16] In most TGI circuits, however, this volume is small (approximately 10 to 20 mL at a catheter flow rate of 10 L/min). The effect of TGI on total inspired V_T depends on the ventilator mode and on FRC in a flow-dependent fashion.[12,82] TGI can increase FRC in three ways. First, part of the momentum of the discharging jet stream is transferred to the alveoli.[101] Second, the catheter decreases the cross-sectional area of the trachea, increases expiratory resistance, and delays emptying. Third, catheter flow through the ETT, expiratory circuit, and expiratory valve can build up a backpressure that impedes deflation and is the major determinant of dynamic hyperinflation.[102] Continuous TGI increases FRC more than expiratory TGI, especially when the inspiratory time fraction is prolonged.[102]

Dynamic hyperinflation caused by TGI may represent either a problem or a therapeutic option[36] and can be manipulated by using an inverted-jet insufflator to achieve a venturi effect.[12,86] Monitoring dynamic hyperinflation during TGI requires a means of external lung-volume measurement, such as impedance plethysmography. Guided by the plethysmograph signal, ventilator-set PEEP can be adjusted to maintain FRC constant as flow rate is varied.[26,32] Alternatively, if the TGI system allows an end-expiratory hold maneuver, the ventilator-set PEEP can be adjusted to maintain total PEEP constant.[37,103] Alternatively, during PCV, a flow-relief valve automatically compensates for the extra gas introduced into the system by TGI and eliminates the need for ventilator adjustments to control total PEEP.[104]

Transtracheal Gas Insufflation–Ventilator Interactions

During flow-controlled, volume-cycled ventilation, total inspired V_T can be maintained relatively constant during continuous TGI by decreasing the ventilator-set V_T.[26,61] During PCV, TGI application does not change the total inspired V_T, provided TGI does not pressurize the respiratory system beyond the set pressure. As catheter flow rate increases, ventilator-delivered V_T declines, but the total inspired V_T remains the same.[26,83] If inspired V_T delivered by the catheter (V_Tc) exceeds the V_T generated by PCV in the absence of TGI, then TGI will overpressurize the circuit, and peak Pao will be greater than that produced by the ventilator-set pressure. Consequently, excessive pressures can be produced within the respiratory system if V_Tc is too large. When this happens, the Pao-time profile becomes a hybrid of PCV and constant-flow volume-cycled ventilation, resembling that generated during volume-assured pressure-support ventilation. This problem can be circumvented by introducing a pressure-release valve into the ventilator circuit that dumps circuit pressure above a set threshold.[105]

The interactions between TGI and ventilator mode, V_T, and Pao that result in development of auto-PEEP deserve mention. During volume-controlled ventilation, when ventilator PEEP is left constant, V_T remains constant, but end-expiratory pressure and Pao increase because of TGI-induced auto-PEEP. During PCV, when ventilator PEEP and peak airway pressure are kept the same as baseline, V_T excursions (and hence minute ventilation) are reduced because of TGI-induced auto-PEEP. When ventilator PEEP is reduced by an amount equivalent to TGI-induced auto-PEEP, V_T, peak airway pressure, and total PEEP remain the same as baseline during PCV [37–88].

During CPAP delivered by a mechanical ventilator in combination with TGI, additional inspiratory effort is required to overcome the insufflation flow and trigger the ventilator valves. Bench studies have found that TGI might interfere with ventilator triggering at low peak inspiratory flow rates, suggesting that weak patients may fail to open the demand valve at high catheter flow rates.[106]

MONITORING

Careful monitoring of delivered volumes and pressures is necessary to ensure safe application and to evaluate the effect of TGI on lung function. A catheter inside the ETT may increase both inspiratory and expiratory resistances, particularly when small endotracheal or tracheostomy tubes are used.[6,11,32,107,108]

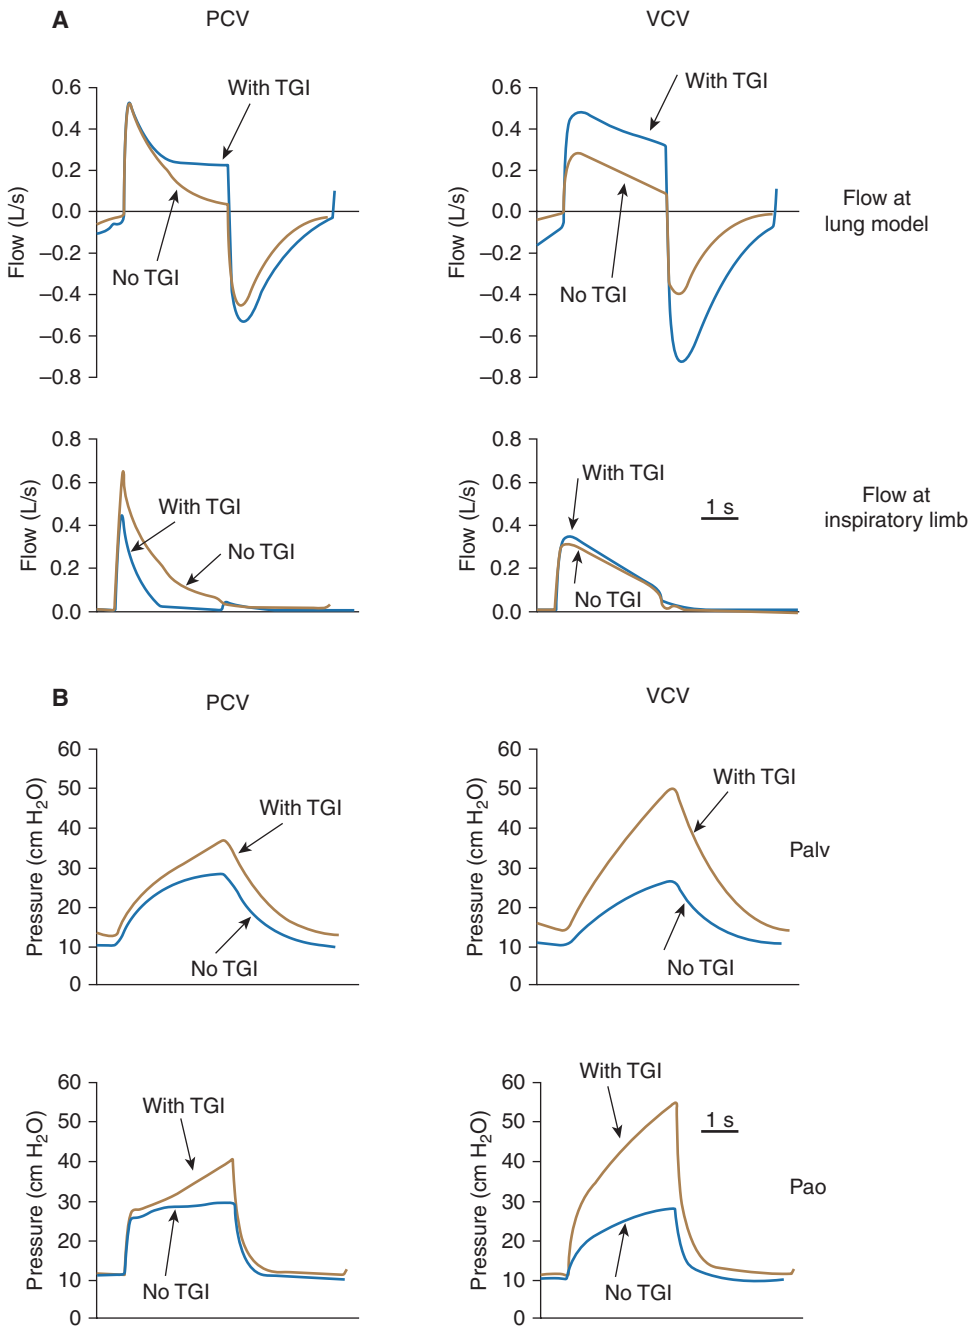

FIGURE 22-10 **A.** Flow-versus-time tracings of delivered gas flow measured both at airway opening and distal to the entrance of tracheal gas insufflation (*TGI*) during both pressure-controlled ventilation (*PCV*) and volume-controlled ventilation (*VCV*) with and without the addition of 12 L/min TGI in a lung model. **B.** Pressure-versus-time tracings of system pressure measured both at the airway opening (*Pao*) and distal to the entrance of the TGI flow (*Palv*) during both PCV and VCV with and without the addition of 12 L/min of TGI flow in a lung model. Regardless of whether VCV or PCV was used, continuous TGI increases Pao and peak carinal pressure (*B*). In association with these changes there is an increase in tidal volume. During VCV (*A*), the flow from TGI is additive to the flow from the ventilator. During PCV, the addition of the TGI flow caused the flow from the ventilator to decelerate more rapidly; once ventilator flow reached zero, a square wave flow pattern derived entirely from the TGI system persisted. (Used, with permission, from Kacmarek RM. Complications of tracheal gas insufflation. *Respir Care.* 2001;46:167–176.)

Because TGI introduces an external flow source independent of the ventilator, it can hinder the ventilator's ability to monitor pressures and volumes and may cause the ventilator alarm to go off incessantly. Catheter flow during expiration disables the monitoring role of the ventilator's expiratory pneumotachograph, triggering ventilator alarms when the difference between the measured inspired and exhaled volumes exceeds a certain value. More importantly, external

flow that can pressurize the ventilator circuit interferes with the ventilator's ability to detect leaks. Using the end-expiratory occlusion technique to measure auto-PEEP may increase lung volume dramatically if TGI flow is not interrupted simultaneously. The same effect will occur with continuous TGI during end-inspiratory occlusions.[6,30] TGI may also interfere with clinicians' ability to measure lung mechanics like respiratory system compliance and auto-PEEP.

Continuous-flow TGI could increase delivered V_T, airway and alveolar pressures, and total PEEP with both PCV and with volume-controlled ventilation. Moreover, in PCV, when ventilator flow reaches zero, continuous flow from continuous TGI increases V_T and airway pressures. These increases occur because the exhalation valve of the ventilator is not active during the inspiratory phase.[24] Overpressurization can be identified by examining the airway pressure tracing,[11] and can be remedied by placing a pressure-relief valve in the ventilator circuit to dissipate insufflated flow that produces excess pressure.[78,109] Complete obstruction of the outflow can cause overinflation of the lungs in seconds, with the potential for pneumothorax or hemodynamic compromise.

The efficacy of TGI can be monitored by capnography. Expiratory capnograms provide an indicator of the effect of TGI on the CO_2 concentration in the gas remaining in the proximal anatomic dead-space compartment at the onset of inspiration.[62,82,90] Although end-tidal P_{CO2} is a poor estimate of Pa_{CO_2}[110,111] in patients with respiratory failure, changes in end-tidal P_{CO2} induced by TGI correlate significantly with changes in Pa_{CO_2} and justify routine measurement of end-tidal P_{CO2} during TGI[33,62,82,90] (Fig. 22-11).

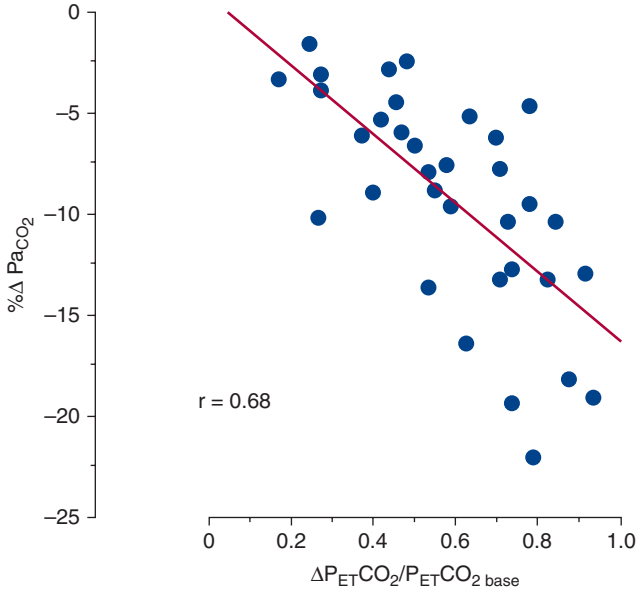

FIGURE 22-11 Percentage reduction in arterial P_{CO2} (Pa_{CO_2}) from baseline as a function of the reduction in partial pressure of end-tidal P_{CO2} ($P_{ET}CO_2$) from the baseline value ($P_{ET}CO_2$ base). As the difference between $P_{ET}CO_2$ and $P_{ET}CO_2$ base widened, larger reductions in arterial P_{CO2} were observed. (Used, with permission, from Ravenscraft SA, Burke WC, Nahum A, et al. Tracheal gas insufflation augments CO_2 clearance during mechanical ventilation. *Am Rev Respir Dis.* 1993;148:345–351.)

UNKNOWNS

The delivery of catheter gas at higher flows must be examined with regard to the need for humidification and the potential for tracheal damage with long-term use. Only inconclusive, limited data are available on the clinical safety of TGI.[85,87,112] Turbulent gas conditions promote shear stress, increased gas impact on the airway walls, and the transfer of a higher kinetic energy to the tracheal mucosa.[101,103] The end-hole TGI catheter mode could theoretically cause more airway damage than large-caliber reverse-thrust catheters because the flow exiting the end-hole catheter is closer to the carina and points directly at it. Further studies are needed to assess clinical safety before broad clinical application.[113–114]

THE FUTURE

TGI remains a promising technique that is only used as an investigational or late option at the bedside. TGI should be weighed against established invasive and noninvasive modes of ventilation. Evidence demonstrating better patient–ventilator interaction and the absence of significant adverse effects must be accumulated before TGI can be considered suitable for standard intensive care practice. Future TGI devices must include certain features:[30,84,105,109,115] (a) good coordination with the ventilator, (b) monitoring capabilities like automatic TGI flow shutoff to prevent overpressurization of the ventilator circuit and airways, (c) contextual alarms for TGI settings and TGI-ventilator–patient interaction, and (d) commercially available devices and catheters.

SUMMARY AND CONCLUSION

TTO therapy is safe for long-term administration of home oxygen. Transtracheal ventilation, using commercially available intravenous catheters and manual jet ventilation valve or wall oxygen supply, can ensure emergency lung ventilation. Experimentally, TGI is very effective at reducing lung volume while maintaining similar levels of Pa_{CO_2} during permissive hypercapnia in patients with ARDS. Similarly, TGI has been successfully used in patients with concomitant severe brain and lung injury and in patients with chronic respiratory failure. Nevertheless, concerns regarding patient application, safety, monitoring, and interaction with the ventilator remain. Further investigations are necessary before TGI can be routinely employed in intensive care units.

23

MECHANICAL VENTILATION IN THE NEONATAL AND PEDIATRIC SETTING

Peter C. Rimensberger
Jürg Hammer

Respiratory disease in its various forms remains the most common cause of pediatric and neonatal morbidity and mortality. One of the most common reasons for admission to pediatric or neonatal intensive care units is the need for ventilatory support for acute or impending respiratory failure. The major challenge for these units is to deal with a very heterogeneous population of patients who are characterized by enormous differences in age and size and marked developmental changes in organ physiology during growth. In particular, the pediatric intensive care unit population is characterized by a wide variety of rare and unique medical problems that make large clinical trials, even on general topics such as ventilator support, very difficult to conduct.[1,2] Despite worldwide daily use of mechanical ventilation in pediatric and neonatal intensive care units, many clinical and practical questions remain unresolved. Answers are often extrapolated from the results of adult studies. This may seem sensible for older children but is dangerous when applied to neonates, infants, and children up to the age of 12 years, because of developmental alterations in the physiology of their organ systems, particularly (but not only) their respiratory system.

PECULIARITIES IN PHYSIOLOGY AND RESPIRATORY MECHANICS

The considerable differences in respiratory physiology and anatomy between infants and adults[3] explain why infants and young children have a higher susceptibility to more severe manifestations of respiratory diseases, and why respiratory failure is a common problem in neonatal and pediatric intensive care units (Table 23-1). The appreciation of the peculiarities of pediatric respiratory physiology is essential for correct management of critically ill and/or ventilated infants and children.

Metabolism

The basal metabolic rate is approximately twofold higher in infants than in adults (7 mL/kg/min at birth vs. 3 to 4 mL/kg/min in the adult). Hence, the normal resting state in infants is already one of high respiratory and cardiovascular activity. This means that infants have less metabolic reserve if O_2 consumption needs to be increased during critical illnesses.

TABLE 23-1: PHYSIOLOGIC REASONS FOR THE INCREASED SUSCEPTIBILITY FOR RESPIRATORY COMPROMISE OF INFANTS IN COMPARISON TO ADULTS

Cause	Physiologic or Anatomic Basis
Metabolism ↑	↑ O_2 consumption
Risk for apnea ↑	Immaturity of control of breathing
Resistance to breathing ↑	
Upper airway resistance ↑	Nose breathing Large tongue Airway size ↓ Collapsibility ↑ Pharyngeal muscle tone ↓ Compliance of upper airway structures ↑
Lower airway resistance ↑	Airway size ↓ Collapsibility ↑ Airway wall compliance ↑ Elastic recoil ↓
Lung volume ↓	Numbers of alveoli ↓ Lack of collateral ventilation
Efficiency of respiratory muscles ↓	Efficiency of diaphragm ↓ Rib cage compliance ↑ Horizontal insertion at the rib cage Efficiency of intercostal muscles ↓ Horizontal ribs
Endurance of respiratory muscles ↓	Respiratory rate ↑ Fatigue-resistant type I muscle fibers ↓

From Hammer J, Eber E. The peculiarities of infant respiratory physiology. In: Hammer J, Eber E, eds. *Paediatric Pulmonary Function Testing. Prog Respir Res.* Basel, Switzerland: Karger; 2005;33:2–7.

Control of Breathing

A considerable amount of maturation of the control of breathing occurs in the last few weeks of gestation and in the first few days of life, which explains the high prevalence of apnea in infants born prematurely.[4] The breathing pattern of newborn, especially premature, infants is irregular with substantial breath-to-breath variability and periodic breathing at times, which increases the risk of prolonged, potentially life-threatening apnea under certain circumstances. The responses to hypercapnia or hypoxia are decreased and of variable sensitivity, making the young infant much more vulnerable to any noxious stimuli and disturbances of the respiratory control mechanisms.[5]

Ineffective breathing can lead to hypoxemia and bradycardia that may be severe enough to require the use of continuous positive airway pressure (CPAP) or intubation and mechanical ventilation, especially in the very preterm baby. Methylxanthines (such as caffeine) are effective in reducing the need of ventilator support for apnea of prematurity.[4] Feedback from vagal stretch reflexes, rib cage muscles, and the changing mechanical state of the respiratory system during each breath influence respiratory activity. If inflation is small, there is little inhibitory vagal feedback. If inflation is excessive, inspiration is inhibited. This inspiratory–inhibitory reflex, the *Hering-Breuer inflation reflex,* is very potent in the preterm and less so in the term newborn and young infant during the first weeks of life.[6] This inflation reflex facilitates passive measurement of respiratory mechanics, but may interfere with ventilator triggering. Babies may become apneic after a mechanical inflation, especially if an excessively prolonged inspiratory time (T_I), is used.[7] Fortunately, CPAP seems to enhance a baby's ability to adjust to increased respiratory loads, possibly by the elimination of the Hering-Breuer deflation reflex.[8]

Upper and Lower Airways

In the newborn, nasal breathing is obligatory, or at least strongly preferential, secondary to the configuration of the upper airways. The epiglottis is relatively large, floppy, and positioned high in the pharynx so that it is in contact with the soft palate, thereby favoring nasal over mouth breathing.[9] The larynx, trachea, and bronchi are considerably more compliant than in the older child, thus making the infant's airway highly susceptible to distending and compressive forces.[10] Thus, with any obstruction of the upper airway, significant dynamic inspiratory collapse of upper airway structures can occur during forceful inspirations, which further adds to the obstruction already present. With lower-airway obstruction, forced expiratory efforts result in increased intrathoracic pressure and dynamic expiratory lower airway collapse further limiting expiratory flow. Positive end-expiratory pressure (PEEP) may help to stent collapsing airways during expiration in some patients (e.g., those with tracheobronchomalacia; Fig. 23-1).[11]

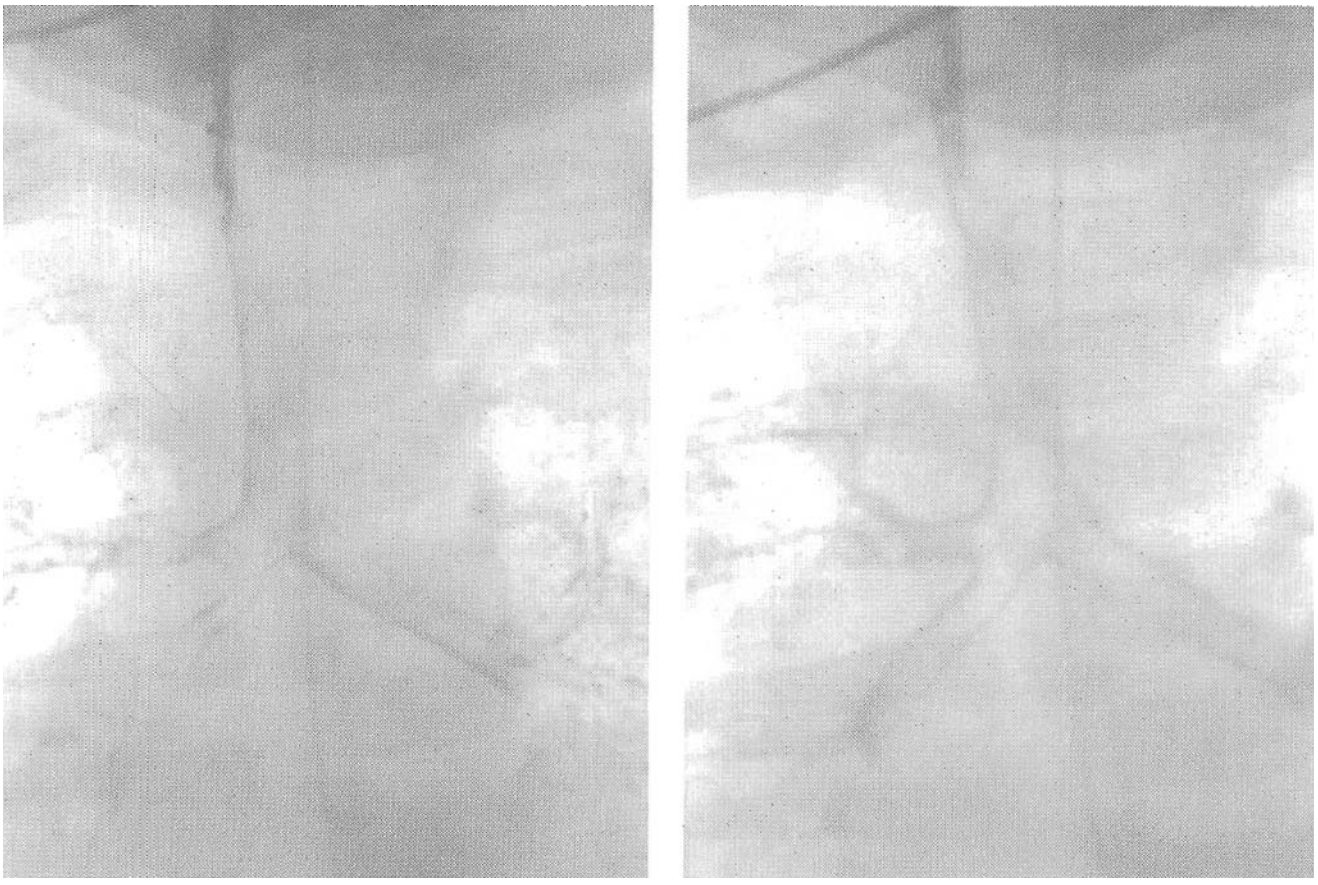

FIGURE 23-1 Bronchography in patient with tracheobronchomalacia without application of positive airway pressure (*left*) and with 10 cm H_2O of positive airway pressure (*right*). Application of positive airway pressure produces stenting of the trachea and the bronchial tree. (Courtesy Quen Mok, Great Ormond Street Hospital for Children, London, UK.)

Small peripheral airways contribute approximately 50% to the total airway resistance in the infant lung (compared to approximately 20% in the adult). As airway diameter and length increase with age and growth, airway resistance falls tremendously from birth to adulthood.[12] Therefore, diseases that affect the small airways and cause large changes in peripheral resistance may be clinically silent in an adult, but can cause significant problems in infants (e.g., bronchiolitis).

The airways of a child are relatively large in comparison with those of an adult, although in absolute terms they are small. Airway resistance in spontaneously breathing infants is normally 20–30 cm H_2O/liter per second; values in intubated infants are 50 to 150 cm H_2O/L/s, consequent to the diameter of the endotracheal tube (ETT).[13] For many years it was thought that small infants could not breathe spontaneously through an appropriately sized ETT (because of the high resistance imposed by the small lumen), but this view is no longer maintained. Under normal tidal flow conditions, resistance imposed by a small tube is not substantially higher than that with larger tubes.[14]

Lung and Chest Wall

Because of its shape, high compliance, and deformability, the contribution of the rib cage to tidal breathing is limited in newborns and infants. The ribs are horizontally aligned and allow for less anteroposterior movement of the chest wall and less efficiency of the intercostal muscles during respiration. The highly compliant chest wall is easily distorted, so that under conditions of respiratory impairment, much energy is wasted by sucking in ribs rather than fresh air. This paradox inward movement of the chest wall during inspiration is a common sign of almost any disorder causing respiratory distress in infants, but is most pronounced in upper-airway obstruction.

The elastic tissue in the septa of the alveoli surrounding the conducting airways provides the elastic recoil that enables the airways to remain open. Early in life there are few relatively large alveoli that provide little support for the airways, which are thus able to collapse easily. Addition of alveoli continues throughout early childhood by septal division, providing more elastic recoil and a decreased tendency for airway collapse with increasing age.[15] Elastic recoil increases

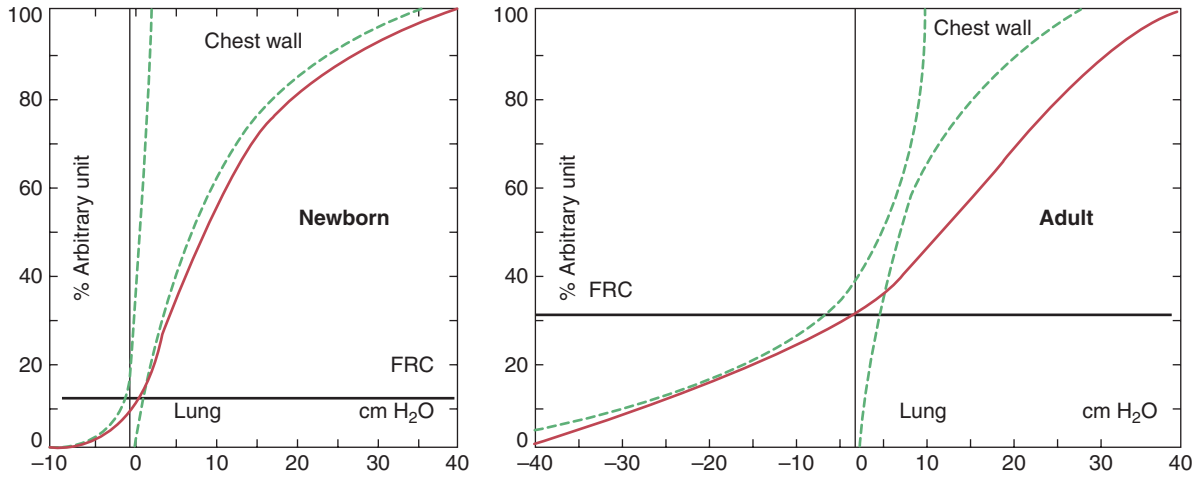

FIGURE 23-2 Characteristics of lung and chest wall mechanics in newborns compared to adults. The compliant chest wall in the newborn leads to lower functional residual capacity (*FRC*) in the newborn. (Based on data published in Agostoni E. Volume-pressure relationships of the thorax and lung in the newborn. *J Appl Physiol.* 1959;14:909–913.)

until adolescence and declines again with aging. Collateral pathways of ventilation (intraalveolar pores of Kohn and bronchoalveolar canals of Lambert) do not appear until 3 to 4 years of age,[16,17] which excludes alveoli beyond obstructed airways to be ventilated by these alternate routes and predisposes the infant to the development of atelectasis.

The balance between the chest and lung recoil pressure that determines the static resting volume of the lung is set at lower lung volumes in infants compared with older children (Fig. 23-2).[18] The highly compliant chest wall results in relatively low transpulmonary pressures at end-expiration that leads to an increased tendency for collapse of the small peripheral airways and ventilation inhomogeneity. The infant adopts several strategies to constantly establish lung volumes, including (a) a higher respiratory rate with insufficient time to exhale to the elastic equilibrium volume, (b) laryngeal adduction during exhalation to increase the resistance to airflow, and (c) constant postinspiratory diaphragmatic muscle activity (i.e., tonic diaphragmatic activity). A PEEP of 5 to 6 cm H_2O is necessary to maintain end-expiratory lung volume in infants under neuromuscular blockade.[19] The highly compliant chest wall also explains the generally high cardiovascular tolerance of infants to high airway pressures that are less efficiently transmitted to the pleural space. The low elastic recoil of the chest, together with a low percentage of slow-muscle fibers in both the diaphragm and intercostal muscles, explain why very little airway pressure is needed to expand the chest wall during inspiration in healthy babies.

Circulatory Changes Pertinent to Mechanical Ventilation after Birth

Before birth, only approximately 10% of blood flow passes through the lungs as a result of high pulmonary vascular resistance, patent ductus arteriosus, open foramen ovale, and the low-resistance placental component to the systemic circulation. Pulmonary vascular resistance falls rapidly in the first minutes of life, but is still elevated and falls only gradually to normal levels over days to weeks. Under certain circumstances (e.g., birth asphyxia, chronic hypoxia, or neonatal septicemia with or without metabolic acidosis), pulmonary vascular resistance increases or remains high, leading to right-to-left shunting through the ductus arteriosus and sometimes even through the foramen ovale. This persistent pulmonary hypertension of the newborn (PPHN) leads to poor systemic oxygenation, as revealed by low postductal transcutaneous saturation levels or desaturation of all four extremities when the right-to-left shunt at the level of the foramen ovale is important.

High inflation pressures to recruit lung volume and improve oxygenation should be used with caution because of the risk of increased pulmonary vascular resistance by overdistension and compromised cardiac output. First-line treatment is directing toward known determinants of pulmonary vascular resistance (Table 23-2) such as acidosis or high interstitial pressures. Second-line therapy includes specific pulmonary vasodilators, such as inhaled nitric oxide (iNO)[20–22] after excluding congenital heart disease with

TABLE 23-2: MAIN DETERMINANTS OF PULMONARY VASCULAR RESISTANCE

Increase in Pulmonary Vascular Resistance	Decrease in Pulmonary Vascular Resistance
High interstitial pressure	Low interstitial pressure
High lung volumes (alveolar overdistension)	Normal lung volumes
Low lung volumes (atelectasis)	
Low alveolar P_{O_2}	High alveolar P_{O_2}
Low arterial pH	High arterial pH

P_{O_2}, partial pressure of oxygen.

duct-dependent systemic circulation, which may deteriorate when pulmonary vascular resistance is lowered (e.g., total anomalous pulmonary venous return or hypoplastic left-heart syndrome).[23]

Oxygen Transport

Fetal hemoglobin is the predominant type of hemoglobin at birth and decreases steadily over the first 6 months. 2,3-Diphosphoglycerate (2,3-DPG) has a lower affinity to fetal hemoglobin and shifts the dissociation curve to the left. This facilitates loading and unloading of O_2, ensuring, together with the high O_2-carrying capacity of fetal hemoglobin, adequate tissue oxygenation despite low partial pressure of arterial oxygen (Pa_{O_2}) values in utero (15 to 30 mm Hg). The predominance of fetal hemoglobin makes it possible, if necessary, to tolerate lower Pa_{O_2} values (but not really arterial oxygen saturation [Sa_{O_2}]) better in early postnatal life than is possible later in life.

Preterm babies can maintain their growth in utero with a mean Pa_{O_2} of 3.2 kilopascals (kPa; approximately 24 mm Hg), equivalent to Sa_{O_2} of approximately 70%. In neonatal intensive care units, clinical practice has long been to keep oxygen levels in preterm newborns in line with those of term infants until neonatal morbidities induced by oxygen have been better understood. To date, there is insufficient evidence to suggest what would be the optimal Sa_{O_2} or Pa_{O_2} values in preterm infants to avoid potential oxygen toxicity while ensuring adequate oxygen delivery to tissues. There is, however, ample evidence to support the notion that a "restrictive" oxygen approach does more good than harm in preterm babies.[24]

SOME SPECIAL CONSIDERATIONS FOR VENTILATOR MANAGEMENT IN NEONATES, INFANTS, AND CHILDREN

The basic objectives of ventilator support remain the same from early life to adulthood[25,26] but ventilator strategies, modes, and targets are not always fully identical to those established in adults.

Lung-Protective Ventilation

Barotrauma zones, safe peak inspiratory pressure and PEEP, are less-well defined in the younger age group, especially the very premature infant. Neonatologists tend to limit peak inspiratory pressure to 30 cm H_2O or lower; some favor the use of high-frequency oscillation ventilation (HFOV) in this age group. Studies investigating lung-protective ventilation in neonates have mainly focused on comparing high-frequency ventilation with conventional mechanical ventilation (CMV), leaving unanswered the important question as to whether reducing tidal volume or increasing PEEP is also lung protective.[27] HFOV is best used with a high-lung-volume strategy, but offers no benefit over conventional ventilation when a lung-protective strategy is applied.[28]

A lung-protective strategy is commonly advocated similar to recommendations for adults following the publication of the ARDS Network trial.[29] Recent observational cross-sectional studies, however, revealed that commonly used tidal volume (V_T) varies between 6 and 10 mL/kg (mean: 8.3 ± 3.3 mL/kg) in children,[2,30] and between 4 and 6 mL/kg (mean: 5.7 ± 2.3 mL/kg) in neonates.[31] Interestingly, V_T up to 10 mL/kg in children does not seem to be associated with increased mortality. Moreover, higher V_T within this range is associated with more ventilator-free days, particularly in patients with less-severe disease.[30] In a recent prospective, multicenter, observational study, higher maximum and median tidal volumes were associated with reduced mortality, even when corrected for severity of lung disease.[32] There is even less data available for neonates than for children to confirm or reject the hypothesis that small-volume ventilation, V_T of 4 to 6 mL/kg, is the best lung-protective approach.[27]

Allowance for Hypercapnia or Hypocapnia, Respectively

Overventilation and hypocapnia have been shown to contribute to adverse neurodevelopment in preterm infants and also in the neonate with hypoxic ischemic encephalopathy.[33–35] Any rapid reduction in partial pressure of arterial carbon dioxide (Pa_{CO_2}), which may occur with surfactant therapy or change in ventilator mode, may lead to cerebral vasoconstriction, increasing the risk of cerebral hemorrhage and/or leukomalacia. Both extremes and fluctuations of Pa_{CO_2} are associated with severe intraventricular hemorrhage. It may be prudent to avoid extreme hypocapnia and hypercapnia during the period of risk for intraventricular hemorrhage in preterm infants. Both minimum partial pressure of carbon dioxide (P_{CO_2}) and cumulative P_{CO_2} less than 35 mm Hg are associated with poor outcome in neonates with hypoxic ischemic encephalopathy.[34]

Volume-Targeted Ventilation in Neonates

Modern neonatal ventilator modes can target a set tidal volume as an alternative to traditional pressure-limited ventilation. Volume-targeted ventilation (VTV) aims to produce a more stable V_T so as to reduce lung damage and stabilize Pa_{CO_2}. Infants receiving VTV had lower rates of death and chronic lung disease compared with infants ventilated using pressure-limited ventilation modes.[36,37] Further studies are needed to identify whether VTV modes improve neurodevelopmental outcomes and to compare and refine VTV strategies.

VTV has some technical limitations. First, the displayed VT can be misleading in the presence of a high ETT leak. Such leak is common in neonatal practice where uncuffed tubes are commonly used and may be noted in approximately 75% of all ventilated neonates, usually without greater clinical relevance.[38] Leaks are associated with an inability to detect the patient's inspiratory effort or autotriggering of the ventilator. The latter also occurs if tubing is not kept dry and if there is water accumulation in the expiratory limb. This complication is more common in the neonate and young infant. Second, inaccurate V_T delivery under specific conditions, especially when rapid changes in respiratory system mechanics occur, has been described with various neonatal ventilators that offer VTV. Such discrepancies between the set V_T and the delivered inflations can be harmful in clinical situations, especially in newborns. Their clinical relevance needs to be clarified with safety studies in the neonatal population, before the "uncritical" use of such new hybrid modes could be advocated for all neonates and for various clinical conditions.[39]

Setting Ventilator Parameters According Respiratory Mechanics

There is a tendency towards using very short inspiratory times in premature infants with respiratory distress syndrome (RDS) secondary to the very low compliance of the lungs. An increase in inspiratory time may sometimes result in lower peak inspiratory pressures and more homogenous ventilation. A good knowledge of respiratory mechanics is helpful to decide on the best settings. In addition, there exists the erroneous belief that expiratory times have to be longer than inspiratory times. While this is the case in obstructive airways disease, it does not apply to the healthy or the stiff lung in neonates and children.

Small Endotracheal Tubes

The small and narrow ETTs are prone to mucus plugging and kinking. Many clinicians believe that for an infant or young child, breathing through a small ETT is equivalent to breathing through a straw, thereby imposing an unacceptable work of breathing. This notion is contrary to both clinical observation and physiology.[14,40] A 3-kg infant accepts a 3-mm inner-diameter ETT, whereas a 60-kg adult can tolerate a 9-mm inner-diameter ETT—a 20-fold increase in body size but only a threefold increase in ETT size. The narrower tube is irrelevant because it is shorter and because lower flows are generated by the infant compared to the adult. The net effect is that the infant is breathing through a hose rather than a straw when compared to the adult. Hence, if an infant or young child cannot sustain a spontaneous breathing trial on CPAP or a T-piece for several hours, he or she is as likely to fail extubation as when pressure support is applied. Furthermore, the addition of pressure support is likely to mask respiratory insufficiency and contribute to a higher failed extubation rate.[41]

Tracheotomy for Long-Term Ventilation

Tracheotomy is withheld for a longer period in critically ill children than in adults. Infants tolerate prolonged intubation much better than adults, although complications, such as subglottic stenosis,[42] can occur. Furthermore, indications for tracheotomy are different between children and adults: Tracheotomy is more often appropriate for bypassing congenital or acquired upper-airway obstruction than for supporting long-term mechanical ventilation.[43]

Closed Suction Systems

There is probably no medical device other than closed-suction systems that has been as enthusiastically accepted in intensive care unit practice without the requirement to prove benefit in a randomized controlled trial. There is still insufficient evidence to decide between endotracheal suctioning with or without disconnection.[44] In the injured lung, however, closed suction is much less effective than open suction, irrespective of the type of secretions.[45] The negative effects of suction on lung volume, heart rate, and Sa_{O_2} are transient and highly variable with both open-suction and closed-suction methods in spontaneously breathing infants.[46] This suggests that it is time to reassess the role of open suction, especially in ventilated infants with narrow tubes and respiratory disease resulting in large amounts of copious secretions.

COMMON CLINICAL CONDITIONS

Neonates

RESPIRATORY DISTRESS SYNDROME (HYALINE MEMBRANE DISEASE)

RDS is characterized by pulmonary surfactant deficiency and transudation of plasma proteins into the alveolar spaces. It typically occurs in preterm infants, and its severity correlates with the degree of immaturity of the lungs and is aggravated by concomitant infection, oligohydramnios, and a variety of other factors. The results are stiff lungs and a tendency to atelectasis. Initial ventilator management aims to recruit collapsed alveoli, restore functional residual capacity, and achieve adequate alveolar ventilation. Technical and pharmacologic advances, with improved understanding of pathophysiology and causes of lung injury, have significantly enhanced the ventilator management of preterm infants with RDS. Ventilator modalities have shifted towards early noninvasive ventilation and decreased and shortened use of invasive forms of ventilation in most preterm infants.

Nasal CPAP applied by various devices has become the primary respiratory support for RDS. When used early, it reduces respiratory failure, the need for surfactant, and the duration and invasiveness of respiratory support without impairing neonatal outcome.[47] It therefore offers a valuable

alternative to intubation and surfactant in preterm infants.[48] It has not, however, proven to allow for better outcome than intubation and mechanical ventilation in preterm infants.[49] Nasal CPAP improves respiration in preterm infants by increasing functional residual capacity and chest wall stability, as well as decreasing upper-airway collapsibility and upper-airway resistance.[50]

Recently, heater-humidifier devices that use novel methods for conditioning respiratory gases from an external source have been introduced. The addition of sufficient warmth and high levels of humidification to a gas has enabled the use of higher flow rates from a nasal cannula. High-flow nasal cannula can be used to provide high concentrations of O_2 and may deliver PEEP. At present, there is insufficient evidence to establish the safety or effectiveness of high-flow nasal cannula as a form of respiratory support in preterm infants. When used following extubation, high-flow nasal cannula seems to result in a higher rate of reintubation than does nasal CPAP.[51]

When positive-pressure ventilation was first introduced in newborn infants with RDS, the use of high peak inspiratory pressures was associated with high mortality rates, air leaks, and the development of bronchopulmonary dysplasia (BPD).[52] In the 1970s, the incidence of pneumothoraces was reduced by adopting a strategy using long T_I values and slower rates.[53] This strategy was widely adopted and only given up after the benefit of PEEP was better understood.[54] Administration of exogenous surfactant and advancements in ventilator technology, which decrease patient–ventilator asynchrony, have further improved the management and outcome of RDS. It is now widely accepted that severe RDS, characterized by poorly compliant lungs and very short time constants, is best managed with short T_I values (0.26 to 0.34 seconds), rapid rates (60/breaths/min or more), and PEEP.[55,56] Such general recommendations help in avoiding major errors when initiating mechanical ventilation in infants suffering from severe RDS. Nevertheless, inspiratory and expiratory time, respiratory frequency, and PEEP need to be customized to an individualized assessment of a patient's respiratory mechanics, which change over the course of disease or with therapeutic interventions such as surfactant administration. The availability of low-dead-space-flow sensors enables continuous measurement of V_T, and eliminated much of the guesswork in setting the ventilator. Volume-targeted modes have now become increasingly popular in the neonatal intensive care unit to improve the stability of ventilation and to reduce unnecessarily high peak pressures.[37] This strategy aims at reducing Pa_{CO_2} fluctuations in very preterm infants (although it is not always as successful as hoped[57,58]), which are associated with the development of intraventricular hemorrhage and leukomalacia. Hence, much emphasis is placed on using ventilator strategies that should best guarantee a constant Pa_{CO_2} and at the same time use of the lowest fractional inspired oxygen concentration (FI_{O_2}) to achieve sufficient tissue oxygenation.

The underlying pathophysiology, decreased lung compliance, high chest wall compliance, and dynamically maintained functional residual capacity above closing volume make RDS a perfect candidate for an open-lung strategy and use of HFOV. Despite many studies of HFOV versus conventional ventilation (and three meta-analyses of these trials) involving 3652 infants, neonatologists remain unsure about the potential benefits and harms of HFOV for support of preterm infants with surfactant-deficient lungs. The Prevention of Ventilator Induced Lung Injury Collaborative Group (PreVILIG collaboration) recently concluded that HFOV seems equally effective to conventional ventilation in preterm infants.[59] Current results do not support selection of preterm infants for HFOV on the basis of gestational age, birthweight for gestation, initial lung disease severity, or exposure to antenatal corticosteroids.[59] Why data from animal models predicted a larger effect size than that observed in human infants remains an unanswered question. Recent data, however, support the usefulness of first-intention HFOV strategy in managing selected subpopulations, such as very-low-birthweight newborns complicated by severe RDS not antenatally treated with glucocorticoids.[60]

Exogenous surfactant therapy has been part of routine care of preterm neonates with RDS since the early 1990s. Animal-derived exogenous surfactants are the present treatment of choice, with few adverse effects. The few adverse effects are largely related to changes in oxygenation and heart rate during surfactant administration.[61] The optimal dose is usually 100 mg/kg. Both prophylaxis and early treatment are successful in infants with established RDS, but prophylaxis appears to produce greater benefit.[62] The concept of using surfactant early in patients with low oxygen needs (FI_{O_2} <0.45), combined with the so-called INSURE approach (intubation-surfactant-extubation to nasal CPAP), has decreases the need for mechanical ventilation, incidence of BPD, and air leak syndromes as compared to subsequent use of INSURE when FI_{O_2} exceeds 0.45.[47,63]

Persistent fetal circulation is a complication of RDS in preterm infants. At present, there is no clearcut evidence in favor of using iNO for preterm infants requiring mechanical ventilation.[64] Clinicians continue to make case-by-case decisions for the treatment of preterm infants with hypoxia unresponsive to other therapies.[65]

PERSISTENT PULMONARY HYPERTENSION OF THE NEWBORN

PPHN is the result of elevated pulmonary vascular resistance to the point that venous blood is shunted to some degree through fetal channels (e.g., ductus arteriosus and foramen ovale) into the systemic circulation. By bypassing the lungs, it causes systemic arterial hypoxemia. It is associated with (a) pulmonary parenchymal disease such as RDS or meconium aspiration and (b) hypoplasia of the lungs, most often in the form of diaphragmatic hernia. It (c) also can occur without an evident cause.

Traditionally, these infants have been hyperventilated to achieve mild hypocapnic alkalosis in an attempt to attenuate

hypoxic pulmonary vasoconstriction. iNO is an approved adjunct to improve oxygenation in term and preterm infants with severe hypoxemic respiratory failure secondary to PPHN and has been shown to reduce the need for extracorporeal membrane oxygenation.[66] Alveolar recruitment should be optimized to achieve best iNO effects on oxygenation.[23] Hence, HFOV is an ideal method to combine with iNO.

MECONIUM ASPIRATION SYNDROME

Meconium aspiration syndrome affects mature infants and is characterized by a mixture of inflammatory pulmonary disease, secondary surfactant deficiency, obstruction of small airways, and pulmonary hypertension. The result is a very inhomogeneous lung with areas of atelectasis and hyperinflation. In terms of pathophysiology and ventilator management, meconium aspiration syndrome resembles acute respiratory distress syndrome (ARDS) of pulmonary origin, favoring the use of similar ventilator strategies (open lung concept, permissive hypercapnia, and so on). Despite the introduction of innovative ventilatory treatments for this disease over the last two decades (e.g., surfactant-lavage, HFOV, iNO, extracorporeal membrane oxygenation), most infants can be successfully managed with CPAP or mechanical ventilation alone.[67,68]

CONGENITAL DIAPHRAGMATIC HERNIA

Congenital diaphragmatic hernia (CDH) is characterized by lung hypoplasia, surfactant deficiency, and an extremely reactive hypoplastic pulmonary vascular system. The hypoplastic lungs are very vulnerable to injury from aggressive ventilation with high inspiratory pressures. Treatment is no longer focused on immediate surgery, but rather on delaying repair until all reversible problems are resolved (i.e., stabilization period).[69,70] The concept of delaying repair until pulmonary hypertension resolves and the patient is hemodynamically stable has increased survival from below 50% to as high as 80%.[69,71] Although high airway pressures may be required with secondary parenchymal injury to ensure adequate oxygenation, special care is necessary to avoid alveolar distension in the setting of pulmonary hypoplasia. Neither the use of HFOV nor early rescue extracorporeal membrane oxygenation, however, has significantly improved outcome in CDH patients, the best survival rates with these options are approximately 80%.[72–77] The discussion on optimal treatment strategies for CDH, in addition to the commonly accepted need for early lung-protective ventilation to avoid lung injury, is not closed.[78]

Pediatric Patients

VIRUS-INDUCED HYPOXEMIC FAILURE

Two distinct patterns of disease occur in infants with virus-induced respiratory failure.[79,80] The primary causative agent is respiratory syncytial virus. The most frequent pattern is acute bronchiolitis characterized by an obstruction of small airways with air trapping and a moderate degree of parenchymal disease from atelectasis. This leads to increased respiratory resistance, a prolonged time constant, intrinsic PEEP, and decreased respiratory compliance.[81] Radiographic findings include hyperinflation, perihilar infiltrates, and atelectasis. The second pattern, which affects approximately 25% to 30% of infants with respiratory syncytial virus-induced respiratory failure, consists of severe restrictive parenchymal disease (usually termed *respiratory syncytial virus-pneumonia*). Typically, respiratory compliance and lung volumes are decreased markedly without significant airway obstruction or air trapping. Alveolar consolidation is the main radiographic feature. This subgroup also usually fulfills the criteria of ARDS. Patients require prolonged ventilation compared with a brief duration (4 to 8 days) for the bronchiolitic pattern.[79,80]

No consensus exists on optimal ventilator strategy. Nasal CPAP appears useful in the early stages of severe bronchiolitis by decreasing the work of breathing needed to overcome the intrinsic PEEP. The evidence supporting the use of CPAP to reduce P_{CO_2} and respiratory distress in bronchiolitis, however, is of low methodologic quality, reporting only short-term effects,[82] and there is no conclusive evidence that CPAP reduces the need for intubation.[83,84] More recently, high-flow nasal cannula, if used early in the treatment of severe bronchiolitis, appears to reduce the need for intubation in infants with viral bronchiolitis.[85]

Pressure-controlled ventilation (PCV) is the mode used most commonly in virus-induced respiratory failure because the decelerating flow pattern achieves a lower mean airway pressure than volume-controlled ventilation (VCV). Most patients need peak inspiratory pressures of 25 to 35 cm H_2O to achieve adequate ventilation. Infants with obstructive disease have long expiratory time constants. They are best ventilated with slow rates and inspiratory-to-expiratory (I:E) ratios of at least 1:3 to prevent breath "stacking" and further hyperinflation. Conversely, patients with restrictive disease may require faster rates and lower I:E ratios. Permissive hypercapnia, to avoid high peak inspiratory pressures and barotrauma, can be used with both pathophysiologic patterns.

Obstructive patients may do poorly with HFOV, although this statement is not as absolute as often thought.[86] Patients with predominant restrictive disease, however, are better candidates for HFOV.

PEDIATRIC ACUTE RESPIRATORY DISTRESS SYNDROME

The causes of ARDS in pediatric patients are the same as in adults, although viral or bacterial respiratory infections are more common in children.[79] Ventilator strategies are the same as in adult patients and include high PEEP and limiting peak inspiratory pressure to below 30(–35) cm H_2O.

Lung-protective ventilation strategies are commonly recommended, although there is doubt as to the best V_T.

Although no single ventilation mode has proven superior, the most common modes are PCV and HFOV,[2,30,87] despite the absence of solid data on the use of HFOV in pediatric patients beyond the neonatal period. Prone positioning is used commonly, but without proven benefit.[88,89] iNO cannot be recommended for routine use, although it is used as rescue therapy (for a short time) in the very early stages of life-threatening hypoxemia and severe pulmonary hypertension.

STATUS ASTHMATICUS

Most complications in patients with asthma receiving ventilation occur during or immediately after intubation. They result largely from gas trapping that causes hypotension, O_2 desaturation, pneumothorax, and cardiac arrest. Institution of positive-pressure ventilation in patients with asthma alters cardiocirculatory and respiratory dynamics dramatically, leading to diminished venous return and hypotension.

The optimal ventilator mode for status asthmaticus is not established. Randomized, controlled trials comparing different modes in pediatric asthma patients are virtually impossible.[90] Most clinicians prefer pressure-limited ventilation, keeping peak inspiratory pressure below 35 to 40 cm H_2O and accepting hypercapnia.[91] Because of their decelerating flow pattern, PCV and pressure-regulated VCV allow for lower peak inspiratory pressures but result in higher mean airway pressures than VCV with identical V_T. Ventilator rates are set well below normal and require an extremely long expiratory and reasonably long inspiratory time. Externally applied PEEP should be, in general, just below auto-PEEP to decrease trigger work but not increase hyperinflation. Duration of mechanical ventilation for status asthmaticus is usually of 1 to 4 days. Children with rapid-onset near-fatal asthma may have a shorter duration of ventilation than children with asthma that progresses slowly to respiratory failure.[92]

HFOV, pressure-support ventilation (PSV), and noninvasive ventilation have been tried in status asthmaticus. HFOV is believed to be contraindicated in children with severe airflow obstruction, although recent experience challenges this belief.[93] PSV enables active exhalation, which may decrease hyperinflation. PSV allows patients to determine their own respiratory pattern (rate, T_I, and V_T) and may decrease patient–ventilator dyssynchrony. PSV decreases work of breathing by partially unloading the respiratory muscles. Careful selection of PEEP decreases the work of triggering during PSV. PSV of 22 to 37 cm H_2O has been used successfully in children with asthma requiring full or near-full support, resulting in rapid improvement in gas exchange.[94] Noninvasive PSV is often poorly tolerated without sedation, and its role in avoiding intubation in children with status asthmaticus remains unclear.[95,96]

CORRECT TIMING OF EXTUBATION

Avoidance of unnecessary weaning delays is important for reducing the risk of nosocomial infection, ETT damage to the airway, development of chronic lung disease in neonates, and prolonged dependency on narcotic drugs.[97,98] Aggressiveness with early weaning, however, must be balanced against the risk of extubation failure that occurs in 2% to 20% of children[41,99] and up to 40% of neonates,[100] and which is associated with increased mortality.[101]

Extubation Readiness

Several indices have been developed to predict successful weaning and extubation. Although these indices have been used in research studies, they have not found widespread use in clinical care, likely because of their complexity and lack of proven benefit over clinical judgment. A trial of spontaneous breathing with a T-piece or the use of 10 cm H_2O of PSV for up to 2 hours has been successful in predicting extubation failure in children.[102] A modified rapid shallow breathing index, also known as frequency-to-tidal-volume ratio, and the compliance, rate, oxygenation, and pressure index has been proposed for weaning prediction in children.[103]

There is fertile ground for future research to identify simple predictors of extubation readiness that would likely shorten the duration of ventilation, decrease length of intensive care unit stay, and potentially reduce ventilator-induced lung injury.[41] Table 23-3 lists proposed clinical and laboratory criteria for weaning failure during 2 hours on CPAP of 5 cm H_2O or a T-piece. The single most common cause

TABLE 23-3: CRITERIA FOR EXTUBATION READINESS TEST FAILURE

Proposed criteria for failure of extubation readiness during 2 hours on CPAP <5 cm H_2O or T-piece

Clinical Criteria:
Diaphoresis
Nasal flaring
Increasing respiratory effort
Tachycardia (increase in heart rate >40 bpm [breaths per minute])
Cardiac arrhythmias
Hypotension
Apnea
Laboratory Criteria:
Increase in end-tidal CO_2 >10 mm Hg
Decrease of arterial pH <7.32
Decline in arterial pH >0.07
Pa_{O_2} <60 mm Hg with an FI_{O_2} >40 (P/F O_2 ratio <150)
Sp_{O_2} declines to <5%

From Newth, et al. Weaning and extubation readiness in pediatric patients. *Pediatr Crit Care Med.* 2009;10:1–11.

of extubation failure in children, however, is upper-airway obstruction, which is difficult to predict with an ETT in place. The air-leak test (an audible air leak when airway pressure ≥25 cm H_2O), although often recommended, has repeatedly been shown to have low sensitivity for testing extubation readiness.[104–106]

Extubation failure is more frequent in children with chronic respiratory disorders, neuromuscular and chronic neurologic disorders, and upper-airway problems.[101] The most common cause of extubation failure in preterm infants is apnea with bradycardia.[107]

Developing reliable thresholds for indices for weaning extremely low-birthweight preterm infants has proven equally difficult as for older children.[108] The percentage of time spent below a target value of spontaneous expiratory minute ventilation (<125 mL/min/kg) during a 2-hour CPAP trial appears promising but requires further testing.[109,110] Another option might be a spontaneous breathing trial of 3 minutes on CPAP after minimal ventilator settings have been reached.[111]

Weaning Modes and Adjuncts to Weaning

The most common approach to weaning infants and children is gradual reduction of ventilator support by decreasing rate and airway pressures during synchronized intermittent mandatory ventilation (SIMV). Other weaning methods include PSV and volume-support ventilation. Both methods involve patient-triggered pressure support. With PSV, the level of PSV is adjusted gradually by the physician to a minimal level that achieves an acceptable breathing pattern. With volume-support ventilation, the level of PSV is adjusted continuously by the ventilator to achieve minimum minute ventilation. It is common practice to extubate infants and children from a low level of ventilator support. Gradual weaning is often unnecessary after the underlying disorder has resolved.[102,112]

Today, many modes have been developed to facilitate weaning by reducing work imposed by the respiratory apparatus.[113,114] Misperceptions about the impact of the ETT resistance may interfere with weaning management. Although it has become fashionable to use pressure support with PEEP, rather than CPAP or T-piece breathing, to overcome ETT resistance, physiologic and scientific evidence shows that the increase in resistance caused by an appropriately sized tube is minimal and the additional work of breathing negligible. Hence, an infant or young child should be able to sustain a spontaneous breathing trial on CPAP or a T-piece for several hours, if he or she is likely to be successfully extubated. A spontaneous breathing trial using pressure support set at higher levels for smaller ETTs overestimates readiness for extubation in children and contributes to a higher failed extubation rate.[115]

The classic approach to weaning neonates from CMV is to extubate them from a rate of about 15 breaths/min to supplemental O_2 or nasal CPAP. Weaning strategies involve decreasing rate (except for patient-trigger ventilation) and positive inspiratory pressure to maintain the V_T at 4 mL/kg or greater. PSV may be combined with SIMV. Newer options include volume-assured pressure support and proportional-assist ventilation.[116] In neonates, direct extubation from a low ventilator rate showed a trend toward greater successful extubation than did extubation after a period of endotracheal CPAP.[117] Weaning from HFOV is performed by switching to CMV or by extubation after gradual reduction of mean airway pressure and amplitude to very low values.

Nasal CPAP, noninvasive positive-pressure ventilation, and methylxanthines are evidence-based treatments to facilitate weaning and extubation of preterm infants, but only the first two can be recommended for routine use. In contrast to adults, steroids are not recommended for prevention of postextubation stridor in pediatric or neonatal populations.[118]

In conclusion, neonates and children can be weaned much quicker than adults, and weaning protocols have proven to be of little or limited value in pediatric patients.

COMMON TECHNIQUES FOR RESPIRATORY SUPPORT

The following invasive and noninvasive techniques are commonly used in infants and children to support spontaneous ventilation or to apply controlled mechanical ventilation:

1. CPAP during spontaneous breathing
2. PSV to assist spontaneous breathing
3. PCV or VCV
4. Intermittent mandatory ventilation (IMV) or SIMV, with or without PSV
5. High-frequency ventilation (HFV) with or without spontaneous breathing

Clinical experience with most of these modes in neonates and infants, although less in children, is distinctly different from that in adults. There is a long-standing neonatal experience of nasal CPAP and HFV. Conversely, assist modes only recently became available in the neonatal field because of difficulties in providing sufficiently sensitive trigger systems, especially for end-expiratory flow termination during PSV. This latter may be enhanced through the availability of neurally adjusted ventilatory assist (NAVA), which appears to lessen asynchrony.[119] All modes, with the exception of HFV, are also used during noninvasive ventilatory support, either by nasal or nasopharyngeal prongs or cannula, nasal or nasofacial masks, or the helmet.

Continuous Positive Airway Pressure in Neonates

In infants, CPAP is commonly applied via the nasal route with a short binasal cannula (nasal prongs), a single

nasopharyngeal cannula, or a soft nasal mask. Short binasal prongs seem to be more effective than a single prong.[120] The feasibility of using a helmet as CPAP interface was documented recently.[121] To apply CPAP, various methods, such as electronic feedback control, underwater seal, flow opposition, and flow opposition with fluidic flow reversal on expiration have been used. Each method imposes a different resistive load and there is ongoing discussion whether one is better than another[122–125] in reducing work of breathing. For practical reasons, it is simpler to divide the commercially available devices into two types: continuous and variable flow systems.

Continuous flow systems adjust the CPAP level by either modulation of the resistance created by an valve in the expiratory circuit (the case for some ventilators with inbuilt CPAP modes) or by placing the expiratory tubing under water, the depth of the tubing allowing for blow-off at a certain CPAP level (the case for bubble CPAP systems). These systems require relatively high constant flow rates (often above 8 L/min) to ensure that flow during inspiration at least matches a patient's peak inspiratory flow. Simple high-flow systems can also be used for CPAP;[51] their efficiency remains doubtful, and pressure variations are poorly controlled.[126]

Variable flow systems maintain a set CPAP level by rapid adjustments in the flow rate. Flow modulation can result from either fast modulation of inspiratory flow or, with a special nosepiece, by entrainment of gas at the inspiratory jets (Infant Flow system) or with a jet device at the nasal prongs (Benenviste system).[127] With the latter systems, CPAP is changed by increasing or decreasing flow. The pressure generated should be measured with an accurate manometer and linked to an alarm.

No clear evidence favors any particular nasal interface[120] or flow pattern.[128] A recent randomized controlled trial that compared various CPAP systems (bubble vs. infant flow) suggested certain advantages with a bubble CPAP system in terms of secondary outcome measures, such as a higher rate of successful extubation or shorter duration of CPAP in infants recovering from RDS.[129] A crossover study in premature infants showed better oxygenation with bubble CPAP when compared to ventilator-derived CPAP.[125] Such observations are intriguing and question the belief that modern expensive CPAP devices perform better than older, simple, and relatively cheap devices.

Nasal CPAP is now used as first-line support in the neonatal field, mainly for premature infants presenting with various forms of respiratory distress (classically, infant RDS). Many unanswered questions remain,[130] such as optimal pressure or flow to be used,[131] whether early CPAP for RDS reduces mortality and morbidity (chronic lung disease remaining a significant problem in neonatal intensive care) as compared with intubation and mechanical ventilation (a large trial failed to give a definitive answer[49]), and the lack of clear criteria to indicate when an infant is unresponsive to nasal CPAP.[132]

Conventional Mechanical Ventilation in Neonates and Infants

TIME-CYCLED, PRESSURE-LIMITED VENTILATION

Pressure-control techniques have been used in neonates for many years. Such neonatal *pressure controllers* deliver a continuous, constant flow during inspiration and expiration, and the inspiratory and expiratory pressure levels cycle at regular intervals (time-cycled, pressure-limited [TCPL] ventilation). In that inspiratory flow characteristics of TCPL ventilation differ from classic PCV, which modulates inspiratory flow in a decelerating pattern (Fig. 23-3), a classic neonatal ventilator that offers TCPL ventilation is nothing more than a simple and easy-to-operate *flow driver.* To achieve an inspiratory plateau pressure, relatively high flow rates are required (6 to 10 L/min), especially when short T_I values (0.3 to 0.4 second) are used to keep mean airway pressures low.

On several occasions, pressure-limited ventilators have failed to provide adequate alveolar ventilation in newborn babies; this can be a problem when T_I is too short or with insufficient inspiratory flows. A second and perhaps more important problem with TCPL ventilation is that delivered V_T varies from breath to breath, coupled with the fact that many flow drivers still do not offer measurements or display of delivered V_T. The same problems, however, hold true for any pressure-control mode.

A third problem with TCPL ventilation is the slow buildup of pressure and cycle to pause as the pressure target is achieved. There is argument as to whether this leads to slow intratidal recruitment of the airways during the insufflation phase, the quantity of which depends on the pressure delivered. This may create less shear force in the airways than does classic PCV with a decelerating flow pattern. Conversely, a potential disadvantage of TCPL ventilation is that as soon as the inspiratory pause time commences, unstable airways are prone to collapse as gas is redistributed to areas with longer time constants. Consequently, a situation arises whereby collapse is already commencing during the inspiratory phase. Conversely, if a fast regulation system is used (variable flow delivery in a pressure-controlled mode) that promptly delivers flow, tightly regulated by pressure, previously collapsed airways will continue to expand; others with a longer time constant experience a chance of opening throughout inspiration. This implies that there is no pause during the inspiratory period and that the regulation system is active even during the "no-flow" phase. Flow during this "no-flow" phase is seen only on high resolution but adds to the efficacy of recruitment by providing extra time for lung inflation; this behavior is best explained by the power law of avalanches.[133]

PRESSURE-CONTROLLED VENTILATION

Classic PCV has been introduced in neonatal ventilation only recently. It differs from TCPL ventilation in that inspiratory

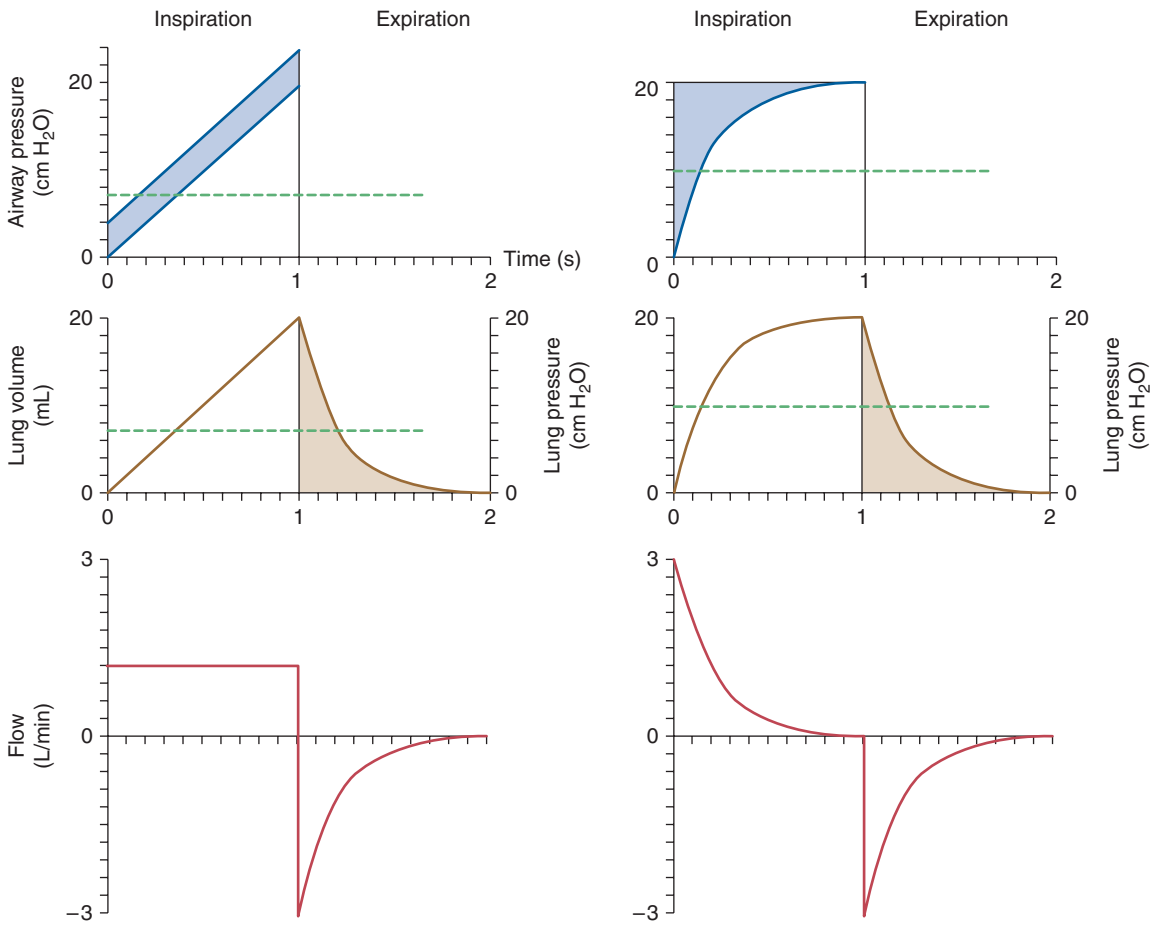

FIGURE 23-3 Graphic representation of the equation of motion for a constant inspiratory flow pattern (*left*) and a constant inspiratory pressure pattern (*right*). The *dotted lines* indicate mean airway and lung pressures. The *shaded sections* represent equal geometric areas proportional to the pressure required to overcome flow resistance. The *unshaded sections* represent equal geometric areas proportional to the pressure required to overcome elastic recoil. Note that for the same tidal volume and mean inspiratory flow rate (i.e., tidal volume-to-inspiratory time, V_T/T_I), the constant flow pattern produces a higher peak airway pressure and lower mean airway pressure but the same peak lung pressure. (Reprinted, with permission, from Chatburn RL. Principles and practice of neonatal and pediatric mechanical ventilation. *Respir Care*. 1991;36:569–595.)

flow is variable (decelerating flow pattern). Peak inspiratory pressure can be reached early during inspiration. This leads to fast increases in circuit and airway pressures, which may help to overcome high airway resistance. For years, this was considered harmful, but no evidence supports this concern.

VOLUME-CONTROLLED VENTILATION

VCV in neonatology was abandoned in the early 1980s mainly because of difficulties in measuring very small V_T values under low-flow conditions. A second concern was the slow rise to peak pressures (with constant inspiratory flow), eventually causing unequal lung-volume distribution within the lung. A third concern was the frequent occurrence of an ETT leak (not using cuffed tubes), which can alter effective delivery of volume substantially. All these concerns are mere assumptions and not supported by clear scientific evidence. Because of technological advances and discussion of small V_T values for lung protection, there is growing interest in this mode again. A single-center, randomized, controlled trial has compared pressure-limited ventilation versus VCV, with identical V_T values in both arms, in newborns presenting with RDS.[134] There was a small benefit, in terms of ventilator duration and significantly less intraventricular hemorrhages and abnormal periventricular echo densities on ultrasound scans, in favor of VCV. The lower rate of cerebral complications with VCV may reflect better P_{CO_2} stability.

VOLUME-TARGETED VENTILATION

Recognition that volume rather than pressure causes ventilator-induced lung injury has led to the development of various techniques that combine features of pressure-limited and volume-limited ventilation in a mode, usually referred to as *volume-targeted ventilation* (VTV; i.e., volume guarantee, pressure-regulated volume control, or volume-assured pressure support). With this, delivery of a set V_T is "guaranteed" by adjusting inspiratory pressure according to changes

in compliance, resistance, or respiratory drive. This usually requires a learning period over a number of breaths, during which dynamic compliance and respiratory system resistance are assessed by the ventilator. Small studies show only small breath-to-breath variability in V_T,[57,135] although there is concern about overshooting volume delivery over several breaths (learning period effect) if compliance or resistance change rapidly.[39] Along the same lines, inbuilt algorithms may cause an increase in airway pressure resulting in larger than targeted V_T over the next few breaths if a spontaneously breathing infant's efforts have interrupted his or her expiration by diaphragmatic braking.[136] Therefore, the safety of these devices may need to be reconsidered.

Recent meta-analytic data suggests that the use of VTV in premature infants with RDS might improve pulmonary and neurodevelopmental outcome.[37] Cross-sectional surveys document a rapid increase in the routine use of VTV,[31,137,138] but with a considerable variation in VTV practice. However, despite the fact that some have provided practical advice on use of VTV in premature infants,[138] we are still far away from establishing best VTV practice.

PATIENT-TRIGGERED VENTILATION

Synchronized Intermittent Mandatory Ventilation. Asynchrony may cause poor gas exchange and air trapping, leading to pneumothorax, hemodynamic instability, changes in cerebral blood flow, and intracranial hemorrhage in newborns.[139] Synchronization of spontaneous inspiration with the ventilator has been attempted, initially with SIMV, which conducts a search for a spontaneous effort within a predefined time frame (Fig. 23-4). Although SIMV was thought to be superior to IMV, no evidence supports this suspicion.[140]

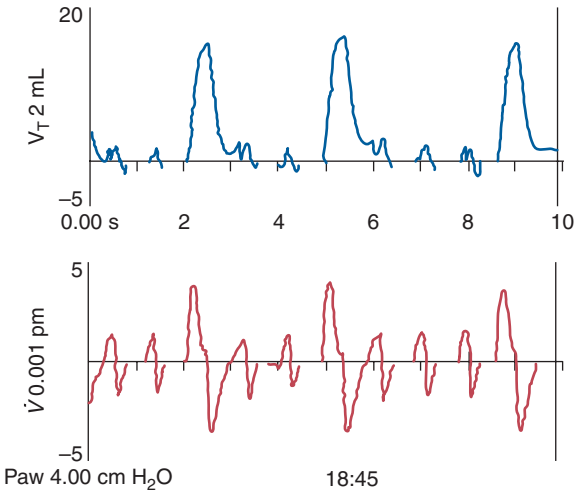

FIGURE 23-4 Volume (*above*) and flow (*below*) waveforms in a patient receiving synchronized intermittent mandatory ventilation (SIMV). The SIMV breaths occur at somewhat irregular intervals because of the timing windows, during which the machine waits to detect spontaneous effort by the patient. *Paw,* airway pressure; *V,* flow; V_T, tidal volume. (Reprinted, with permission, from Donn S. Invasive and noninvasive neonatal mechanical ventilation. *Respir Care*. 2003;48:426–439.)

Assist-Control, Intermittent Mandatory, and Pressure-Controlled Ventilation. Assist-control ventilation, IMV, and PCV were developed to assist all spontaneous breaths that exceed a trigger threshold; in the case of apnea or bradypnea, a mechanical breath is provided by the machine according the rate set. The inspiratory time is set by the operator. Asynchrony occurs when the machine's T_I exceeds the infant's T_I.

Pressure-Support Ventilation. It is possible to terminate a machine breath based on a decline in inspiratory flow to below a certain percentage of peak inspiratory flow, as with PSV. Algorithms such as this help to synchronize patient effort with ventilator assistance.[141] PSV increases inspiratory pressure to a preset level and is intended to decrease the work of breathing. Flow delivery is variable and proportional to patient effort. Initially, PSV was viewed mainly as a weaning mode, but subsequently, it was used more widely in the adult field.[142] Since the development of sensitive flow triggers and variable inspiratory flow termination, PSV can be used in neonates.[143]

SIMV, assist-control ventilation, IMV, pressure-control ventilation, and PSV can be grouped under the generic term of *patient-triggered ventilation.* In neonates, and especially in preterm infants, the trigger needs to sense any weak spontaneous breathing effort. It also must minimize artifacts that may result from other sources: heartbeat-induced variations in intrathoracic pressure or variations in pressure oscillations induced by rainout in the ventilator tubing. Various trigger signals have been used: flow or pressure triggers, abdominal or thoracic impedance methods, and detection of abdominal motion. Flow triggering is more sensitive than pressure triggering for neonatal ventilation.[144] Two major sources of patient–ventilator dyssynchrony are (a) inappropriate long delays in inspiratory triggering (preterm infants with a short T_I may have completed much of the inspiratory phase before ventilator assistance commences) and (b) inappropriately selected inspiratory flow termination ("cycling off" or "flow termination" setting given as a percentage of maximum inspiratory flow; if set too low, inflation times will be too long). With this, the flow at which the ventilator cycles to exhalation does not coincide with the end of patient T_I.

Neurally Adjusted Ventilatory Assist. NAVA offers a new approach to patient-triggered ventilation. This mode provides ventilator support triggered by, and proportional to, the electrical activity of the diaphragm (see Chapter 13). Experience with NAVA in the neonatal field is sparse. In a small series of premature infants, better patient–ventilator synchronization (more appropriate cycling off) was observed as compared to PSV.[145] This was the case even with large air leaks, suggesting that NAVA may improve ventilator synchrony during noninvasive ventilation through nasal prongs or masks. Whether this will decrease the need

for intubation in infants with RDS is unknown. In pediatric patients, synchrony has undergone less evaluation, although neural triggering has been shown to precede pneumatic triggering in more than two-thirds of breaths during NAVA.[119]

Conventional Mechanical Ventilation in Children

In pediatric intensive care units, conventional mechanical ventilation is used in a similar fashion to adult intensive care units. With today's ventilators, which offer various control (pressure or volume control) or assist (mainly PSV) modes, trigger systems (flow or pressure), and cycle criteria (time or flow based), even small children can be satisfactorily assisted. In the pediatric setting, PCV and PSV are most commonly used,[2] although volume control or VTV are sometimes preferred and useful for assuring stable P_{CO_2} values in patients with pulmonary hypertension (reactive pulmonary vasculature) or increased intracranial pressure. Otherwise, there is no proven benefit for these latter modes in children.

High-Frequency Ventilation in Neonates and Infants

HFV is defined by a frequency that greatly exceeds the normal respiratory rate and a V_T that approximates anatomic dead space (see Chapter 19). There are three major types of HFV:

1. *High-frequency positive-pressure ventilation* (rate: 60 to 150 Breaths/min)
2. *High-frequency jet ventilation* (HFJV; rate: 100 to 600 Breaths/min)
3. HFOV (rate: 180 to 1500 oscillations/min or 3 to 25 Hz)

HFOV is the most commonly used method in pediatric and neonatal intensive care units. High-frequency positive-pressure ventilation and HFJV promote gas exchange in a conventional way with V_T greater than dead-space volume. Expiration is passive. In contrast, HFOV uses V_T values that are less than dead space, and expiration is active.

HFJV is used mainly during (adult) laryngeal surgery; few randomized, controlled trials exist in neonates, with conflicting results.[146,147] Concerns have been raised about prolonged HFJV not only in neonates but also in adults regarding airway damage, ranging from focal necrosis to complete airway obstruction with mucus and severe necrotizing tracheobronchitis.[148,149] Increased risk of adverse cerebral outcome has been reported.[150] Studies have not used consistent criteria for assessment, however, and HFJV systems have varied widely.

All these methods are highly effective in eliminating CO_2, but the effect on oxygenation is less uniform. This is one reason that these modes (especially HFOV) have failed to sustain their initial attraction. Within the context of ventilator-induced lung injury and lung-protective strategies, HFV could be viewed as the optimal protective mode. By providing very small VT values, it is possible to ventilate the lung within a safe zone of the pressure–volume curve of the respiratory system.[151] Side effects, such as from respiratory acidosis (permissive hypercapnia), are not associated with HFOV, and spontaneous ventilation can be often maintained, at least in neonates and small children. Thus, use of sedation is decreased, and muscle relaxants are avoided. In larger patients, inspiratory flow demands are higher; thus, spontaneous breathing is not managed as easily, and heavy sedation and/or paralysis may be required.

INDICATIONS AND TIMING FOR HIGH-FREQUENCY OSCILLATION VENTILATION IN NEONATES AND CHILDREN

HFOV is still used mainly as rescue therapy despite clear indicators from experimental and clinical experience that it is most beneficial when initiated before major lung injury has developed[152–155] because no ventilator strategy can repair preexisting lung injury.[156,157]

Classic indications for HFOV in neonatal patients include:

1. *RDS* characterized by surfactant deficiency, high chest wall compliance, and low functional residual capacity. This is the constellation for easy and efficient lung recruitment, at least with early disease.[153,156] Conceptually, the success of HFOV depends on its ability to recruit lung volume, which is not always easy late in disease when substantial ventilator-induced damage is superimposed on preexisting injury. Most randomized controlled trials, comparing HFOV to CMV in infants with RDS, produced controversial outcome data.[28,59,158] This has been partially attributed to flaws in study design and noncompliance with study protocols.[27] A recent small randomized controlled trial (HFOV vs. CMV) in a well-defined patient group (minimizing heterogeneity) and employing comparable ventilator strategies in both arms, showed a benefit[60] in favor of HFOV. This may revitalize the debate on the use of HFOV in neonates with RDS.
2. *CDH,* usually associated with alveolar and pulmonary vascular hypoplasia,[159] resulting in increased risk of ventilator-induced lung injury[160] and presenting with PPHN requiring aggressive P_{CO_2} control. Lung recruitment should be applied with great caution because of the difficulty in estimating the degree of lung hypoplasia.
3. *Air-leak syndrome,* such as pneumothorax or interstitial emphysema. HFOV can achieve early improvement and resolution of air leak in patients with interstitial emphysema, enabling better gas exchange and lower airway pressures than with CMV.[161]
4. *PPHN.* Although iNO is the classic treatment for PPHN, HFOV can enhance delivery of iNO by achieving adequate lung recruitment[162] and enable easier CO_2 control and correction of respiratory acidosis.

The classic indication for HFOV in pediatric patients is *diffuse alveolar disease* (*primary or secondary ARDS*)[152,163]

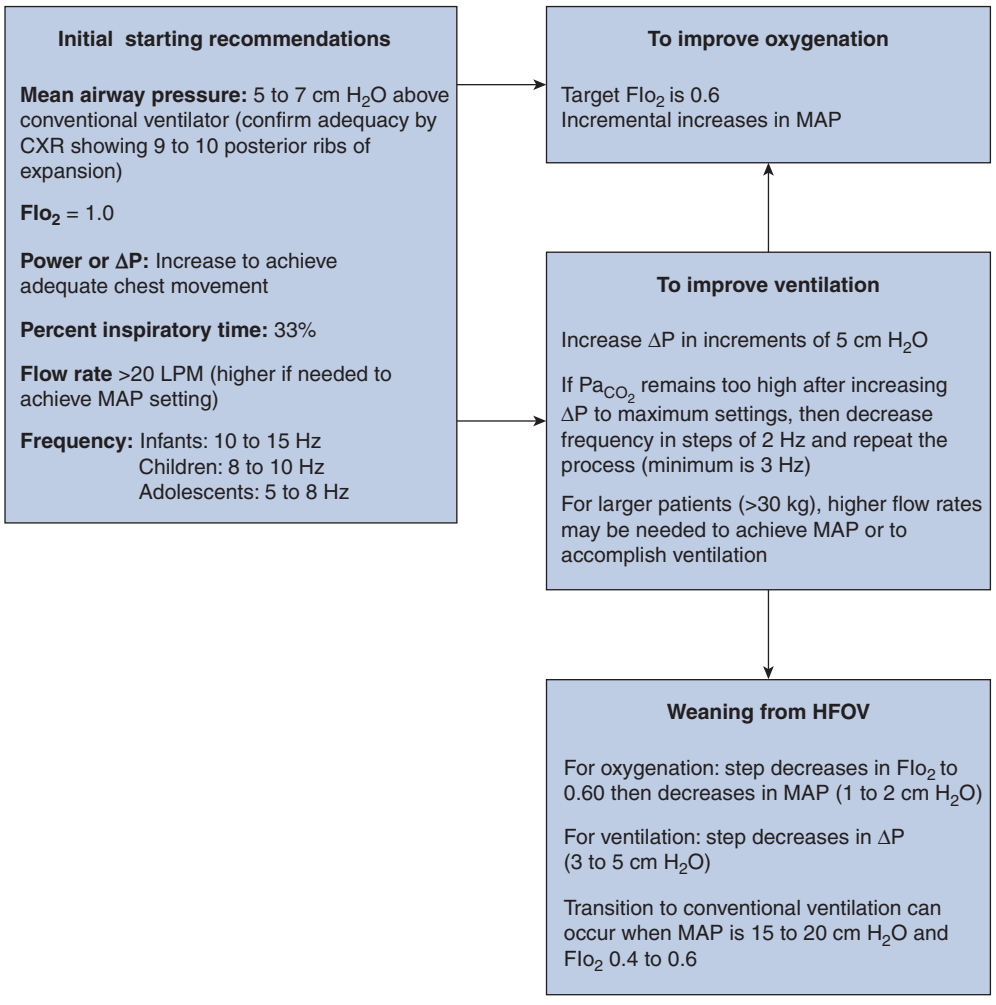

FIGURE 23-5 Recommendations for instituting high-frequency oscillatory ventilation (*HFOV*) and the transition to conventional ventilation during weaning. CXR, chest X-ray; LPM, liters per minute; MAP, mean airway pressure. (Courtesy Martha Curley, Children's Hospital Boston, Harvard Medical School. See also ref. 89.)

as rescue therapy to improve oxygenation. The only pediatric randomized controlled trial[152] did not show any difference in survival or duration of ventilation duration, although duration of supplemental O_2 was shorter with HFOV than with CMV. Recommended strategies for use of HFOV (Fig. 23-5) are empirical and derive mainly from the neonatal field and experience with HFOV in adult patients.[164]

UNIQUE NEONATAL AND PEDIATRIC MACHINES AND INTERFACES

Neonatal and Pediatric Ventilators

Conventional pediatric and/or neonatal ventilators can be divided in three groups: (a) neonatal ventilators, (b) pediatric ventilators (which generally are identical to adult ventilators), and (c) all-age-group ventilators (from neonates to adults). Traditionally, a neonatal ventilator was used for neonates or toddlers up to a body weight of 10 kg. Neonatal ventilators were mainly constant-flow generators that build up pressure and cycle to pause as the pressure target is achieved (TCPL ventilators). This type of ventilators are limited to neonates and infants, because inspiratory flow does not allow a buildup of sufficient airway pressure in bigger patients and such ventilators are not able to adapt to the high inspiratory peak flows of bigger patients with spontaneous breathing activity. Today, some neonatal ventilators, mainly all-age-group ventilators, also offer classic pressure-control and volume-control modes.

The following are the characteristics of a good neonatal ventilator: (a) small apparatus dead space; (b) stiff but flexible circuit tubing; (c) reliable tidal-volume measurement device (hot-wire or pressure-differential flow meter or fixed or variable orifice device) placed between the Y piece

and ETT; (d) highly sensitive trigger device (flow triggering preferred to pressure triggering at least in premature infants,[144] which provides adjustable inspiratory flow triggering and in PSV modes cycles off criteria ranging from 5% to 25% or more of peak inspiratory flow); (e) built-in leak compensation, which can be turned off if there is a large leak around the ETT (this is important with PSV to enable inspiratory flow termination so as to avoid excessive T_I in relation to patient need); and (f) airway humidification with cascade humidifiers and heated-wire ventilator circuitry.[165]

The new-generation all-patient units offer all these neonatal requirements and perform as well as those designed specifically for neonatal and pediatric patients.[166] Detailed specifications on "only neonatal" and "all-patient" ventilators can be found in Tables 23-3 and 23-4 in the second edition of this book.

High-Frequency Ventilators

Important differences in performance characteristics of devices for HFV have been shown repeatedly.[167–170] Thus, it is not possible to compare settings from one device to another. Three major systems are used: HFOV, HFJV, and HFV with a flow-interrupter (HFFI) device.

HIGH-FREQUENCY OSCILLATION VENTILATION

HFOV is characterized by use of mean airway pressure (continuous distending pressure), on top of which square-wave or sinusoidal pressure swings are added by means of a piston, diaphragm, or bidirectional high-velocity flow in the expiratory limb. This leads to a more or less active aspiration during the "expiratory" phase of the oscillatory cycle. The best studied and most widely applied HFOV system is the SensorMedics 3100 high-frequency oscillator (VIASYS Healthcare, Palm Springs, CA). This exists in two versions: the 3100A for neonatal use and the 3100B for pediatric and adult use. The Humming V (Metran Medical Instruments, Saitama, Japan) exhibits similar performance to the SensorMedics 3100A in vitro and bench studies and also can be switched to CMV. Other neonatal ventilators combine conventional and HFOV. There is tendency to use the term HFOV for various forms of HFV, but to qualify as an oscillator, a device has to generate a waveform that has both positive and negative pressure deflection. Each system has a slightly different design (piston or diaphragm, Venturi-valve or jet injector) for creating biphasic pressure waveforms (high frequency oscillations). Therefore, the oscillation power of each machine is slightly different from the other, which explains their various ability to support children only to a certain weight limit.

A new development in many neonatal oscillators (Fabian, Leoni-plus, and VN500) is the ability to servo-control the delivered V_T (measured as exhaled or inhaled tidal volume at the airway opening) by means of HFOV+Volume Targeted Ventilation (volume guarantee) option. This allows the user to preset a V_T during HFOV. Whether this new mode offers any advantage is unknown; using target V_T ventilation during HFOV has no sound background and it goes against the principle of maintaining a mean airway pressure for lung-volume optimization and superimposing the lowest amplitude needed for acceptable CO_2 washout. We still do not know which V_T is appropriate in the various situations, given that V_T during classic HFOV shows large variations (0.5 to 2.5 mL/kg). V_T depends on the oscillation frequency and there is no consensus on the optimal frequency in various settings. Given these unknowns, HFOV with the VTV option should not be used until more data on its safety are available. Making extrapolations based on protective V_T during conventional ventilation to V_T during HFOV is inappropriate because of completely different gas-exchange mechanisms (convection vs. molecular diffusion) between the two modes.

HIGH-FREQUENCY JET VENTILATION

HFJV is characterized by the delivery of small, high-velocity breaths at fast rates coupled with passive exhalation. HFJV allows the application of relatively low airway pressure to maintain reasonable oxygenation. Pulses of gas are delivered at high velocity through an orifice at frequencies of 10 to 100 Hz. The orifice may be in a T-piece connected to a conventional ETT or a narrow tube incorporated in the wall of a special ETT or at end of a fine-bore catheter placed in the trachea. Available HFJVs for pediatric use include the Acutronic Monsoon Deluxe Jet Ventilator (Acutronic Medical Systems, Hirzel, Switzerland), and for pediatric and neonatal use the Life Pulse High Frequency Ventilator (Bunnell, Salt Lake City, UT). In the pediatric field, indications for HFJV are available in the operating room during endolaryngotracheal surgery.[171] In the neonatal field, HFJV has been proposed as rescue treatment for severe pulmonary dysfunction in infants with RDS, CDH, and meconium aspiration syndrome.[147,172–174] Although promising results have been reported with HFJV as early or late rescue[172] treatment in infant RDS, benefit in terms of pulmonary or neurodevelopmental outcome has not been documented.[175]

HIGH-FREQUENCY FLOW-INTERRUPTER

For HFFI (basically a CMV mode) gas flow from a high-pressure source is interrupted at a high rate. Expiration is passive, but additional negative pressure generated by a Venturi effect on the expiratory side may enhance lung emptying. The Infrasonics Infant Star 950 (Nellcor Puritan-Bennett, Inc., Pleasanton, PA) is an example. HFFI devices are available only for neonatal ventilation, and little data exist on their clinical use.[176,177]

Interfaces

Much progress has been made in improving interfaces. For the invasive airway management, improvements in ETT design have changed the traditional teaching to avoid use of cuffed ETTs in infants and children younger than 8 years of age because of increased risk of subglottic injury. This dogma had inhibited research on this topic despite major technological advances with the development of low-pressure, high-volume cuffs and new material. Recent studies show that cuffed tubes can be safely used in children of all ages, provided the correct size is used and cuff pressure is continuously monitored, without an increase in postextubation stridor.[178,179] Advantages include a lower reintubation rate, and control of leakage causing less autotriggering and more stable ventilation. Pediatric advanced life support recommendations have also changed and now suggest the use of cuffed tubes of appropriate size for emergency tracheal intubations in children.[180]

For noninvasive ventilation, the fit and comfort of an interface together with patient–ventilator synchrony are the most important factors for success. There have been significant improvements in mask designs and in plastic materials used for mask seal interfaces (air-cushion seal, gel interfaces). The availability of bilevel-pressure masks for pediatric patients, however, is still very limited, and one has often to rely on petite versions of adult masks.[181] Aside from the known complications related to nasal mask ventilation (skin irritation or breakdown, headache, eye irritation, gastric distension, leakage), certain problems and complications are unique or more pronounced in children. Leakage can simulate patient effort, causing some bilevel generators to autotrigger when set in spontaneous or timed mode. In these circumstances, the ventilator can be set in a timed or control mode at a rate that overrides the patient's respiratory drive during sleep. The pressure on facial structures from a nasal mask is associated with flattening of facial structures, especially the midface, leading to malocclusion with retrusion of the maxillary ridge.[182,183] The choice of the interface also influences the type of ventilator used. Nonvented masks are designed for use with more sophisticated intensive care unit-type ventilators (requiring an active exhaust valve), whereas vented masks are used for the more traditional flow-cycled bilevel-pressure home ventilator (not requiring an active exhaust valve).

MONITORING OF MECHANICAL VENTILATION: SPECIFIC PEDIATRIC AND NEONATAL CONSIDERATIONS

Several specific pediatric and neonatal issues about respiratory monitoring must be noted. First, ventilator-circuit dead space should be kept as small as possible when monitoring devices are added. Second, flow measurements must be made as close as possible to the airway opening to get true delivered V_T.[184,185] Third, with standard practice of using uncuffed ETTs air leakages around the ETT are observed in approximately 70% of all ventilated neonatal infants, rendering tidal volume monitoring less reliable.[186] Fourth, little is known about the reliability of end-tidal CO_2 measurements in the presence of ETT leakage (>30%).[187] Fifth, accurate measurements of exhaled CO_2 in pediatric and especially neonatal patients is challenging because of limitations in size of the analyzer chamber (to reduce instrumental dead space), the amount of flow that must be suctioned by side-stream devices, and the need for fast response times because of rapid respiratory rates. Therefore, small dead-space volume mainstream sensors, which have a faster response time (than side-stream devices) and do not need suction flow, are preferred.[188] Recently, a microstream capnograph (suction flow of only 30 mL/min) with a miniaturized sample chamber was developed, thus, improving the measurement accuracy of end-tidal CO_2 in intubated infants.[189,190] Volumetric capnography, measuring CO_2 elimination per breath (V_{CO2}), may assist with optimal PEEP titration: atelectatic or overdistended areas reduce alveolar ventilation and therefore CO_2 elimination.[191,192] The concept is used by companies that offer inbuilt volumetric capnography (e.g., "the open lung tool" on the Servo-I ventilator by Maquet, Solna, Sweden). V_{CO2} monitoring has also been proposed for guiding weaning but the concept has been questioned.[193]

COMPLICATIONS OF MECHANICAL VENTILATION

In addition to barotrauma (e.g., pneumothorax and interstitial emphysema), three other complications include postextubation stridor, development of chronic lung disease or BPD (classic in the preterm infant), and ventilator-associated pneumonia.

Postextubation Stridor

Acquired subglottic stenosis became a well-recognized problem with use of long-term endotracheal intubation. Serious tube trauma and postextubation stridor have decreased markedly with improvements in material and tube design and greater care in choosing appropriately sized tubes. Tube complications usually arise from incorrect size, traumatic or multiple intubations, up-and-down movements of the tube, and inadequate analgesia and sedation, causing intubated infants to struggle. Poor design can result in a cuff being positioned too high within the larynx (Fig. 23-6), causing severe trauma.[194] These observations have led to new design for ETTs.[195,196] With newly designed cuffed-ETTs (cuff pressure held ≤20 cm H_2O), side effects, such as an increased rate of postextubation stridor, were not observed in large observational studies[178,197–199] and in one randomized controlled trial.[179] Specifically designed cuffed ETTs, such as the Microcuff PET tubes, have proven safe in neonates of birthweight greater than 3 kg and in children,[200] and no real arguments remain against their use.[201] Other risk factors of postextubation stridor include duration of intubation,

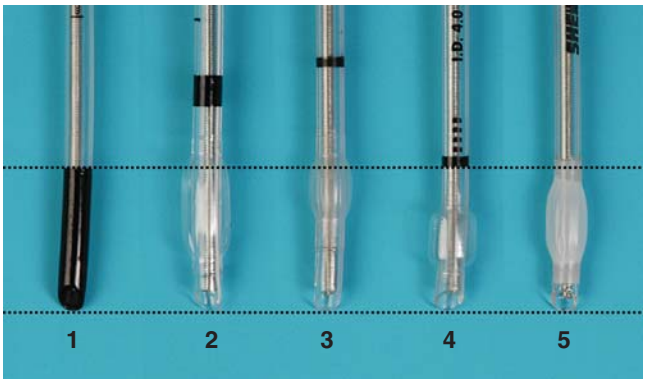

FIGURE 23-6 Positioning of the cuff on various endotracheal tubes: (*1*) uncuffed tracheal tube, inside diameter 4.5 mm; (*2*) Rueschelit Super Safety Clear, inside diameter 4 mm; (*3*) Mallinkrodt Hi-Contour P, inside diameter 4 mm; (*4*) Microcuff PET, inside diameter 4 mm; and (*5*) Sheridan CF, inside diameter 4 mm. Note that only tube 4 has a cuff of appropriate size and positioning. (Courtesy Markus Weiss, Pediatric Anesthesia, Children's Hospital of Zurich, Switzerland.)

gastroesophageal reflux, and tracheobronchial infection. Checking for a cuff leak is of little help in predicting postextubation problems in young children.[104]

Most injuries causing postextubation stridor are superficial and include nonspecific changes such as laryngeal edema, granulation tissue, and ulcerations. Stridor usually resolves with medical therapy. Inhaled epinephrine is successful in treating subglottic edema. If reintubation is required, a smaller ETT should be used to prevent additional trauma. The nasal route is preferred to optimize tube stabilization and to minimize the tube shifting with head movement. The child should be weaned rapidly from the ventilator to humidified O_2 delivered via a light T tube. These measures prevent infants from pushing out the tube with their tongue and allow for better head movements, thereby minimizing risk of further trauma. Alternatively, the child must be heavily sedated and eventually receive neuromuscular blockade. In most cases of simple subglottic edema, extubation is successful after a rest period of approximately 2 to 3 days with or without a short course of dexamethasone (1 to 2 mg/kg/day in divided doses). It is reasonable to administer dexamethasone to patients at risk of stridor for 24 hours before and 24 hours after extubation. Such prophylactic steroids may reduce postextubation stridor and the rate of reintubation.[202]

Bronchopulmonary Dysplasia in the Preterm Baby

The pathogenesis of BPD is multifactorial.[203,204] The principal risk factors are lung immaturity, barotrauma, volutrauma, O_2 toxicity, prenatal and nosocomial infections, and increased pulmonary blood flow secondary to a patent ductus arteriosus.[205,206]

Changes in neonatal care of very-low-birthweight infants, including antenatal corticosteroids, postnatal surfactant, and modified respiratory support, have improved survival and have changed the clinical picture of BPD. "Old" BPD described above is a consequence of ventilator-induced lung injury, whereas "new BPD" is mainly a developmental disorder in which the immature lung fails to reach its full structural complexity.[204,207] Improved survival of very immature infants has led to more infants with this disorder. Changes in clinical practice have improved the clinical course and outcomes for infants with BPD over the past decade, but the overall incidence has not changed[208] and there are large variations among centers.[153,209–214] This wide range reflects the heterogeneity of study populations, management practices, and disease definitions. The initial description of BPD by Northway et al[52] and Bancalari et al[215] was based on O_2 requirements at 28 days of age. As newborns of lower gestational age survived, Shennan[216] later proposed the term *chronic lung disease.* The diagnosis of BPD is currently based on the need for supplemental oxygen for at least 28 days after birth, and its severity is graded according to the respiratory support required at 36 postmenstrual weeks.[217]

Management of BPD includes minimizing ventilator duration and avoiding high O_2 concentrations. Fluid restriction, diuretics, and bronchodilators are helpful but do not alter disease course. Pulmonary vasodilators are not beneficial for BPD-associated pulmonary hypertension.[218] Dexamethasone can accelerate ventilator weaning and shorten the period of O_2 supplementation but is associated with worse neurologic outcome (increased leukomalacia, impaired brain growth) and more frequent severe gastrointestinal complications.[219,220] Dexamethasone therapy, if given at all, should be brief[221] and early, but initiated only beyond the first week of life.[219] Hydrocortisone has been recommended in place of dexamethasone because the latter may impair neurodevelopment. The efficacy of hydrocortisone, however, is questionable.[222] Inhaled steroids have some efficacy, but only in ventilated patients.[223] Despite several attempts for severity grading and various approaches for treatment and prevention, long-term prognosis remains uncertain.[224,225]

Ventilator-Associated Pneumonia

Ventilator-associated pneumonia (VAP) is the second most common nosocomial infection in the pediatric intensive care unit.[226–228] VAP occurs in approximately 5% of ventilated children, and nearly 20% of affected children die. *Pseudomonas aeruginosa,* enteric gram-negative bacilli, and *Staphylococcus aureus* are isolated most commonly from endotracheal aspirates, particularly with VAP of late onset.[229] Specific risk factors associated with pediatric VAP include the presence of a genetic syndrome, tracheal reintubation, transport out of the pediatric intensive care unit, subglottic or tracheal stenosis, trauma, and tracheostomy.[230] VAP is

associated with increased pediatric intensive care unit length of stay, ventilator days, and mortality rates. Adherence to a VAP-prevention bundle decreases VAP rate in pediatric patients.[231] For diagnostic purposes, protected bronchial brushing (sensitivity 72%, specificity of 88%) offers an alternative to poorly supported bronchoscopic bronchoalveolar lavage.[232]

IMPORTANT UNKNOWNS

Mechanical ventilation has increased survival of acutely ill neonates and children. A better understanding of pathophysiology has led to newer ventilator strategies. Many of these strategies, however, have not been tested in the pediatric setting, but simply adapted from adult experience. Recent research suggests that comparable ventilator settings are more injurious in the adult than in the infant lung.[233] This latter is supported by conflicting results from observational cross-sectional studies investigating the relationship between V_T and outcome.[30,32]

Approaches to optimizing ventilation are based on bedside assessment of respiratory mechanics and blood-gas response. Unfortunately, no characteristic of the pressure–volume curve can predict end-expiratory atelectasis, overstretching, or optimal airway pressure.[234,235] Despite improved understanding of pediatric diseases and mechanical ventilation, we still do not know the best settings for an individual child. To date, evidence is confined to bad ventilator settings.

Noninvasive ventilation has proven safe and feasible in pediatric settings and can help to avoid intubation, although we do not know whether to avoid intubation is a wise decision in some conditions. This latter is true for the pediatric and neonatal field.[49,236,237] Ventilator discontinuation is believed to decrease several complications, but proof is limited.

THE FUTURE

Respiratory monitoring has been used to decrease complications and improve patient–ventilator interactions. We need to develop approaches whereby this knowledge can be used to improve patient outcome. Tools that provide continuous recordings of pulmonary function have yet to be incorporated into ventilator equipment. For example, the continuous monitoring of functional residual capacity might improve ventilator strategies and enhance assessment of lung recruitment. Newer imaging techniques, such as bedside ultrasonography, electrical impedance tomography,[238] or optoelectronic plethysmography,[239] may help to monitor regional ventilation.[240–242] In the end, such techniques will need to prove cost-effectiveness and/or improve outcome. Furthermore, we need a better description of what constitutes "standard" care.

SUMMARY AND CONCLUSION

Mechanical ventilation of infants or small children requires fundamental knowledge of the anatomic and functional characteristics of the respiratory system in a growing child. Clinicians also require good knowledge of specific pediatric pathologies, which sometimes results in a different approach to ventilation than in an adult patient. Nevertheless, adult experience has influenced many strategies applied in pediatric and even neonatal settings because it remains difficult to do well-controlled trials of mechanical ventilation in the pediatric intensive care unit.

MECHANICAL VENTILATION DURING GENERAL ANESTHESIA

Paolo Pelosi
Claudia Brusasco
Marcelo Gama de Abreu

In the early years following the first demonstration of anesthesia with an inhalation device, different inhalation anesthetic agents were developed and tested in spontaneously breathing subjects. However, the increasing complexity of surgical procedures, the discovery and use of neuromuscular blocking as well as intravenous anesthetic agents, and the need to protect the airways resulted in the need for mechanical ventilation during general anesthesia. Accordingly, anesthesia ventilators were developed to match the particular needs of general anesthesia, which differ from those in other settings, such as the intensive care unit (ICU). Moreover, modern anesthesia is not restricted to the intraoperative period and mechanical ventilation may be required preoperatively and postoperatively.

This chapter provides a comprehensive review of aspects related to the principles and practice of mechanical ventilation during general anesthesia, as well as during the perioperative period.

RESPIRATORY EFFECTS OF ANESTHESIA AND SURGERY

General anesthesia has several effects on respiratory function, most notably on control of breathing and the activity of respiratory muscles, which influence the distributions of ventilation and perfusion within the lungs. Moreover, surgery-related positioning of patients, as well as manipulation or displacement of intraabdominal and thoracic organs may further affect ventilation and perfusion, with deterioration in pulmonary gas exchange.

Control of Breathing and General Anesthesia

OBJECTIVES OF THE CONTROL OF BREATHING

The main objective of control of breathing is the maintenance of blood gases, especially of arterial carbon dioxide (Pa_{CO_2}), which is kept within a relatively restricted range. Even a small

increase in Pa_{CO_2} may result in a significant increase in minute ventilation. The output of the respiratory center is less sensitive to reductions in partial pressure of arterial oxygen (Pa_{O_2}), but hypoxia may enhance the response to Pa_{CO_2}.[1] Another objective of the control of breathing is to maintain the brain pH. Because CO_2 is highly diffusible across the blood–brain barrier, this is achieved through modulation of alveolar ventilation, which regulates Pa_{CO_2}. Last but not least, control of breathing aims at optimizing breathing frequencies and maximizing the work output of the respiratory muscles to maintain adequate gas exchange.[2]

CONTROL OF BREATHING

The respiratory rhythm originates from complex neuronal network interactions throughout the nervous system.[3] This network consists of smaller and larger networks that interact in generating different breathing patterns, including the regular breathing (eupnea), but also sighs and gasping. The group of neurons responsible for the control of breathing is dispersed across a region in the brainstem termed the *respiratory centers*. These centers are located bilaterally in the reticular formation of the medulla oblongata and pons, beneath the floor of the fourth ventricle, and are grouped into inspiratory, pneumotaxic, and expiratory areas.[4]

The inspiratory area is located in the dorsal part of the medulla and generates rhythmic cycles that are transmitted to the diaphragm, upon contraction of which alveolar ventilation takes place. Impulses originating in peripheral and central chemoreceptors (e.g., in carotid bodies and in the brainstem, respectively), and lungs are transmitted through the vagus and glossopharyngeal nerves to the inspiratory area, downregulating its activity in a negative-feedback mechanism.[5] Impulses from the pneumotaxic center located in the pons inhibit the inspiratory area continuously, contributing to avoidance of overinflation and modulation of respiratory rate.[6] Normally, exhalation is a passive process resulting from the elastic recoil of the lungs and chest wall, and the expiratory center located in the ventral portion of the medulla is silent. This center, however, may be activated for increased alveolar ventilation, leading to recruitment of thoracic and abdominal muscles and forced expiration. In addition, alveolar ventilation is regulated by the cerebral motor cortex during voluntary control of breathing, and impulses bypass the respiratory centers being transmitted directly through corticospinal to respiratory motoneurons.[7]

EFFECTS OF ANESTHESIA AND ANALGESIA ON THE CONTROL OF BREATHING

Most drugs used to achieve hypnosis, sedation, and relief or suppression of the response to pain affect the control of breathing. Such drugs, which usually result in depression of the alveolar ventilation, have their effects mediated by direct interference with peripheral and central chemoreceptors, changes in behavioral control, suppression of the function of the motoneurons and respiratory muscles, and by general depression of the respiratory center.[8]

Volatile halogenated anesthetic drugs like halothane, isoflurane, enflurane, desflurane, and sevoflurane reduce the response of the respiratory center to hypoxia even at subanesthetic concentrations.[9–13] In addition, volatile anesthetics can potentiate the effects of neuromuscular blocking agents on the respiratory muscles in a dose-dependent and time-dependent fashion.[14] Intravenous anesthetic drugs like midazolam and propofol also blunt the response to hypoxia at subhypnotic concentrations,[15,16] while hypnotic concentrations of barbiturates are necessary for decreasing the ventilatory response to hypoxia.[17] Although anesthetics usually depress the respiratory center activity, subhypnotic concentrations of etomidate stimulate ventilation,[18] while during infusion of ketamine, the response to hypercapnia is fairly well maintained[19] or even increased.[20]

Opioids represent a mainline therapy for analgesia and anesthesia. These drugs, however, can reduce and make the respiratory rate irregular,[21] resulting both in hypercapnia and hypoxemia. Such effects are mediated mainly by opioid receptors expressed in the peripheral chemoreceptors.[22] When infused rapidly as boluses, opioids have the potential to abolish the respiratory center activity completely without producing unconsciousness. Furthermore, opioids can increase the resistance of the upper airway by enhancing the discharge activity in the recurrent laryngeal nerve, and reduce the compliance of the respiratory system through increases in tonic discharges from the expiratory area of the respiratory center.[23]

Even when administered in the intrathecal or epidural space, or intramuscularly, opioids have the potential to induce respiratory depression in approximately 1% of patients.[24] Respiratory depression induced by epidural opioids results either from systemic absorption, when delayed, or from cephalad migration through the cerebrospinal fluid, when it immediately follows the administration of the drug. Factors that magnify respiratory depression following intrathecal and epidural opioids are: (a) use of intravenous anesthetic drugs; (b) coughing, which may contribute to spread of the drug within the cerebrospinal fluid; (c) accumulation through higher and/or repeated doses; (d) use of morphine; (e) advanced age; (f) lack of opioid tolerance; (g) thoracic epidural placement; (h) general anesthesia; and (i) increased thoracic pressure.[24]

Pattern of Contraction of Respiratory Muscles and General Anesthesia

INSPIRATION

Depression of inspiratory muscle activity during anesthesia occurs not in a global but rather in a selective manner. The intravenous administration of the barbiturate thiopentone decreases the mean activity of the genioglossus, sternothyroid and sternohyoid (strap muscles), and scalene muscles in

patients.[25] Furthermore, tonic pattern of activity of the strap and scalene muscles disappears and those muscles become synchronized with inspiration.

Although diaphragmatic activity is fairly well preserved, the intercostal muscles become silent at concentrations between 0.2 and 1.0 of the minimal alveolar concentration.[26,27] As a result, a pattern of breathing originates where diaphragmatic activity expands the lower ribcage and the resulting negative intrathoracic pressure moves the upper ribcage inwards. Such pattern can be even more pronounced if the resistance of the upper airways is increased, for example, when narrow endotracheal tubes are used. In fact, it is conceivable that increased resistance solely determines the limited expansion of the ribcage during inspiration. It has been namely shown that one minimal alveolar concentration isoflurane does not reduce ribcage motion, unless hyperpnea occurs.[28] Accordingly, ribcage motion during inspiration is not depressed by anesthesia with ketamine.[29]

EXPIRATION

In contrast to the inspiratory muscles, the expiratory muscles are usually inactive in awake subjects, becoming active during anesthesia. In patients anesthetized with halothane, Warner et al[26] attributed active expiration to the motion of the internal intercostal muscles. In fact, most anesthetic agents have been implicated with active expiratory muscle activity.

The purpose of active expiration is not well determined, and its contribution in reducing functional residual capacity (FRC) during anesthesia is controversial.[30,31]

Functional Residual Capacity during General Anesthesia

Reductions in FRC of as much as 20% during general anesthesia have been reported in healthy individuals and can be larger in the presence of pulmonary comorbidities and obesity.[32] Such deterioration occurs early after induction of anesthesia and is stable over time.[33] Also, spontaneous breathing or increases in airway pressure cannot easily reverse a reduced FRC, which persists for hours after recovery from anesthesia.[32] Various mechanisms explain the reduction of FRC during anesthesia: (a) changes in the chest wall; (b) changes in the diaphragmatic shape and position; and (c) increase in thoracic blood volume.

CHANGES IN THE CHEST WALL

The loss of inspiratory muscle tone associated with anesthesia results in reduced outward recoil of the chest wall, and of the internal diameters of the ribcage,[32] leading to changes of approximately 200 to 300 mL in lung volume.[34–37] In addition, an increase in the anterior curvature of the border of vertebral bodies consistent with increased spinal curvature has been detected.[37]

CHANGES IN THE DIAPHRAGM SHAPE AND POSITION

Loss of muscle tone during induction of anesthesia may favor a cephalad movement of the diaphragm secondary to pressure of the intraabdominal organs. Although such a mechanism hypothesis has been supported by some authors,[34,38] it has been challenged by others. Using a dynamic spatial reconstructor technique, Warner et al[31] showed that it is not the position, but the shape of the diaphragm, that is altered during anesthesia. They[31] postulated that the most dorsal part of the diaphragm shifts cephalad, while the most ventral part shifts only minimally, or even caudally. Figure 24-1 schematically illustrates the concepts of change in diaphragmatic position and shape.

INCREASE OF THORACIC BLOOD VOLUME

Increases in intrathoracic blood volume resulting from redistribution of blood from the periphery could theoretically further reduce FRC, although this mechanism is controversial.[34,39]

Atelectasis Formation during General Anesthesia

The concept of atelectasis formation during general anesthesia was first proposed by Bendixen et al[40] in 1963 to explain a progressive decrease in oxygenation and compliance. Those authors, however, could not confirm that hypothesis using chest radiographs. In addition, other authors were not able to reproduce those findings, observing a prompt rather than gradual change in respiratory mechanics under anesthesia.[33]

Collapse of lung zones during anesthesia was first confirmed using computed tomography,[41] and it has been estimated that 90% of patients develop atelectasis under general anesthesia.[42] Several mechanisms have been suggested to explain the formation of atelectasis during anesthesia: (a) collapse of small airways; (b) compression of lung structures; (c) absorption of intraalveolar gas content; and (d) impairment of lung surfactant function. These mechanisms are not mutually exclusive and may interact with each other.

COLLAPSE OF SMALL AIRWAYS

A reduction in FRC below the closing capacity during anesthesia can result in collapse of lung units.[43] Two studies documented a decrease of closing capacity and FRC in anesthetized patients,[44,45] but this finding is not indisputable.[46] In the presence of increased smooth muscle tone of the small airways, collapse can occur even at FRC values above the closing capacity, for instance in patients with chronic obstructive pulmonary disease (COPD) and asthma, or those receiving anesthetic drugs that promote histamine release and cause bronchoconstriction (e.g., thiopental, atracurium, D-tubocurarine).

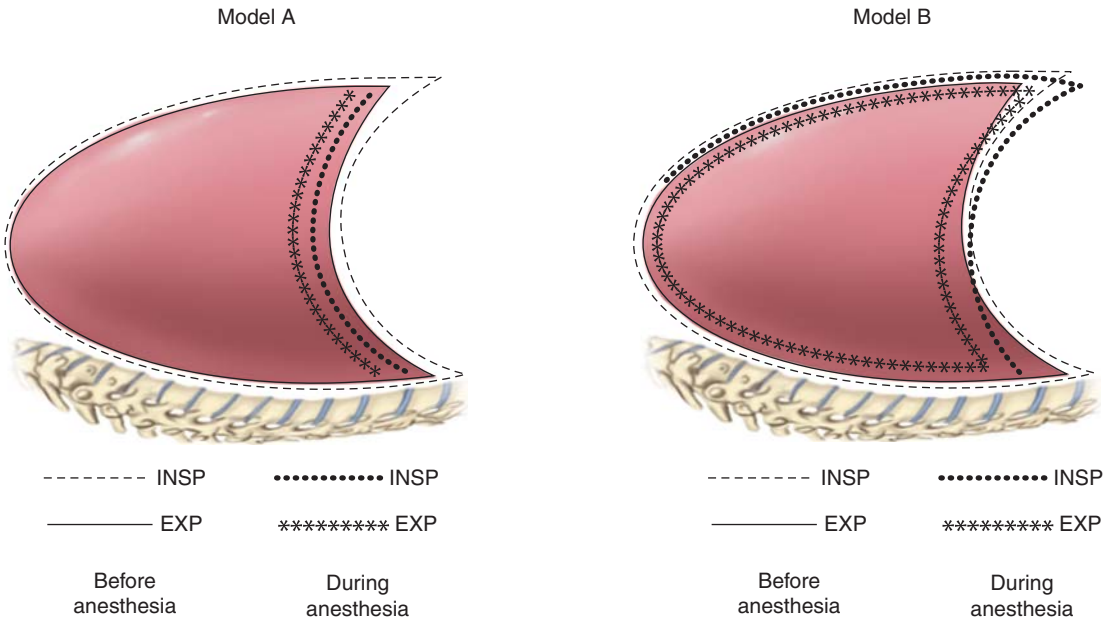

FIGURE 24-1 Models of chest wall and diaphragmatic displacement during general anesthesia. In model **A**, a cephalad shift of the diaphragm is postulated;[34] in model **B**, the displacement of the ventral part of the diaphragm is caudal, while the dorsal part shifts cranially.[31] Both models are associated with a decrease in functional residual capacity (FRC). *Exp*, expiration; *Insp*, inspiration.

COMPRESSION OF LUNG STRUCTURES

In the supine position, there is a ventral–dorsal gradient in the transpulmonary pressure.[47,48] This gradient is determined by the shape of the chest wall and lungs, as well as by lung height multiplied by the tissue density, which may promote atelectasis. Similarly, because the lung area under the heart is greater in the supine than in the prone position,[49] the weight of the heart could theoretically favor atelectasis during general anesthesia. Furthermore, the pressure of intraabdominal organs can be transmitted in part to the lung structures in the absence or reduction of diaphragmatic muscle tone.[50] In addition, increases in intrathoracic blood volume resulting from redistribution of blood from the periphery could theoretically further reduce FRC but this mechanism is controversial.[34,39]

ABSORPTION OF INTRAALVEOLAR GAS CONTENT

In the presence of an increased ventilation-to-perfusion ratio, high alveolar oxygen concentrations can lead to a progressive loss of alveolar total gas volume. A computed tomography study showed that 16% to 20% of lung tissue develops collapse or is poorly aerated in patients under general anesthesia.[51] Absorption atelectasis is most relevant when small airway closure occurs, as for instance following reduction of the FRC beyond the closing capacity. The pulmonary circulation then takes up the trapped gas enriched with oxygen, resulting in atelectasis. This mechanism is supported by the fact that lower oxygen fractions at induction of anesthesia limit the development of intrapulmonary shunt.[52] Mathematical modeling of gas exchange suggests that absorption atelectasis achieves a maximum as fast as 9 minutes if preoxygenation with 100% oxygen is performed over 3 minutes.[53]

IMPAIRMENT OF LUNG SURFACTANT FUNCTION

An early study implicated the volatile anesthetic agents halothane and chloroform in the reduction of lung volume of excised lung dogs. In rabbit lungs, the combination of halothane with higher inspiratory oxygen concentrations increased the permeability of the alveolar–arterial barrier, possibly because of additional effects on the lung surfactant. Also in patients without pulmonary disease, the inhalation of volatile anesthetics reduced the surface tension of tracheobronchial secretions.[54] Furthermore, inactivation of lung surfactant may occur as a result of large changes in alveolar surface area, which are associated with surfactant aggregate conversion.[55]

General Anesthesia and Distribution of Ventilation and Perfusion

Chapter 37 discusses the effects of mechanical ventilation on the distribution of alveolar ventilation ($\dot{V}_A$) and perfusion ($\dot{Q}$) in detail. Basically, mechanical ventilation is associated with $\dot{V}_A/\dot{Q}$ mismatching and increased intrapulmonary shunt, while diffusion limitation to O_2 plays a marginal role. General anesthesia and surgery have the potential to aggravate the deterioration of gas exchange by further impairment of $\dot{V}_A$ and diversion of perfusion from better ventilated lung zones.

Induction of anesthesia with certain barbiturates (thiopental and thiamylal[56]), opioids (morphine[57]), and neuromuscular blocking agents (atracurium and D-tubocurarine[58]) induces histamine release by mast cells, possibly resulting in bronchoconstriction. Also, endotracheal intubation can elicit an increase of the smooth muscle tone of smaller peripheral airways.[59] In contrast, volatile anesthetics, including halothane, isoflurane, sevoflurane, and desflurane, exert bronchodilatory effects.[60]

Patient positioning and the surgical procedure itself may affect the distributions of $\dot{V}_A$ and $\dot{Q}$. During anesthesia in the supine position, a cephalad displacement of the diaphragm with reduction in FRC and impairment of $\dot{V}_A$ in juxtadiaphragmatic zones is commonly observed.[61] Some authors, however, suggest that only the dorsal part of the diaphragm is shifted cranially, while the ventral part is displaced caudally.[31] Such a displacement pattern has been attributed to anesthesia-induced changes in other chest wall structures, like the ribcage, where the diaphragm attaches. On the other hand, surgical procedures requiring the use of the Trendelenburg position and capnoperitoneum, which have more pronounced effects on the respiratory function than the supine position and open abdominal surgery,[62] may lead to a displacement of the whole diaphragm. Interestingly, however, increased pressure in the lung base during the combination of the Trendelenburg position and laparoscopy also shifts $\dot{Q}$ to lung apical zones, resulting in a preserved $\dot{V}_A/\dot{Q}$ matching, despite deterioration in respiratory mechanics.[63] During upper abdominal surgery, the use of retractors also importantly impair lung compliance[64] and their effects on $\dot{V}_A$and $\dot{Q}$ are probably the same as those of laparoscopic surgery.

ONE-LUNG ANESTHESIA AND DISTRIBUTION OF VENTILATION AND PERFUSION

One-lung anesthesia has singular effects on $\dot{V}_A$, $\dot{Q}$, and $\dot{V}_A/\dot{Q}$ matching. Secondary to the collapse of the operated lung, $\dot{V}_A$ is limited to a single lung during such procedures. Gravity, however, slightly favors a shift of $\dot{Q}$ toward the dependent lung,[65] resulting in a better-preserved gas exchange during one-lung anesthesia in the semilateral and lateral decubitus than in the supine position.[66] Furthermore, hypoxic pulmonary vasoconstriction contributes to further redistribute the blood flow toward the ventilated lung. Theoretically, anesthesia has the potential to interfere with hypoxic pulmonary vasoconstriction. In dogs, volatile anesthetics cause pulmonary capillary dilation that may blunt the redistribution of blood flow and worsen oxygenation.[67] The use of volatile anesthetics in patients, however, especially at the minimal alveolar concentration, has not been associated with worsening of oxygenation when compared to intravenous anesthetics.[68–70] On the other hand, the use of epidural anesthesia in combination with intravenous anesthetics seems to result in better oxygenation by mechanisms not related to hypoxic pulmonary vasoconstriction, for instance, reduction of cardiac output.[71]

Assistance of the Respiratory Pump during General Anesthesia

General anesthesia does not necessarily require controlled mechanical ventilation. In fact, for more than a century after its description in 1846, volatile anesthetics have been administered to spontaneously breathing patients.[72] General anesthesia, however, may be associated with a reduction in FRC, tidal volume, changes in breathing pattern, and alterations in the mechanical properties of the respiratory system, resulting in impairment of oxygenation secondary to $\dot{V}_A/\dot{Q}$ mismatching. Furthermore, the need to protect the airways from aspiration by means of endotracheal intubation and the use of neuromuscular blocking agents to facilitate surgery and endotracheal intubation itself led to the regular use of controlled mechanical ventilation to maintain an adequate gas exchange. Nevertheless, certain surgical procedures can be performed without neuromuscular blocking agents, and endotracheal intubation is not always necessary. In this context, facemasks, laryngeal masks, and other supraglottic devices have largely replaced endotracheal tubes. Accordingly, the interest of anesthesiologists in maintaining spontaneous breathing activity during general anesthesia has been increasing.

In view of these facts, anesthesiologists must be able to partially and fully assist the respiratory pump. For this purpose, several assisted spontaneous breathing and controlled mechanical ventilation modes that are present on ICU ventilators are required. Anesthesia ventilators, however, must be able also to deliver inhalation anesthetics in an environmental and economically friendly way, which is not feasible with semiopen systems. Table 24-1 lists the ventilator modes commonly used during anesthesia in the operating room. Obviously, not all anesthesia ventilators offer all of those modes and some of them are not available on anesthesia machines, as they are currently not appropriate for use in combination with volatile anesthetics—for example, modes based on high-frequency ventilation. However, developing technologies may overcome this limitation in the near future.

Ventilator-Associated Lung Injury during Anesthesia

The main goals of mechanical ventilation during general anesthesia are to oxygenate arterial blood and secure adequate CO_2 elimination.[77] To achieve those aims, tidal volumes as high as 12 to 15 mL/kg of predicted body weight for two-lung ventilation, and 8 to 10 mL/kg for one-lung ventilation have been advocated and represent common practice. It was recognized early that the use of high tidal volumes helped in avoiding intraoperative lung atelectasis[40] and decreased FRC. Accordingly, the use of positive end-expiratory pressure (PEEP) has been primarily linked to its potential for increasing FRC and avoiding airway closure, even though PEEP does not necessarily improve oxygenation during general anesthesia.[78,79] Because of the potential

TABLE 24-1: VENTILATOR MODES USED FOR ASSISTING THE RESPIRATORY PUMP DURING GENERAL ANESTHESIA

Mode	Comment	Possible Indications in Anesthesia
CPAP (continuous positive airway pressure)	Increases mean airway pressure and allows spontaneous breathing	Induction of anesthesia to avoid major decrease of FRC; decrease inspiratory effort in the presence of an endotracheal tube; increase tidal volume during decreased inspiratory drive; before extubation to avoid loss of the FRC
PSV (pressure-support ventilation)	Increases the pressure at the airway above the expiratory pressure in response to an inspiratory effort; can be triggered either by flow or pressure	Maintenance of adequate ventilation in presence of reduced inspiratory drive, restrictive lung disease, partial neuromuscular blockade or neuromuscular disease; increased inspiratory effort in presence of a narrow airway device; reduction of atelectasis, improved gas exchange, decreased level of sedation;[73] weaning from controlled ventilation
V- or PACV (volume or pressure assist-control ventilation)	Guarantees that the desired tidal volume or driving pressure is delivered upon an inspiratory effort	Allow patients with respiratory drive to control the respiratory rate and/or tidal volume
SIMV (synchronized intermittent mandatory ventilation; also SIMV-VC and SIMV-PC)	With SIMV, if an inspiratory effort is sensed either by pressure or flow during a sensitive time window, the ventilator applies a preset tidal volume (VC) or pressure (PC); a minimum mandatory ventilation can be set, which will guarantee acceptable gas exchange. SIMV has greater acceptance in the operating room than in the ICU	Maintenance of adequate ventilation in presence of inspiratory effort; emergence from anesthesia
VCV (volume-controlled ventilation)	VCV is time-cycled and volume-targeted; PCV is time-cycled and pressure-limited; corresponds to the default mode on most anesthesia ventilators	Tight control of tidal volume in the absence of inspiratory effort, allows better control of partial pressure of end-tidal carbon dioxide ($P_{ET}CO_2$)
PCV (pressure-controlled ventilation)	PCV is time cycled and pressure-limited	Tight control of inspiratory peak pressure; possibly of value in combination with supraglottic airway devices to avoid gastric insufflation[74] and upper airway surgery to avoid anastomose insufficiency. Also useful with uncuffed endotracheal tubes to compensate for leaks
VCV+AutoFlow	Used in the volume-controlled ventilation mode, autoflow automatically adjusts the inspiratory flow to achieve the desired tidal volume with lowest possible inspiratory pressure, resulting in an inspiratory decelerating flow pattern. It is also known as pressure-regulated volume-controlled ventilation (PRVCV) and is similar to pressure control with volume guarantee (PC-VG)	In combination with a supraglottic airway or surgery of the upper airways to reduce peak pressures and avoid gastric insufflation and airway anastomose insufficiency
APRV (airway pressure release ventilation)	Time-cycled ventilation with a higher continuous airway pressure that is maintained for longer periods of time (usually >2 s) and periodically released until positive end-expiratory pressure (PEEP) for short periods of time (usually <1 s, typically 0.5 s), resulting in an inverse inspiratory-to-expiratory timing (I:E) ratio. Free (nonassisted) spontaneous breathing activity is possible at any time at the higher airway pressure	Mainly for patients with acute lung injury and/or acute respiratory distress syndrome to increase mean airway pressure and functional residual capacity; may be helpful to limit the pressure in the airways at comparatively higher levels, while allowing spontaneous breathing (e.g., in combination with supraglottic airway devices) and promoting CO_2 washout
BIPAP (biphasic [intermittent] airway pressure ventilation)	Works similarly to APRV, changing the airway pressure between two levels but allowing more time for expiration than inspiration. BIPAP can be used with time windows that sense inspiratory and expiratory efforts and in combination with pressure-supported breaths at the lower airway pressure level. Also known as BiPAP (bi-level positive airway pressure). A variant called Bi-Vent also provides pressure support for spontaneous breaths at the higher airway pressure level	Similar indications as for PCV and PSV; smoother transition from controlled to assisted spontaneous breathing; maintenance of adequate ventilation in presence of reduced inspiratory drive, restrictive lung disease, partial neuromuscular blockade, or neuromuscular disease

(*continued*)

TABLE 24-1: VENTILATOR MODES USED FOR ASSISTING THE RESPIRATORY PUMP DURING GENERAL ANESTHESIA (*CONTINUED*)

Mode	Comment	Possible Indications in Anesthesia
HFJV (high-frequency jet ventilation)	Usually with respiratory frequencies of 100 to 150 breaths/min and pressure of 1.5 to 2.5 bars; useful with infraglottic, supraglottic, transtracheal, and transluminal airway devices	Surgery and diagnostic procedures of the upper respiratory tract, ventilation of the dependent lung during one-lung anesthesia, emergency transtracheal ventilation[75]
HFOV (high-frequency oscillatory ventilation)	Usually with respiratory frequencies of 600 to 900 breaths/min and increased mean airway pressure; active instead of passive expiration; requires higher bias gas-flow rates. The resulting tidal volume is relatively low and, in case of CO_2 retention, can be increased by reducing the respiratory frequency	Ventilation of the dependent lung during one-lung anesthesia, CT-guided percutaneous procedures of the kidneys to reduce movement artifacts, thoracic and abdominal neonatal surgery where an increase of mean airway pressure is indicated (e.g., congenital diaphragmatic hernia, esophageal atresia, correction of abdominal wall defects)[76]

harmful effects of PEEP, however, especially on hemodynamics, its use during anesthesia does not represent the standard of care.

There is unequivocal evidence that mechanical ventilation can worsen injury in previously damaged lungs. On one hand, high tidal volumes may promote overdistension of the alveoli (volutrauma). On the other hand, the lack of PEEP can lead to destabilization of lung units at end-expiration, resulting in repeated collapse and opening during tidal ventilation (atelectrauma). The mechanical stress caused by volutrauma and atelectrauma can be translated into the activation of the inflammatory cascade, culminating in the release of proinflammatory mediators by cells, a phenomenon known as mechanotransduction and that represents the basis of the so-called biotrauma. The exact mechanisms by which mechanical stress is sensed and then transduced into inflammation are not fully elucidated, but activation of stretch-sensitive channels, partial cell membrane disruption, and conformational changes in membrane-associated molecules and cytoskeletal structure have been implicated in the gene expression and production of cytokines.[80] Following, and most probably also simultaneously with the proinflammatory response, the remodeling process can be activated, with upregulation of gene expression and synthesis of collagen types I and III fibers by fibroblasts.[81–83] Furthermore, the mediators involved in repair and remodeling can also trigger the expression of metaloproteinases,[84,85] enzymes that promote the degradation of components of macromolecules of the extracellular matrix, namely proteoglycans and glycosaminoglycans, as well as fibrous (collagen and elastin) and structural or adhesive proteins (fibronectin and laminin).[86] In addition, the mechanical stress generated by high tidal volumes also elicits changes in the expression of some proteoglycan components of the extracellular matrix, possibly changing its mechanical properties.[87] In fact, fragmentation of pulmonary glycosaminoglycans has been detected with tidal volumes as low as 8 mL/kg in healthy rats, resulting in decreased lung compliance and edema.[88]

Although mechanical stress per se is able to activate the proinflammatory and remodeling responses in noninjured lungs, tidal volumes as high as 22 mL/kg do not exceed the threshold of stress and/or strain necessary to cause lung weight gain, systemic inflammation, and multiple organ dysfunction in healthy pigs.[89] In line with these findings, nonprotective mechanical ventilation with high tidal volume and zero PEEP did not increase the release of inflammation mediators in surgical patients without lung disease.[90–92] Such reports support the hypothesis that ventilator-associated lung injury occurs only if the lungs are predisposed to injury by a first hit, that is, an inflammatory process already present in the lungs (the two-hit hypothesis). In this context, inappropriate mechanical ventilation would represent the second hit that elicits lung injury. The two-hit hypothesis, however, has been challenged. In patients undergoing one-lung anesthesia, protective mechanical ventilation with low tidal volume and PEEP decreased the proinflammatory systemic response after esophagectomy.[93] Also during two-lung anesthesia, the use of low tidal volume and PEEP attenuated the levels of interleukin (IL)-8 and myeloperoxidase in bronchoalveolar lavage fluid in patients without preexisting lung injury.[94] Furthermore, in patients admitted to the ICU, large tidal volumes represent a major risk factor for the development of acute lung injury (ALI).[95,96] Possibly, cytokines released by surgical trauma and surgery-related conditions, for instance, ischemia or reperfusion of different organs, as well as subclinical lung inflammation, could function as a first hit, and thus explain those discrepancies.

Whether protective mechanical ventilation strategies during anesthesia in patients without lung injury may avoid the onset of ALI, the acute respiratory distress syndrome, or other forms of pulmonary complications remains to be determined.

Postoperative Pulmonary Complications

Approximately 234 million major surgical procedures are performed every year worldwide, with 2.6 million representing high-risk procedures.[97] About half of the patients undergoing high-risk interventions develop complications and 315,000 die during their hospital stay. Postoperative pulmonary complications are as common as cardiac complications following noncardiac surgery[98] and occur in approximately 5% of all patients undergoing surgery and anesthesia.[99] This number, however, increases importantly in the presence of certain risk factors, including older age, low preoperative oxygen saturation, respiratory infection in the last 30 days preceding surgery, anemia (hemoglobin level <10 g/dL), surgery of the upper abdominal or thorax, surgery lasting longer than 2 hours, and emergency procedures.[99]

The incidence of postoperative pulmonary complications also vary according to their definition,[98,100–102] and the following entities and/or findings have been classified as a postoperative pulmonary complication: respiratory failure from pulmonary or cardiac origin; pneumonia and respiratory infection; pleural effusion and atelectasis; pneumothorax; bronchospasm; and need for noninvasive respiratory support or reintubation. Once a postoperative pulmonary complication occurs, the average hospital stay is prolonged and the risk of in-hospital death increases.[99,103]

Different strategies have been proposed to reduce the incidence of postoperative pulmonary complications, including postoperative lung-expansion maneuvers, preoperative intensive inspiratory muscle training, selective rather than routine use of nasogastric tubes, use of short-acting rather than long-acting neuromuscular blockade, and laparoscopic instead of open bariatric surgery.[98,104,105] Despite the compelling rationale for the use of PEEP (combined or not with lung-recruitment maneuvers) to prevent formation of atelectasis in the intraoperative period, an increase of FRC did not improve outcome following surgery in a nonselected population.[106] The outcome might be different if patients with higher risk for postoperative pulmonary complications were selected. For this purpose, different propensity scores are available, as shown in Table 24-2. The major weakness common to all of those prediction models is that events and interventions in the intraoperative period, for example, bleeding and hemodynamic instability, are not taken into account and may impair their accuracy. Accordingly, the impact of the intraoperative ventilation strategy is not taken into account. In view of these facts, such scores require validation in independent trials.

ANESTHESIA VENTILATORS

General anesthesia was first delivered using an open-inhaler system by John Snow as early as 1846. Because anesthesia itself often resulted in depression of the respiratory motor output, ventilation had to be assisted by bag ventilation. Thus, besides vaporizers, anesthetic circuits, and scavenging systems, mechanical ventilators became a fundamental part of the anesthesia machine as a means to automate ventilation. Mechanical ventilators, however, represent nowadays more than simple bag substitutes. Rather, they play a central role in the anesthesia machine and must match different requirements than their counterparts in the ICU, justifying the use of the term *anesthesia ventilator*.

Most commonly, the anesthesia ventilator is used in combination with the so-called circle system, which is depicted in Figure 24-2. That system includes an adjustable airway-pressure limiting valve that can be set by the anesthesiologist to limit airway pressure during bag ventilation, a bag ventilation valve itself with a respective on/off valve, an entrance for a fresh mixture of respiratory and anesthetic gases, a scavenging system, an absorber for CO_2, and the anesthesia ventilator. During the expiratory phase, the anesthesia ventilator is filled with a gas mixture coming from the patient, which is pressed again into the anesthesia circuit during inspiration. In other words, such system permits exhaled air to be rebreathed by the patient, thus reducing the consumption of anesthetic gas agents. In general terms, the anesthesia ventilator is embedded in a semiclosed system in contrast to ICU ventilators, which represent open or semiopen systems.

Chapter 2 presents a comprehensive scheme for classification of mechanical ventilators, which also applies for devices embedded in anesthesia machines. The classification of anesthesia ventilators, however, according to: power source, driving mechanism, cycling mechanism, and design, that is, bellows, piston, or turbine, is useful for the anesthesiologist, because it allows inference of expected performance and safety aspects of the anesthesia machine.

Power Source

Some anesthesia ventilators are powered by compressed gas, but most modern ventilators are operated either by electricity alone or a combination of electricity and compressed gas. When compressed gas is used, the ventilator can function even in the absence of electricity.

Driving Mechanism

Several anesthesia machines have high-pressure and low-pressure circuits, that is, are a double-circuit. In the low-pressure circuit, the mixture consisting of anesthetic and respiratory gases are contained in a bag or bellows. Gas at higher pressure, usually oxygen (sometimes mixed with air), compresses the bellows to move the anesthetic gas mixture into the lungs.

Cycling Mechanism

The cycling mechanism describes how the ventilator initiates inspiration in the control mode. Most contemporary anesthesia ventilators are time cycled and use solid-state electronics for timing. Older devices may be based on pneumatic and fluidic timers.

TABLE 24-2: STUDIES ON PREDICTION OF POSTOPERATIVE PULMONARY COMPLICATIONS

Ref	Type of PPC	Predictors of PPCs	Type and Number of Patients/Setting
Christenson 1996[107]	ARDS (1%)	Hypertension; Diabetes mellitus Smoking Reoperative surgery NYHA functional class 3 or 4 Low left-ventricular ejection fraction (<40%)	Cardiac surgery with cardiopulmonary bypass ($n = 3848$)

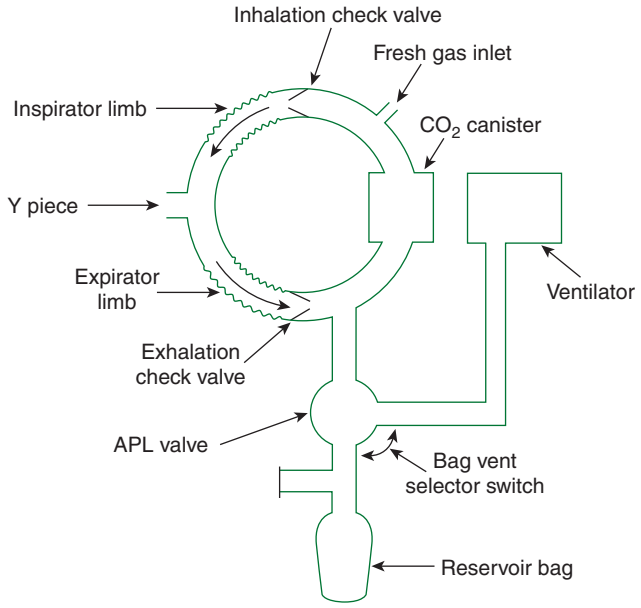

FIGURE 24-2 Schematic of the circle system used in most anesthesia machines. Fresh gas consisting of a mixture of oxygen, nitrogen, and anesthetic gases flows into the circle system between the CO_2 canister, which contains a CO_2 absorber salt, and the inhalation check valve. Gas exhaled by the patient passes an exhalation check valve and refills the anesthesia ventilator and/or reservoir bag. Because the flow rate of fresh gas can be as low as the gas consumption rate, the circle system can recirculate most of the exhaled gas. The anesthesiologist can ventilate the patient manually by bag or using an anesthesia ventilator upon switching of a selector valve. During bag ventilation, the adjustable pressure-limiting (*APL*) valve is set to limit the maximal pressure in the circuit, while, during function of the anesthesia ventilator, the maximal pressure is usually fixed at 70 cm H_2O by an internal pressure-relief valve. (Adapted from Andrews JJ. Inhaled anesthetic delivery systems. In: Miller RD, ed. *Anesthesia.* New York: Churchill Livingstone; 1994.)

Design

BELLOWS DESIGN

The first anesthesia ventilators were based on the bellows design. Bellows ventilators more or less simply automate bag ventilation, and can be still found in modern anesthesia machines. Bellows are located in a chamber where a driving gas flows in to generate an external pressure that squeezes out their contents. The driving gas mixture, which usually consists of oxygen (sometimes mixed with air), is completely separated from the anesthetic gas mixture delivered to the patient.

Bellows are classified according to their motion during expiration, as shown in Figure 24-3. Accordingly, ascending (standing) bellows move upwards, while descending (hanging) bellows move downwards in the expiratory phase. Alternatively, bellows may be displaced horizontally, minimizing the effect of gravity on bellows movement. In addition, horizontal bellows that have a large surface area offer reduced mechanical resistance to movement.

Given that the weight of a descending bellows promotes its expansion, it may continuously inflate and deflate even in the absence of adequate patient ventilation, for instance during patient disconnection from the anesthesia circuit. Because of this serious safety concern, most bellows ventilators in anesthesia machines are of the ascending type. During inspiration, a driving gas squeezes the bellows downward, pushing its content into the anesthesia circuit. Simultaneously, the driving gas closes a relief valve, avoiding escape of the anesthetic gas mixture into the scavenging gas system. During expiration, the pressure around the bellows is reduced to zero, allowing escape of the driving gas and upward movement of the bellows, which is mainly driven by the pressure in the patient's airways. Because the ventilator relief valve opens first at 2 to 3 cm H_2O during expiration, the bellows are filled first before any gas is scavenged, and a minimal PEEP of 2 to 3 cm H_2O results. Another problem associated with the bellows anesthesia ventilator is that fresh

gas flow is permanently added to the anesthesia circuit during the whole-breath cycle. Accordingly, the effectively delivered tidal volume may differ from the anesthesia ventilator settings depending on inspiration time. Furthermore, the compliance of the breathing circuit may also result in differences between desired and delivered tidal volume.

The problem of fresh gas flow-dependence on tidal volume is not exclusive to bellows anesthesia ventilators and can be fixed by decoupling systems that are present in some anesthesia machines. For instance, the fresh gas can be decoupled from the anesthesia circuit by a valve that closes during inspiration, diverting the fresh gas to the bag reservoir during inspiration. Furthermore, flow and volume sensors placed near the patient–airway interface may be used to compensate for differences between desired and effectively delivered tidal volume (V_T). Such differences may result not only from inappropriate fresh gas flow rates, but also from expansion of the breathing circuit during inspiration. Those sensors, however, are prone to accumulation of moisture, which may impair their accuracy, jeopardizing the performance of the ventilator.

PISTON DESIGN

The use of mechanical ventilators based on piston (Fig. 24-4) instead of bellows design in anesthesia machines is increasing. Anesthesia piston ventilators are able to deal more efficiently with volume compensation secondary to compliance of the breathing circuit because they depend not on measurement of airflow or volume but rather pressure, which is less sensitive to the accumulation of moisture or secretions. Furthermore, control of the piston's displacement allows more accurate volume delivery, especially in situations where low tidal volumes are required, for example, in neonatal anesthesia. In addition, the piston ventilator allows a more rapid increase in flow than a bellows ventilator, which is particularly important for pressure-controlled ventilation (PCV).

Because of the ease and accuracy with which the piston can be controlled, advanced ventilation modes can be implemented through software enhancements to the piston ventilator. The basic piston design has proven itself to be a versatile platform for anesthesia ventilator design, which permits transferring differentiated mechanical ventilation modes from the ICU to the operating room.

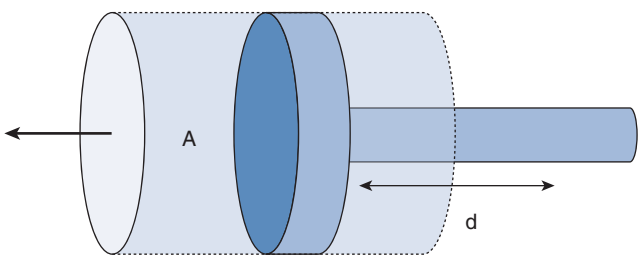

FIGURE 24-4 Schematic of an anesthesia machine piston. *A*, area; *d*, displacement.

TURBINE DESIGN

An innovative anesthesia ventilator design is the electrically driven and controlled compressor turbine. The turbine has a two particularities that make it attractive for anesthesia ventilators:[118] (a) it builds up the breathing pressure and delivers the corresponding flow to the patient during inspiratory time; and (b) it delivers a circuit flow that is required to mix the gas within the breathing system independently of patient inspiratory effort. During the inspiratory phase of controlled ventilation, the turbine transports the breathing gas from the breathing bag reservoir to the patient. During expiration, the gas returns to the bag and is additionally circulated and mixed.[118] This anesthesia ventilator design is particularly important for closed-systems, which allow minimal consumption of anesthetic gases, that is, quantitative anesthesia. Because a turbine-based ventilator performs as well as the best compressed-gas ICU ventilators,[119] it offers a useful platform for implementation of advanced mechanical ventilation modes in anesthesia.

Table 24-3 depicts the basic characteristics of some available anesthesia ventilators. For a complete and comparative description of those devices we recommend the reader to assess the homepage of the nonprofit research agency ECRI Institute at www.ecri.org.

MECHANICAL VENTILATION STRATEGIES DURING GENERAL ANESTHESIA

Current Clinical Practice and Evidence

Mechanical ventilation strategies can influence the development of ventilator-induced lung injury and affect clinical outcome following surgery. Despite a compelling rationale for the use of lower V_T, PEEP, and recruitment maneuvers, the role of protective mechanical ventilation during general anesthesia has not been established. Nevertheless, several clinical trials have addressed the impact of mechanical ventilation on pulmonary function, lung injury, and clinical outcome (Table 24-4).

The clinical practice of mechanical ventilation may vary widely across countries and even within a single department. In fact, anesthesiologists ventilate noninjured lungs with both high and low tidal volumes, as well as high and low levels of PEEP, because definitive evidence supporting the one or the other approach is still missing.

TIDAL VOLUMES

As shown in Table 24-4, the effects of tidal volumes have been investigated during different surgical conditions, including elective abdominal surgery, cardiopulmonary bypass, and thoracic and esophageal surgery, as well as in patients admitted to the ICU after surgery. The lower V_T used in those

studies was 6 mL/kg (ideal body weight), while the higher V_T ranged from 10 to 15 mL/kg. Furthermore, lower V_T were used in combination with higher PEEP (5 to 10 cm H_2O), while high V_T were used in combination with moderate PEEP (2 to 5 cm H_2O).

Both physiologic and clinical parameters have been investigated in those trials. In elective abdominal surgery, the combination of higher V_T and lower PEEP resulted in no differences in pulmonary biomarkers (inflammatory mediators), in two studies,[90,91] whereas IL-8 in was higher in one study[94] and bronchoalveolar coagulation was more pronounced in another trial.[124] In patients undergoing cardiopulmonary bypass, higher V_T were associated with increased lung inflammation in three trials,[121–123] although one study could not confirm such detrimental effect.[92] High V_T resulted in elevation of plasma levels of inflammatory mediators in one study on thoracic-esophageal surgery,[93] but that finding has been disputed.[91] In postoperative patients recovering in the ICU, lower V_T was associated with decreased plasma levels of IL-6.[127]

With respect to gas exchange, the combination of lower V_T and higher PEEP resulted in improved oxygenation in different trials,[94,121,122] but also increased Pa_{CO_2} and lowered arterial pH in two investigations.[94,124]

The number of hospital-free days could be reduced by protective mechanical ventilation with lower tidal volume and higher PEEP in a postoperative mixed medical surgical patients in one study,[120] but several trials failed to show such a beneficial effect.[91,93,121,124,127,129] In cardiac surgery patients, the use of a ventilation strategy with V_T of 6 mL/kg resulted in a higher proportion of patients extubated 6 hours after surgery and a lower reintubation rate as compared with a nonprotective strategy of V_T 10 mL/kg.[128]

POSITIVE END-EXPIRATORY PRESSURE

Table 24-5 depicts selected prospective randomized trials that adjusted the level of PEEP while maintaining V_T approximately constant during open abdominal,[130–132] laparoscopic,[133–135] bariatric,[136–138] and neurosurgery.[139] Except for

one study,[137] the lower level of PEEP was zero in those trials, while the highest levels varied between 5 and 12 cm H_2O. In four studies, a recruitment maneuver was performed before setting high PEEP.[131,133,136,137] In most studies in Table 24-5, higher PEEP was associated with better intraoperative oxygenation, with no major changes in pulmonary inflammation. In three studies, a reduction in atelectasis was also observed in the postoperative period.[136,138,139] The use of higher PEEP during surgery improved oxygenation in the postoperative period in two studies,[131,138] while the other four trials observed no benefit.[132–134,136]

There is also uncertainty with regard to the effects of PEEP on outcome of surgical patients. Higher PEEP levels contributed to prevent postoperative pulmonary complications in one study,[138] but two trials reported no effect.[131,137]

RECRUITMENT MANEUVERS

The use of recruitment maneuvers in patients with ALI and/or acute respiratory distress syndrome is controversial. Moreover, alveolar flooding and consolidation of lung parenchyma are common findings in injured lungs, which challenge the rationale for the use of recruitment maneuver. In contrast, the presence of atelectasis has been well documented during general anesthesia and is found in as many as 90% of patients,[42] beginning during the induction period.[140] Thus, unlike ALI or acute respiratory distress syndrome, there is a strong physiologic rationale supporting the use of recruitment maneuvers for reversing lung collapse during general anesthesia.

Recruitment maneuvers in anesthesia are most commonly performed by "bag squeezing," that is, as sustained inflation, using the airway-pressure limiting valve of the anesthesia machine (see Fig. 24-2). Although simple, this maneuver has some drawbacks. First, the airway pressure is not kept constant, changing with the pressure applied on the bag by the anesthesiologist and the fresh gas flow from the anesthesia machine. Second, switching from manual to controlled ventilation usually leads to a loss of pressure in the anesthesia circuit, and the PEEP valve may require a couple of cycles to achieve the desired level. Thus, depending on the time constant of lungs and breathing circuit, derecruitment can occur with this kind of maneuver. Third, if the anesthesia ventilator initiates an inspiration immediately after switching and the airway pressure is still high, pressure overshoot with barotrauma may result.

Such limitations can be overcome by applying sustained inflations by means of continuous positive airway pressure (CPAP). Unfortunately, CPAP is not available on all anesthesia ventilators (see Table 24-1). Alternatively, the limitations of manual recruitment maneuvers can be avoided if airway pressure is increased during tidal ventilation (so-called cycling maneuver [141]), for example, with a stepwise increase of PEEP during volume-controlled ventilation (VCV), or even PCV, if this latter mode is available on the anesthesia ventilator.

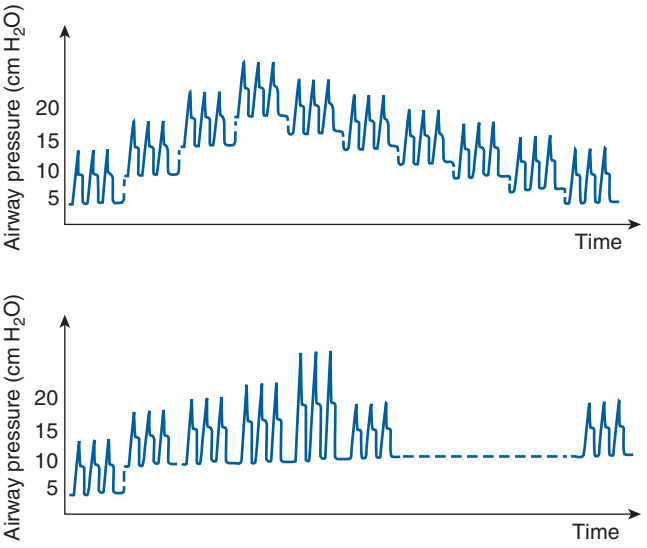

FIGURE 24-5 Schematic of airway pressure during two-lung recruitment maneuvers that can be performed in the volume-controlled ventilation mode on most anesthesia machines. *Top*: in the ascending part, a stepwise change of positive end-expiratory pressure (PEEP) by 5 cm H_2O at constant tidal volume is performed until the desired inspiratory plateau pressure; in the descending part, PEEP is decreased by steps of 2 to 3 cm H_2O and the respiratory system elastance measured at each step; a second recruitment maneuver must follow before the PEEP of minimal elastance is set. *Bottom*: stepwise change of tidal volume at constant PEEP until the desired inspiratory plateau pressure, as described in reference 142.

Figure 24-5 illustrates two possible ways of recruiting the lungs with cycling maneuvers in the VCV mode. Initially, the intravascular volume is expanded to achieve normovolemia, and the fractional inspired oxygen concentration (FI_{O_2}) is increased to 1. Tidal volume is set at 8 to 12 mL/kg and the inspiratory pause at 20% to 50% of inspiration. In the first variant, PEEP is increased in steps of 5 cm H_2O up to 20 cm H_2O every three to five breaths. Then, the PEEP is reduced in steps of 2 to 3 cm H_2O and static elastance of the respiratory system measured at each step (decremental PEEP trial). In the second variant, the PEEP is increased to 10 to 12 cm H_2O and maintained constant thereafter. V_T is increased in steps of 2 to 4 mL/kg until an inspiratory plateau pressure of 30 to 40 cm H_2O is achieved. Finally, V_T is again set at the initial value. This maneuver has been proposed recently for recruitment of noninjured lungs within a multicenter randomized clinical trial on the use of PEEP intraoperatively.[142]

In PCV, the driving pressure is kept constant at 15 to 20 cm H_2O and the stepwise increase and decrease of PEEP is performed as for VCV. Also with this mode, the goal is to achieve an inspiratory plateau pressure of approximately 30 to 40 cm H_2O during three to five breaths.

If the anesthesia ventilator does not enable higher levels of PEEP, V_T or driving pressures may be changed to achieve the desired opening-pressure target. Obviously, this target must be adapted according to a patient's condition, for example,

increased elastance of the chest wall, which will reduce the effective transpulmonary pressure. In patients with normal lungs and chest wall elastance, airway pressure of 40 cm H_2O is sufficient to recruit the lungs,[131] but morbidly obese patients may require up to 60 cm H_2O.[136]

Table 24-6 depicts some of the clinical studies that have addressed the effects of recruitment maneuvers during general anesthesia, including the type of maneuver used. Oxygenation was effectively improved in all but one study, mainly when combined with higher levels of PEEP. In patients undergoing cardiac surgery, Pa_{O_2} was still higher 24 hours after surgery. In some of the trials, moreover, the FRC was increased and respiratory system mechanics improved, while a decrease in atelectasis was documented in children undergoing magnetic resonance imaging (MRI),[143] coronary artery bypass,[144] and bariatric[137] surgery. Recruitment maneuvers after cardiac surgery resulted in a decrease of cardiac output.[145] Recruitment maneuvers, however, performed during elective cardiac surgery did not lead to hemodynamic instability in another study.[146]

As can be inferred from those trials, recruitment maneuvers are effective in reversing atelectasis, increasing FRC and improving oxygenation in general anesthesia, with little or no effect on hemodynamics. Their impact on clinical outcome, however, is not established and, therefore, their routine use cannot be recommended for unselected patient populations.

Spontaneous and Assisted Spontaneous Breathing

Most anesthetic agents are depressants of the respiratory center and some have additional muscle relaxant properties, most notably the volatile anesthetics. Because induction of general anesthesia is conducted with comparatively high dosages of anesthetic drugs, apnea usually develops. Furthermore, endotracheal intubation is frequently needed during general anesthesia to protect the airways from aspiration of gastric contents. To facilitate laryngoscopy and placement of an endotracheal tube, muscle paralytic agents are used. In view of these facts, spontaneous breathing activity is frequently abolished following induction of general anesthesia, and controlled mechanical ventilation is required in order to maintain an adequate gas exchange.

Nevertheless, endotracheal intubation itself can result in different complications, including injuries of the teeth, vocal cords, and arytenoids, which may be avoided if the patient is not at risk of aspiration. For example, supraglottic devices, and more specifically laryngeal masks, can maintain the patency of the upper airways and facilitate ventilation by spontaneous breathing or positive pressure ventilation. Furthermore, short anesthesia procedures may be conducted with a facemask, with or without placement of a Guedel tube, in a spontaneously breathing patient. Even if the use of an endotracheal tube is necessary, general anesthesia can be titrated to allow spontaneous breathing activity, mainly when combined with regional anesthesia techniques. Thus, maintenance of adequate gas exchange during general anesthesia may be possible by spontaneous breathing alone or, alternatively, with assisted ventilation, if tidal volume has to be increased or the work of breathing reduced.

POSSIBLE ADVANTAGES

General anesthesia leads to a decrease in FRC and development of atelectasis in dependent lung zones, which may, in turn, impair gas exchange. Spontaneous breathing activity can counteract such effects if enough transpulmonary pressure is generated in dependent lung zones.[150] Even in the absence of alveolar lung recruitment, spontaneous breathing activity may improve gas exchange by facilitating the redistribution of perfusion towards better aerated and ventilated ventral areas.[151] Also, inspiratory efforts may reduce the mean intrathoracic pressure, contributing to an increase in venous return to the heart and the perfusion of different organs.[152] Furthermore, the maintenance of spontaneous breathing during anesthesia may also have beneficial effects on the lung tissue. In healthy rats under general anesthesia, controlled mechanical ventilation elicits a degradation of glycosaminoglycans of the extracellular matrix and promotes edema formation, which can be prevented by spontaneous breathing.[88]

The presence of spontaneous breathing during general anesthesia is usually associated with a reduction in the use of anesthetic drugs and obviates the need for neuromuscular blocking agents, which may speed the recovery from anesthesia and contribute to avoid complications from inadvertent residual sedation and/or muscle paralysis.[153] Furthermore, a reduction in the use of anesthetic agents will increase the levels of stress hormones, for example, adrenaline, noradrenaline, adrenocorticotrophic hormone, and cortisol, decreasing the requirements for exogenous vasoactive drugs.

POSSIBLE DISADVANTAGES

Some anesthesiologists fear that the decrease in depth of anesthesia for maintaining spontaneous breathing activity may result in intraoperative awareness and recall. Indeed, anesthesia depth requirements may vary according to the surgical stimulus and maintenance of adequate analgesia while avoiding respiratory depression can be challenging. Also, spontaneous breathing activity may be insufficient to generate adequate alveolar ventilation or result in increased work of breathing secondary to a relatively low diameter of the airway assist device, requiring assistance by positive pressure. When pressure-support ventilation, which is the most common mode of assisted mechanical ventilation in anesthesia ventilators, is used for assisting spontaneous breathing, not enough transpulmonary pressure is generated in dependent zones to recruit the lungs.[154] Furthermore, other modes of assisted ventilation also available on anesthesia machines, for example, synchronized intermittent mandatory ventilation, may result in patient–ventilator asynchrony, leading to patient discomfort and even arousal.

Nonconventional Modes of Mechanical Ventilation during Anesthesia

In contrast to the ICU, where nonconventional modes of mechanical ventilation are used for severe impairment of gas exchange, respiratory system mechanics, or both, patients under general anesthesia may require differentiated ventilator strategies as a means to facilitate the surgical approach or diagnostic procedures. High-frequency ventilation modes, especially high-frequency jet ventilation (HFJV) and high-frequency oscillatory ventilation (HFOV), are particularly interesting for the anesthesiologist, because they achieve adequate gas exchange while limiting lung and chest excursion, or saving space in the larynx for placement of surgical and diagnostic tools. HFJV is also helpful in emergency situations where supraglottic obstruction is present and percutaneous transtracheal ventilation through a small-bore catheter becomes necessary.

The devices used for high-frequency ventilation during general anesthesia are virtually the same as those found in the ICU. Obviously, those systems do not support use of volatile anesthetics and anesthesia is performed with intravenous drugs.

HIGH-FREQUENCY JET VENTILATION

The possible indications for HFJV include: (a) surgery and diagnostic procedures of the larynx and trachea (e.g., endoscopy, placement of tracheal stents, laser surgery); (b) improvement of oxygenation during one-lung anesthesia; and (c) transtracheal oxygenation in emergency situations. This ventilation mode, however, is contraindicated in patients who are at risk for aspiration and with upper airway obstruction.

HFJV can be delivered either through a tube or cannula placed supraglottically or subglottically. With the supraglottic approach, the jet ventilator can be attached to an endoscope; with the subglottic approach, either a transtracheal or a transglottic route can be used. In the transtracheal variant, a 13-gauge to 14-gauge (adults) or 18-gauge (children younger than age 3 years) catheter is introduced through the cricothyroid membrane into the trachea using the Seldinger method or under endoscopic control. The catheter tip is then advanced and placed 2 to 4 cm above the carina.[155] In the transglottic variant, a catheter with an internal diameter of 1.5 to 3.0 mm and up to 30 cm length is introduced transnasally or transorally and its multipore tip is advanced into the trachea under direct visualization by laryngoscopy using intubation-assist devices.

Jet ventilators apply pressures in the range of 1.5 to 2.5 bars with a respiratory frequency of 100 to 150 breaths/min and inspiration time of 50% (30% to 70%) on the jet catheter.[75] These settings result in airway pressures lower than those obtained with conventional mechanical ventilation, provided there is no stenosis or obstruction of the upper airways. Also, those settings result in tidal volumes of 1 to 3 mL/kg, which can be increased by augmenting the pressure, reducing the respiratory frequency, and increasing the duration of inspiration. Accordingly, if the tidal volume has to be reduced, for example, during arousal from anesthesia, so as to stimulate spontaneous breathing, the respiratory frequency is increased up to 300 breaths/min. Inspiratory oxygen fractions during HFJV are in the range of 50% to 100%, but the effective oxygen fraction in the trachea is usually lower because of air entrainment,[156] that is, mixing of oxygen from the ventilator with air surrounding the jet catheter by means of the Venturi effect.

Although adequacy of oxygenation can be monitored by usual means, for example, noninvasive pulse oximetry, capnography is not suitable for accessing the efficiency of ventilation during HFJV. Thus, transcutaneous or partial pressure of arterial carbon dioxide (P_{CO_2}) measurement may be required for appropriate titration of HFJV. Furthermore, the measurement of the effectively delivered tidal volume during HFJV is not possible in clinical practice, although it can be performed by body plethysmography in the lab. In contrast, airway pressure can be monitored by some jet ventilators through an accessory route in double-lumen jet catheters, or during end-expiratory pauses in conventional single-lumen jet catheters.

Serious complications from HFJV are rare.[155] Pneumothorax and pneumomediastinum have been reported in less than 1% of patients,[155,157] while subcutaneous emphysema has been observed in approximately 8% of patients.[155] Such complications result from pulmonary hyperinflation in presence of obstruction to expiratory flow and may occur even with devices that control tracheal pressure. Newer jet ventilators offer active expiratory assistance that could minimize such events. Supraglottic devices can theoretically promote transport of particles and liquid into the trachea, including tumor tissue, and also cause gastric inflation and rupture.[158] Also, when gas from the jet ventilator is not humidified, drying of the trachea mucosa and tracheobronchitis may occur.[159]

HIGH-FREQUENCY OSCILLATORY VENTILATION

Chapter 19 explains the principles of HFOV in detail. In brief, during HFOV a diaphragm or piston pump generates quasisinusoidal oscillations in airway pressure. This technique has been described originally with oscillation frequencies as high as 50 Hz,[160] but nowadays frequencies of 5 to 15 Hz are used clinically. To remove CO_2 from the respiratory circuit, an inspiratory bias flow of humidified and warmed air is used. The inspiratory bias flow and a gas outflow valve, which regulates the resistance of the expiratory limb, determine the mean airway pressure (mPaw).[161] The amplitude of pressure oscillation (ΔP), which is usually in the range of 60 to 90 cm H_2O, determines the effectively applied V_T, and an inspiratory-to-expiratory timing (I:E) ratio of 1:2 to 1:1 is set separately. Although the ΔP in the HFOV is high, the downstream pressure in the airways is obviously much lower,[162] and the resulting V_T is only a fraction of that obtained with

conventional mechanical ventilation, in the range of 1 to 3 mL/kg. The major factors that determine the V_T during HFOV are the diameter and length of the endotracheal tube, ΔP itself, inspiratory time, impedance of the respiratory system and the oscillation frequency, whereby higher frequencies result in lower V_T.[163]

The possibility of combining the lowest possible V_T with relatively high mPaw, and thereby reduce volutrauma and atelectrauma, respectively, makes HFOV particularly attractive for lung-protective ventilation. HFOV has become popular for the ventilator management of acute pulmonary dysfunction in infants, even if there is no clear evidence that it is superior to conventional ventilation.[164,165] In the operating room, HFOV may be a valuable alternative to limit the tidal excursion of the lungs, while allowing expansion and counteracting increases in abdominal pressure that would otherwise lead to shrinkage of the lungs. Accordingly, possible indications of HFOV in pediatric anesthesia include surgery for[76] congenital diaphragmatic hernia, congenital cystic adenomatoid malformation, esophageal atresia, patent ductus arteriosus, abdominal wall defect, and enterocolitis.

The use of HFOV during general anesthesia of adult patients is practically restricted to cases where HFOV has been initiated in the ICU and continued in the operating room. Possible reasons for that restriction are the time required for stabilization of lung recruitment and gas exchange after beginning of HFOV, lack of experience of anesthesiologists with this mode, and the fact that HFOV is currently not available on anesthesia machines, precluding its use with volatile anesthetics.

Special Situations

MECHANICAL VENTILATION DURING LAPAROSCOPY

Laparoscopy is widely used in the surgical treatment of a number of diseases. Its advantages are generally believed to lie with its minimal invasiveness, better cosmetic outcome, and shorter length of hospital stay based on surgical expertise and state-of-the-art equipment. The insufflation of the abdomen, however, might cause derangements of respiratory mechanics, lung volumes, and hemodynamics. Furthermore, laparoscopy may be associated with longer operation times.

Most patients tolerate mechanical ventilation during laparoscopy without major problems. Pneumoperitoneum, however, with increased intraabdominal pressure may pose difficulties for mechanical ventilation in patients with underlying lung disease and higher-than-normal body mass index.[166]

Abdominal insufflation of gas during laparoscopy, usually within the range of 10 to 15 mm Hg, greatly affects the respiratory mechanics, promoting an upward shift of the diaphragm and reducing lung volume.

Lung Volumes at End Expiration. The reduction in lung volume depends not only on intraabdominal pressure but also on the position of the patient. It is expected the Trendelenburg position will result in further reduction in lung volume, reducing FRC.

Lung and Chest Wall Mechanics. Insufflation of gas into the abdomen causes a rightward shift of the pressure-volume curve of the respiratory system. Such changes reflect the increase in both the lung and chest wall components of elastance. Also, the decrease in lung volume narrows the airways, increasing lung resistance. These effects have profound impact on the correct interpretation of the pressures displayed on the ventilator.

Contemporary anesthesia ventilators assess peak and plateau airway pressures, thus allowing discrimination between dissipation of pressure secondary to airway resistance (difference between peak and inspiratory plateau pressure) and the elastic properties of the respiratory system (inspiratory plateau pressure minus PEEP).

In the presence of abnormal chest wall mechanics, however, airway pressure does not adequately represent the transpulmonary pressure. Thus, it is necessary to closely monitor airway pressure before initiation of pneumoperitoneum, so as to set a new reference point of airway pressures that takes into consideration changes of lung and chest wall elastance, airway narrowing, and lung distortion.

Setting the Mechanical Ventilator for Laparoscopy. During laparoscopic surgery, CO_2 is absorbed from pneumoperitoneum, increasing CO_2 content in blood. Thus, to keep a normal Pa_{CO_2}, an increase in minute ventilation of approximately 30% is needed, which can be accomplished by increasing tidal volume, respiratory rate, or both. An increase in respiratory rate, however, in patients with expiratory flow limitation can worsen the auto-PEEP, whose monitoring may be difficult with ventilators that do not allow an end-expiratory hold or do not display flow-versus-time curves.

Arterial oxygenation is barely impaired during general anesthesia for laparoscopic surgery, even in morbidly obese patients.[167] Nonetheless, tissue oxygenation during laparoscopic surgery is lower than during open surgery.[168] The use of PEEP during laparoscopy increases Pa_{O_2} but such effect is only marginal, independently of body weight.[134] In obese patients in beach-chair position, however, the improvement in arterial oxygenation induced by PEEP may be significant,[169] but higher V_T does not seem to be useful for increasing Pa_{O_2} in such patients.[170]

Table 24-7 shows a list of randomized controlled trials on PEEP during laparoscopy. In most studies, the effects of zero end-expiratory pressure versus PEEP of 6 to 10 cm H_2O, with[133,137,149] or without[134,135,138] recruitment maneuvers, and V_T of 8 to 10 mL/kg were compared. All studies showed an increase in Pa_{O_2} intraoperatively, while two investigations reported an increase in respiratory compliance.[137,149] In one study,[137] there were no significant differences in Pa_{O_2} postoperatively, length of stay, and postoperative pulmonary

complications when comparing low versus high PEEP combined recruitment maneuvers. Some investigators, however, reported a reduction in postoperative atelectasis and postoperative pulmonary complications with high, compared to low, PEEP.[138] With regard to hemodynamic side effects, use of PEEP during pneumoperitoneum has produced conflicting results. Although some authors found that cardiac output was decreased during pneumoperitoneum combined with high PEEP,[137,171] others did not observe such deterioration.[134,172]

Mechanical Ventilation Mode and Laparoscopy. Because pneumoperitoneum can markedly affect compliance and resistance, it can also adversely affect tidal volume, minute ventilation, and alveolar ventilation during PCV. Thus, VCV is a valid choice to keep alveolar ventilation constant in the presence of changing lung mechanics. Most interest in the use of PCV during pneumoperitoneum is related to its potential for reducing peak airway pressures at similar levels of alveolar ventilation. In VCV, if end-inspiratory airway pressure does not equilibrate with alveolar pressure, transpulmonary pressure will be considerably less that the set value. Accordingly, for a given inspiratory time and peak target pressure, PCV applies greater cumulative pressure to the respiratory system than VCV, theoretically providing better oxygenation. Despite these theoretical advantages, however, PCV and VCV resulted in comparable oxygenation and respiratory mechanics during laparoscopy,[174,175] but CO_2 elimination was more effective with VCV than PCV in the morbidly obese patients.[175]

Patient Positioning and Laparoscopy. Patient positioning is extremely important during mechanical ventilation and laparoscopy. In morbidly obese patients under laparoscopy,[169] reverse Trendelenburg improved end-expiratory lung volume both before and after pneumoperitoneum induction and was associated with improved arterial oxygenation. Most importantly, head-up positioning alone or the application of PEEP in a supine position produced similar effects on lung volume and oxygenation. Airway pressures, however, were much lower during the beach-chair position. These data suggest that the combination of beach-chair position with PEEP, when feasible, improves oxygenation and favors a protective lung strategy.

MECHANICAL VENTILATION OF OBESE PATIENTS

The prevalence of adult obesity has increased in the last decade in most countries,[176] reaching up to 35% in North America and 15% to 20% in Europe.[177] Because these patients show several systemic pathophysiologic alterations, intraoperative mechanical ventilation and perioperative respiratory care may be challenging to the anesthesiologist.

After induction of anesthesia in obese patients, FRC decreases to approximately 50% of preanesthesia values,[136,178] and such change correlates well with body mass index.[179] The mechanism leading to reduction in FRC, with consequent development of atelectasis, is enhanced in obese patients, secondary to a possible increase in intraabdominal pressure.[38] Because of gravity, increased intraabdominal pressure is mainly directed toward the most dependent lung regions, leading to further reduction in diaphragmatic excursion and/or cranial displacement. Such changes in the obese patient favor the development of pulmonary atelectasis and ventilation–perfusion mismatching, which combined with anesthesia and muscle paralysis worsens arterial oxygenation.[179]

The loss in FRC also promotes an increase in lung elastance, while increased intraabdominal pressure promotes a further increase in chest wall elastance, resulting in higher elastance of the total respiratory system. Additionally, the lung resistance is increased in obesity,[179] mainly secondary to the reduction in lung volume, although specific resistance remains relatively normal.[62]

Preoperative Measures. It is beyond the scope of this chapter to describe the innumerable particularities concerning the induction of anesthesia in the obese patient, especially those concerning difficult intubation and risk of aspiration. Some aspects, however, are relevant for mechanical ventilation following induction.

In morbidly obese patients, the time to desaturate following standard preoxygenation with pure oxygen at barometric pressure conditions is reduced. The use of CPAP or noninvasive positive pressure ventilation during induction of anesthesia can minimize the loss in FRC, preventing formation of atelectasis and increasing the duration of non-hypoxic apnea.[180,181] In fact, use of noninvasive positive pressure ventilation before intubation improves oxygenation in obese patients undergoing different kinds of surgical approaches,[79,182] and contributes to better preservation of FRC during laparoscopic surgery.[183] Furthermore, induction of anesthesia in obese patients in the Trendelenburg position may additionally contribute to increase the FRC.

Intraoperative Mechanical Ventilation. In the intraoperative period, the following strategies should be considered for mechanical ventilation of the obese patient: (a) the lowest possible inspiratory oxygen fraction to achieve peripheral oxygenation saturation greater than 92%;[52] (b) tidal volumes less than 13 mL/kg (ideal body weight);[184] (c) a recruitment maneuver;[50,136] and (d) PEEP equal to or greater than 10 cm H_2O. Additionally, the use of large, manually or automatically periodically lung inflations (sighs) can be useful.[52]

Inspired oxygen fractions greater than 0.8 should be avoided in obese patients, because they favor the formation of progressive reabsorption atelectasis in the presence of zones with a low ventilation–perfusion ratio. The use high tidal volumes (>13 mL/kg ideal body weight) does not result in further improvements in oxygenation, although it can induce hypocapnia if the respiratory rate does not decrease. Moreover, the continuous use of high tidal volumes even during anaesthesia can promote ventilator-induced lung injury and negative effects on hemodynamics.

Adequate opening pressures can be applied by periodic lung inflations (recruitment maneuvers).[136] Airway pressures up to 60 cm H_2O, however, may be necessary to achieve a transpulmonary pressure that reopens collapsed lung areas. In fact, obese patients have an increased abdominal load secondary to increased intraabdominal pressure as well as thoracic fat mass, with resulting in an increase in chest wall elastance. In these circumstances, transpulmonary pressure is reduced, making the recruitment maneuver less effective. The duration of a recruitment maneuver should be limited to a maximum of 10 seconds so as to minimize as much as possible the negative effects on hemodynamics. Importantly, recruitment maneuvers should be performed only in patients who have stable volume and hemodynamic conditions. In the absence of PEEP, recruitment maneuvers can be repeated every 30 minutes to reopen atelectasis. PEEP levels 10 cm H_2O after a recruitment maneuver, however, may prevent small airways from collapsing. Obviously, excessive PEEP may lead to negative effects, like compression of lung capillaries with increased ventilation–perfusion ratios, alveolar overdistension and reduction of cardiac output. Recruitment maneuver and higher PEEP have also proven effective to improving respiratory function during laparoscopy.[79]

Postoperative Measures. The respiratory function of obese patients is considerably impaired in the postoperative period.[185] Such impairment is mainly related to the postoperative pulmonary restrictive syndrome, which can lead to secondary hypoxemia.[186,187]

A number of measures to reduce postoperative pulmonary complications have been proposed, including chest physiotherapy, patient positioning (30 to 45 degrees semirecumbent position), incentive spirometry, and noninvasive respiratory support.[187–191] The main goal is to restore lung volumes to the preoperative values, improving oxygenation and reducing work of breathing.[192] In this context, CPAP may be useful, especially when it is used before important deterioration of oxygenation.

MECHANICAL VENTILATION OF PATIENTS WITH CHRONIC OBSTRUCTIVE PULMONARY DISEASE AND ASTHMA

Bronchial asthma and COPD are the most common obstructive disorders of the lung. The prevalence of asthma is increasing worldwide, but improvements in medical care have led to a progressive decrease in morbidity and mortality.[193] Conversely, the prevalence of COPD is widely variable among the different regions of the world, and although different medical treatments of COPD have been developed, mortality is high and expected to occupy the second or third place among all causes of deaths within the next decade.[194]

The common feature of bronchial asthma and COPD is an increase of airway resistance, which represents a challenge for anesthesiologists. In addition to basic drug therapy, patients with asthma or COPD require different ventilation strategies for perioperative management.[195,196]

Various pathophysiologic mechanisms may contribute differently to airway narrowing in bronchial asthma and COPD. In asthma, acute episodes of bronchoconstriction are mainly secondary to an exaggerated response of airway smooth muscle to constrictor stimuli; in COPD, persistent airway narrowing is believed to be the result of airway wall thickening secondary to chronic bronchitis, and loss of lung elastic recoil secondary to emphysema.[197]

Airway narrowing has three major consequences, especially during acute exacerbations of bronchial asthma or COPD, that are relevant for the management of mechanical ventilation: dynamic hyperinflation, inefficient gas exchange, and cardiovascular abnormalities.

Mechanical ventilation may affect each of these features, though significant interactions exist between them.[198]

Dynamic Hyperinflation. Lung hyperinflation indicates an increase of any absolute lung volume, for example, FRC, above its predicted value. This may have two main causes: first, an increase of the relaxation volume of the respiratory system (static hyperinflation); second, failure to reach relaxation volume at end-expiration (dynamic hyperinflation). The former is caused by loss of elastic recoil (emphysema) and is not amenable to current pharmacologic treatments. The latter is the consequence of increased expiratory resistance and is mechanically characterized by an elastic threshold load, so-called intrinsic positive end-expiratory pressure (PEEPi), which must be overcome before inspiratory flow can be generated.

During mechanical ventilation, the occurrence of PEEPi can be caused by several mechanisms including (a) increased time-constant (product of resistance and compliance), (b) increase in breathing frequency or decrease in expiratory time, (c) an increase in V_T, and (d) airflow limitation during tidal expiration. In cases *a* to *c*, the airways remain open during the whole breathing cycle, although their diameter may be decreased; in case *d*, the airways collapse at end-expiration. The latter can be easily inferred from flow-time, pressure-time, and flow-volumes curves. On flow-time curves, flow at end-expiration does not equal zero, even when the pressure-time curve indicates that airway pressure has reached the level of set external PEEP. On the flow-volume curve, the expiratory limb of the loop shows a curvilinear shape, and it appears truncated when expiratory flow persists at end-expiration. It is worth noting that: (a) in the case of airway narrowing without achieving flow limitation, one should expect to see the following: (i) flow at end-expiration on the flow-time curve, (ii) increased pressure at end-expiratory occlusion on the pressure–time curve, (iii) a linear flow-volume curve, with a truncated flow-volume loop; and (b) in the case of airflow-limitation, the only difference is the presence of a curvilinear (convex toward the volume axis) flow-volume curve.

When PEEPi occurs secondary to mechanisms other than expiratory flow limitation, application of external PEEP produces a further increase in PEEPi and a plateau pressure of the respiratory system, with possible negative hemodynamic

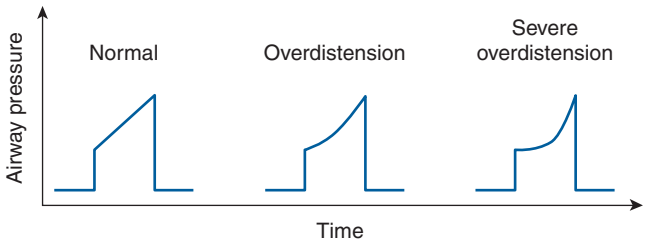

FIGURE 24-6 Schematic of airway pressure versus time curves in a normal subject and in patients with lung overdistension and severe overdistension. The degree of curvature can be related to the severity of overdistension, but is not always present.

effects. Conversely, application of external PEEP in the presence of flow limitation will not affect plateau pressure and hemodynamics, provided it is limited to equal to or less than 75% of PEEPi.

For practical purposes, continuous displays of ventilator waveforms can assist the clinician in detecting and monitoring pathophysiologic changes, optimize ventilator settings and treatment, determine effectiveness of ventilator settings, and minimize the risk of ventilator-induced complications. Flow and volume waveforms can be employed to directly estimate end-expiratory volume above passive FRC. The volume expired during a prolonged apnea (up to 40 seconds) may be used to determine the volume of gas above FRC. The total exhaled volume is measured from the end of inspiration until there is no visually detectable change in volume.

Monitoring of pressure–time curves can also be helpful in avoiding excessive hyperinflation (Fig. 24-6). In the case of normal inflation, the pressure–time curve during inflation at constant flow in VCV is linear (i.e., pressure increases in proportion to an increase in volume); in the case of overdistension, a convexity toward the time axis appears (i.e., a progressive increase in pressure that is not proportional to increase in volume).

In summary, the monitoring of pressure, flow, and volume over time associated with end-inspiratory and end-expiratory occlusion maneuvers is essential to better define the presence and causes of dynamic hyperinflation.

Gas Exchange. Inefficient gas exchange is signaled by $\dot{V}_A/\dot{Q}$ hypercapnia or hypoxemia. Hypoxemia of variable degree, caused mainly by mismatching (mainly venous admixture), is almost invariably present in COPD and during asthma attacks. Hypercapnia reflects both $\dot{V}_A/\dot{Q}$ mismatching and alveolar hypoventilation, the latter resulting from both respiratory muscle dysfunction and increased ventilatory requirements. During asthma attacks, hypoxia is generally associated with hypocapnia, and increasing values of Pa_{CO_2} are a warning sign of potential fatality secondary to respiratory arrest.

Cardiovascular Abnormalities. Cardiovascular dysfunction is usually related to acute and chronic blood-gas derangement, dynamic hyperinflation, and increased right-ventricular afterload. Increases in pulmonary artery pressures may result from hypoxic pulmonary vasoconstriction mainly in hypoxemic patients with COPD, and also from low-grade systemic inflammation as evidenced by elevated levels of serum C-reactive protein and tumor necrosis factor. Left-heart failure may also develop in hyperinflated patients with COPD because of an altered mechanical interaction between heart and lung. Nevertheless, the association between COPD and left-ventricular dysfunction may be simply reflect old age and exposure to common risk factors, such as smoking habit.

Postoperative Pulmonary Complications. Patients with COPD are at increased risk for postoperative atelectasis, pneumonia, and even death.[199] In patients with severe COPD undergoing noncardiothoracic surgery, the incidence of postoperative pulmonary complications is approximately 37% (excluding atelectasis) and the 2-year mortality is approximately 47%. A recent study, however, in cardiothoracic surgery reported that COPD is not a major independent risk factor for postoperative pulmonary complications.[200]

Risk Stratification. In a general surgical population, independent risk factors for postoperative pulmonary complications in adults with respiratory disease include advanced age, preexisting pulmonary disease, cigarette smoking, congestive heart failure, functional dependence (e.g., the inability to perform activities of daily living), and site of surgery (with highest risks for thoracic and abdominal surgery).[102] Epstein et al[201] developed a cardiopulmonary risk index that is a combination of the modified Goldman cardiac index and pulmonary risk factors [obesity, productive cough, wheezing, tobacco use, forced expiratory volume in 1 second (FEV_1)-to-forced vital capacity (FVC) ratio of Pa_{CO_2} >45 mm Hg]. Those with a cardiopulmonary risk index of equal to or greater than 4 were twenty-two times more likely to develop a complication following major thoracic surgery.

In patients with severe COPD, Wong et al. [199] estimated the incidence of five different postoperative complications: death, pneumonia, prolonged intubation, refractory bronchospasm, and prolonged ICU stay. From multivariate analysis, they concluded that American Society for Anesthetists (ASA) physical status equal to or greater than IV, Shapiro score equal to or greater than 5, and FEV_1 were preoperative risk factors, and emergency operation, abdominal incision, anesthesia duration longer than 2 hours, and general anesthesia were intraoperative risk factors. Risk stratification of COPD patients by ASA physical status was associated with higher incidence of postoperative pneumonia, prolonged postoperative intubation, and higher mortality. Additional risk factors include the severity of COPD, assessed by spirometry and 6-minute walk distance results, and body mass index.

More recently the use of dedicated scores has been proposed. A surgical lung injury prediction model to predict risk of postoperative ALI based on readily available preoperative risk factors has been developed. It includes

high-risk cardiac, vascular, or thoracic surgery, diabetes mellitus, COPD, gastroesophageal reflux disease, and alcohol abuse.[117]

Other investigators[99] did not identify COPD or bronchial asthma as individual risk factors for postoperative pulmonary complications after general anesthesia for thoracic or nonthoracic surgery. Seven independent risk factors were identified: low preoperative arterial oxygen saturation (SaO_2), acute respiratory infection during the previous month, age, preoperative anemia, upper abdominal or intrathoracic surgery, surgical duration of at least 2 hours, and emergency surgery. The factor capturing a low preoperative SaO_2 likely included patients with severe COPD.

We believe that the use of scores for better predicting postoperative pulmonary complications should be further developed to better identify patients at risk for complication in the intraoperative and postoperative period.[202]

Preoperative Preparation. Preoperative management involves assessment of general physical status (pulmonary, cardiac, neurologic diseases) and treatment of any reversible signs or symptoms. As a general principle, pulmonary function should be optimized preoperatively by standard treatments. In asthmatic patients, good preoperative control of symptoms and lung function should be achieved by bronchodilator and anti-inflammatory treatment (combination treatment with long-acting β_2-agonists and inhaled corticosteroids), also including leukotriene-receptor antagonists, to reduce the incidence of life-threatening perioperative complications possibly linked to airway hyperresponsiveness.[198] Additional preoperative management includes adequate control of secretions and infection and sound control of anesthesia.

Spirometry is generally used as a guide for both diagnosis and treatments of asthma and COPD, although a chest radiograph may be occasionally necessary for diagnosis.[203] Arterial blood-gas measurements are performed as needed. Indicators for arterial blood-gas analysis include spirometric values of FEV_1 and FVC less than 50% of predicted, FEV_1 less than 1 L, or FVC less than 1.5 L. Pa_{CO_2} greater than 45 mm Hg is a strong risk factor for postoperative pulmonary complications in patients with COPD; Pa_{CO_2} values greater than 50 mm Hg are likely to require postoperative mechanical ventilation following major surgery, whereas preoperative values equal to or less than 45 mm Hg can be usually managed by controlled oxygen therapy and careful monitoring of arterial blood gases.[204,205] Postponing elective surgery should be considered if improvement of pulmonary function can be expected to occur over extended time periods. Preoperative education regarding postoperative deep breathing, incentive spirometry, or CPAP may improve the final outcome.

General Anesthesia in Patients with Chronic Obstructive Pulmonary Disease. Patients with chronic lung hyperinflation may actually be less prone to develop computed tomography scan evidence of dependent atelectasis during anesthesia and paralysis. In awake patients with COPD, the $\dot{V}_A/\dot{Q}$ distribution is more heterogeneous than in healthy subjects, showing zones of relatively low $\dot{V}_A$, although with the amount of intrapulmonary shunt is negligible. In addition, computed tomography scanning shows significantly larger cross-sectional thoracic areas than in subjects with healthy lungs. During anaesthesia and paralysis, patients with COPD suffer a further worsening of $\dot{V}_A/\dot{Q}$ mismatch without increase in intrapulmonary shunt. Furthermore, FRC is only minimally reduced,[36] which is in contrast to findings in patients with healthy lungs.[206]

Therefore, general anesthesia with controlled ventilation should be avoided whenever possible in patients with COPD, and regional anesthesia techniques are preferred if there are no contraindications.

Targets for Controlled Mechanical Ventilation. In COPD or bronchial asthma, mechanical ventilation may be difficult for the following reasons: high level of lung hyperinflation; high risk of barotrauma and volutrauma; and hemodynamic instability. Thus, minimizing the magnitude of dynamic hyperinflation during mechanical ventilation is central to the management of asthma and COPD and the following are some strategies that can be adopted:

1. Decreasing minute ventilation by reducing tidal volume, respiratory frequency, with permitted hypercapnia and mild respiratory acidosis.
2. Increasing expiratory time. In patients with asthma or COPD the time required for a complete expiration often requires 3 seconds or more, and ventilator settings that do not allow adequate time for exhalation can lead to or worsen dynamic hyperinflation.[207] An increase in expiratory time can be achieved by increasing inspiratory flows, at the expense of increasing peak dynamic pressures, and avoiding end-inspiratory pause.
3. Reducing expiratory flow resistance through use of bronchodilators or low-density gas mixtures (e.g., 80% helium and 20% O_2), which may help reduce dynamic hyperinflation.

We recommend, whenever possible, to simultaneously apply all of these strategies. As a starting point for ventilating patients with COPD or severe asthma, we recommend that the ventilator be used in the PCV mode, setting the pressure to achieve a tidal volume of 6 to 8 mL/kg, respiratory rate of 11 to 14 breaths/min, and PEEP at 0 to 5 cm H_2O. We recommend the use of these settings with a goal of obtaining a pH generally greater than 7.2 and an inspiratory plateau pressure less than 30 cm H_2O. If plateau pressure is less than 30 cm H_2O cannot be maintained, then the patient must be evaluated for causes of decreased respiratory system compliance or increased resistance (i.e., pneumothorax, misplaced endotracheal tube, pulmonary edema). In absence of one of these findings, efforts to further limit gas trapping must be considered. Administration of sodium bicarbonate to maintain a pH of 7.2 during controlled hypoventilation has been investigated in patients with COPD and/or status asthmaticus; however, no studies have demonstrated any benefit associated with bicarbonate infusion.

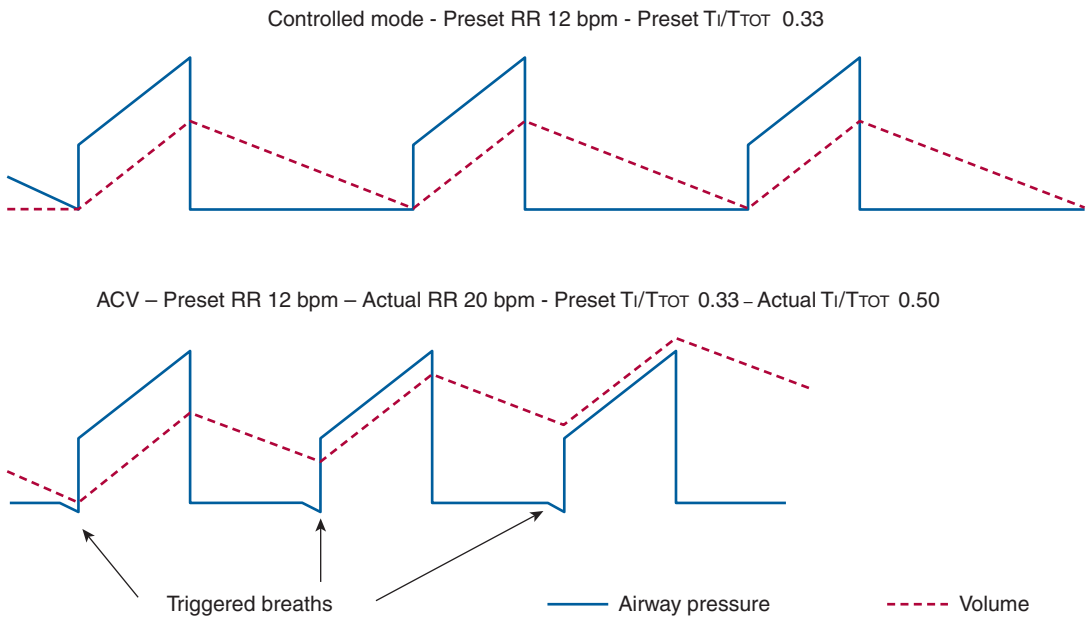

FIGURE 24-7 Schematic of airway pressure and volume versus time curves during mechanical ventilation with controlled (*top*) and assist-control ventilation (*ACV*) in a patient with expiratory flow limitation. Because of the short expiratory time in ACV, dynamic hyperinflation is exacerbated (dashed red line). *ACV*, assist-control ventilation; *RR*, respiratory rate; T_I/T_{TOT}, inspiratory to total respiratory time.

Lung recruitment maneuvers should be cautiously applied in presence of asthma or COPD. Furthermore, particular care should be given to avoid excessive spontaneous breathing during time-cycled ventilation, because the reduction of expiratory time may lead to an increased hyperinflation and PEEPi, as shown schematically in Figure 24-7. For these reasons, ACV should not be routinely used in asthma or COPD patients in the awakening phase from general anaesthesia, while pressure-support ventilation and others modes of mechanical ventilation not cycled by time may be useful.

THE IMPORTANT UNKNOWNS

Approximately 234 million major surgical procedures per year are performed under general anesthesia worldwide, and 1.3 million patients develop complications that result in up to 315,000 in-hospital deaths.[97] The incidence of pulmonary complications following surgery seems to be situated between 2.7%[98] and 56%,[101] depending on individual predisposing factors, as well as type and duration of surgery.[99] Once a patient presents with a pulmonary complication, the length of hospital stay and probability of death increases significantly. It is unknown, however, whether mechanical ventilation management during general anesthesia influences patient outcome, and current data on this issue are conflicting. Given that most patients undergoing general anesthesia have no significant lung disease, it is important to identify by appropriate scores patients who will be at higher at risk of developing pulmonary complications.[202] The importance of selecting appropriate settings of mechanical ventilation in the intraoperative phase is unclear, and argumentation is based on physiologic and pathophysiologic conjectures and laboratory experience, rather than outcome evidence.

THE FUTURE

As discussed above, there is an increased interest in different modes of mechanical ventilation during general anesthesia. We believe that ventilator modes and strategies that have been available only for critically ill patients will become available in the operating room, including modes of assisted spontaneous breathing and high-frequency ventilation. Moreover, strategies to ventilate the lungs during general anesthesia in different conditions, including open-abdominal surgery, one-lung anesthesia, patients with obesity, asthma, COPD or in combination, and laparoscopic surgery, among others, will be investigated and their importance in the development of pulmonary complications better defined. For this purpose, multicenter clinical trials on intraoperative mechanical ventilation will be necessary.

SUMMARY AND CONCLUSIONS

Mechanical ventilation is becoming increasingly complex not only in the intraoperative phase, but throughout the whole perioperative period. Accordingly, ventilator modes that have been used almost exclusively in the ICU can now be found on anesthesia ventilators. Such development is guided by the needs to provide adequate ventilator support

in a variety of situations, including open and laparoscopic surgery, diagnostic procedures of the airways, one-lung anesthesia, presence of expiratory flow limitation (e.g., asthma, COPD), and also morbid obesity. Also, strategies of protective ventilation with low V_T and higher levels of PEEP combined with lung-recruitment maneuvers, as well as invasive and noninvasive assisted spontaneous ventilation, are becoming more popular in general anesthesia, even in the absence of ALI. Whether such protective ventilation or the use of advanced modes of ventilator support during general anesthesia will contribute to reduce the incidence of pulmonary complications has yet to be determined.

INDEPENDENT LUNG VENTILATION

David V. Tuxen

Independent lung ventilation (ILV) was first used in thoracic surgery and the intubation devices were developed for this purpose. Gale and Waters first reported ILV in 1931, by passing a single-lumen endobronchial tube into the main bronchus of the dependent nonoperative lung for ventilation and exclusion of purulent secretion (if present) from the operative lung. In 1936, Magill[1] reported endobronchial placement of a suction catheter with a balloon to occlude the operative bronchus and tracheal placement of an ETT to ventilate the nonoperative lung. In 1947, Moody[2] encased the endobronchial balloon with metal studs to reduce the risk of balloon dislodgment.

The first double-lumen tube (DLT), enabling independent ventilation of both lungs, was reported by Carlens[3] in 1949. Thus, tube was similar to current left DLTs, but had a rubber "hook" to engage the carina for accurate placement. Although a major advance, this tube caused trauma and was unsuitable for left pneumonectomy. The first right DLT, which did not occlude the right upper lobe bronchus, was not reported until 1960 by White.[4] In 1962, Robertshaw[5] reported right and left DLTs, which served as the prototype of today's DLTs. Current DLTs have replaced red rubber with polyvinyl chloride (PVC) to reduce mucosal injury and improve malleability and airflow (Fig. 25-1).

For many years, DLTs and ILV were used entirely for thoracic surgery.[2,5,6] In 1976, Glass and Trew[7,8] and their coworkers reported ILV for nonsurgical purposes: respiratory insufficiency from unilateral lung disease. Since then, application of ILV has broadened to a wide range of conditions (Table 25-1) employing a variety of techniques. Institutions specializing in conditions commonly requiring ILV (such as single lung transplantation or alveolar proteinosis), ILV may be used in approximately 0.5% of all mechanically ventilated patients.[9,10] Although most intensive care units use ILV in fewer than one in 1000 patients requiring mechanical ventilation, it can be a lifesaving measure in specific conditions, making maintenance of suitable equipment and knowledge of its use required.

ILV is infrequently and often urgently required when conventional mechanical ventilation is not a viable alternative. As a result, there have been no randomized controlled trials of ILV in patients and current evidence is based almost entirely on animal models, case reports, and case series with before and after analyses.

BASIC PRINCIPLES OF INDEPENDENT LUNG VENTILATION

All the indications for ILV (see Table 25-1) are based on one or two fundamental requirements.

1. *The need to protect one lung from harmful effects of fluid in the other lung* (blood, purulent or malignant secretions, lavage fluid). Placing the fluid-filled lung in the dependent position (lateral decubitus) minimizes the risk of unwanted fluid entering the other lung but also maximizes hypoxia[11] by maximizing blood diversion to the less-functional lung. Placing the fluid-filled lung in the nondependent position improves oxygen saturation

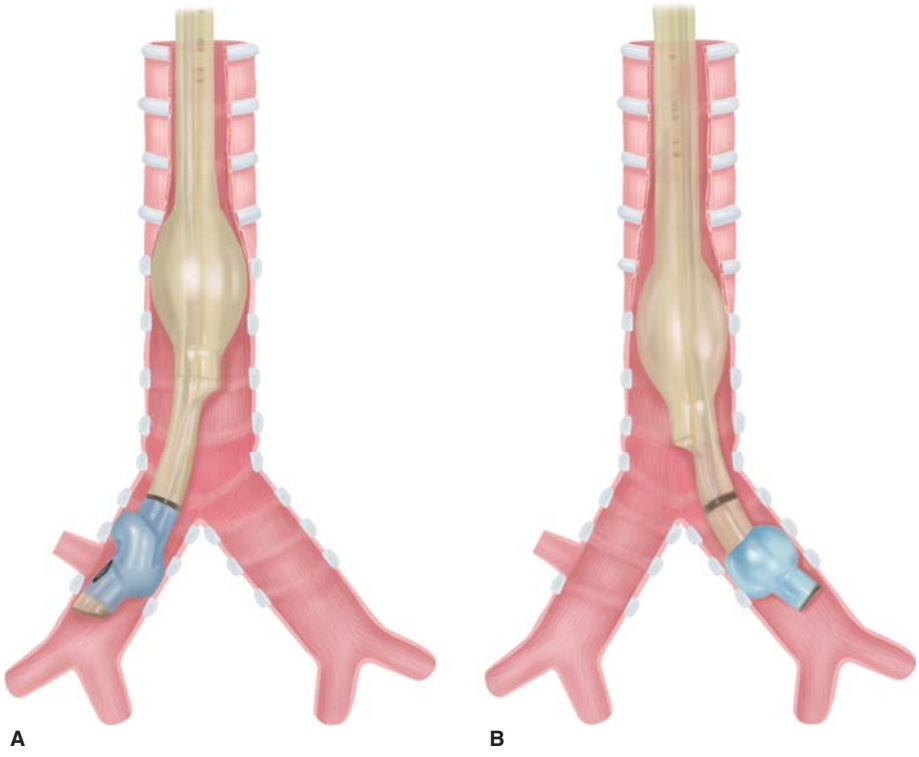

FIGURE 25-1 (**A**) Right and (**B**) left polyvinyl chloride (PVC) (Mallinckrodt) double-lumen tubes (DLT) shown against a schematic of the trachea and major airways.

(SaO_2), but the risk from fluid spillage in this position is unacceptably high.[11] The supine position is usually the best compromise, except during thoracic surgery, where the operative lung must be in the uppermost position.

2. *The need to isolate the ventilatory patterns to each lung.* In each case, the ventilatory pattern for one lung has disadvantageous effects if applied to both lungs. This includes one-lung ventilation (OLV; e.g., thoracic surgery, whole-lung lavage), ventilation to each lung differing in only a single variable (e.g., positive end-expiratory pressure [PEEP]), or ventilation requirements differing in every variable (e.g., single-lung transplant for obstructive airways diseases), or the need to prevent air loss from one lung (e.g., massive air leak).

If OLV is required, a bronchial blocker and endobronchial tube or a DLT may be used. If ILV is required, then a DLT is usually used, although some bronchial blockers can allow limited ventilation such as continuous positive airway pressure (CPAP) or jet ventilation.

TABLE 25-1: POLYVINYL CHLORIDE DOUBLE-LUMEN TUBES: CHOICE OF SIZE

Size (French)	OD (mm)	Tracheal ID (mm)	Bronchial ID (mm)	Use	Manufacturer[a]
26	8.7	3.5	3.5		Rüsch
28	9.3	3.1	3.2	Children weighing <40 kg	Mallinckrodt
32	10.7	3.5	3.4		Sheridan
35	11.7	4.5	4.3	Children weighing >40 kg	Mallinckrodt
37	12.3	4.7	4.5	Small adult	Mallinckrodt
39	13.0	4.9	4.9	Medium adults, usual female size	Mallinckrodt
41	13.7	5.4	5.4	Large adult, usual male size	Mallinckrodt

Abbreviations: *ID*, internal diameter; *OD*, outside diameter.

[a]Rüsch: Duluth, GA; Sheridan: Argyle, NY; Mallinckrodt: St. Louis, MO.

Adapted, with permission, from Campos JH.[267]

Irrespective of technique, tube or blocker position is usually checked using fiberoptic bronchoscopy immediately after instigation, and lung isolation is leak tested. This is important for all indications for ILV but is most critical where protection from secretions is required.

INDEPENDENT LUNG VENTILATION TECHNIQUES

Lung Separation

ILV must be preceded by the placement of a DLT or alternate lung isolation device. These must be introduced, correctly positioned, and then tested to ensure isolation of lung ventilation.

Compared with red-rubber DLTs,[3,4,12] PVC-type DLTs (see Fig. 25-1, e.g., Mallinckrodt, Sheridan, Rusch, Concord, Portex, Marraro) are more flexible, have better internal–external diameter[10] ratios, better gas-flow characteristics, easier suction and bronchoscopy access,[13] allow airway seal with lower cuff pressures,[14] are less irritating to respiratory mucosa, have a lower risk of trauma, and are easier and quicker to position.[15] These characteristics make PVC types the DLTs of choice, although airway injury from PVC DLTs may still occur.[16,17]

For most indications, a left DLT (see Fig. 25-1) should be used because placement is easier than for a right DLT, which has a high risk of right upper-lobe occlusion.[18] A right DLT (see Fig. 25-1) is required for thoracic surgical procedures that include the left main bronchus (left pneumonectomy, left main bronchial lesions, stenosis, or rupture), thoracic aortic aneurysm repair, or anatomic abnormalities that prevent satisfactory access to the left main bronchus.[19–21] A right DLT is also required for ILV with a recent left single lung transplantation to avoid injury to the anastomosis and distal airway. To minimize airflow resistance and maximize endobronchial access, the largest DLT that will not cause laryngeal or airway injury should be chosen (see Table 25-1).

PVC DLTs are usually introduced with the endobronchial curvature angled anteriorly and a rigid stylet in situ to facilitate the passage of the tip through the vocal cords. Once through the cords, the stylet is usually removed and the DLT is rotated through 90 degrees so that the endobronchial curvature is directed toward the appropriate side. The tube is then advanced until an increase in resistance is detected. In a randomized trial of sixty patients receiving a DLT for thoracic surgery, Lieberman et al[22] compared removal of the stylet (as above) and leaving the stylet in situ until placement was complete; the latter increased the correct placement rate from 17% to 60%.

DLT tube position and function must then be confirmed by one or more of three techniques:

1. **Auscultation.** Following cuff inflation, the tracheal port should be clamped and the bronchial port ventilated.[19] Bilateral or contralateral breath sounds indicate placement is too proximal and a need to reposition the DLT (Fig. 25-2A), whereas breath sounds heard only on the correct side indicate correct placement (see Fig. 25-1). Difficulty with ventilation should be resolved by deflating the bronchial cuff: bilateral breath sounds indicate that placement is too proximal, whereas breath sounds heard only on the side of the endobronchial tube indicate that placement is too distal (Fig. 25-2B). Lung auscultation should always include both upper and lower lobes, to ensure correct placement of the endobronchial port within the bronchus, especially with a right DLT where the right upper lobe is easily occluded.
2. **Bronchoscopy.** Following DLT insertion, a small fiberoptic bronchoscope may be passed through the tracheal lumen to confirm position of the tracheal port and that the endobronchial tube is in the correct position.[19,23] The endobronchial cuff should be visible just distal to the carina. Subsequent insertion of the bronchoscope down the endobronchial lumen may be used to confirm that endobronchial placement is not too distal and that, with right DLTs, the right upper-lobe bronchus is over the corresponding fenestration. Although not essential for DLT placement, bronchoscopy reliably confirms accurate placement and should be used routinely. It has an advantage with anatomic variations and in detecting partial airway occlusions.[17]
3. **Leak test.** While ventilating one lung, a connection to the second airway can be placed under water. Any bubbling indicates air leak from the ventilated lung to the opposite side. Such leaks may not be detected by auscultation or bronchoscopy and may be important, particularly when one of the goals is to protect one lung against fluid (whole-lung lavage, blood, or purulent secretions) from the other lung. Bubbling may indicate the need for tube repositioning or higher bronchial-cuff inflation.

Chest radiography may be used to visualize DLT position, but is insufficient to verify critical tube placement or functional isolation.

DLTs may be connected to a single ventilator (e.g., for hemoptysis or at the beginning and end of whole-lung lavage; Fig. 25-3A) or connected to two separate ventilators (see Fig. 25-3B).

Bronchial blocking techniques and selective endobronchial intubation are alternatives to a DLT. The right or left main bronchus may be blocked by placement of a balloon-tipped catheter into that bronchus. This allows OLV and is suitable for thoracic surgery, bleeding, or fistula control. The catheter (Arndt endobronchial blocker, Magill blocker, Cohen Flexitip Endobronchial Blocker, Fogarty or Foley catheter)[24–28] may be placed outside or within a standard cuffed endotracheal tube (ETT) lumen or passed down a specially designed second small lumen in the ETT (Univent tube).[29–31] A Univent tube (Fig. 25-4) has a coudé-tipped bronchial blocker that allows blind guidance of the blocker into the desired bronchus with auscultatory confirmation of correct positioning. Bronchoscopic confirmation of best

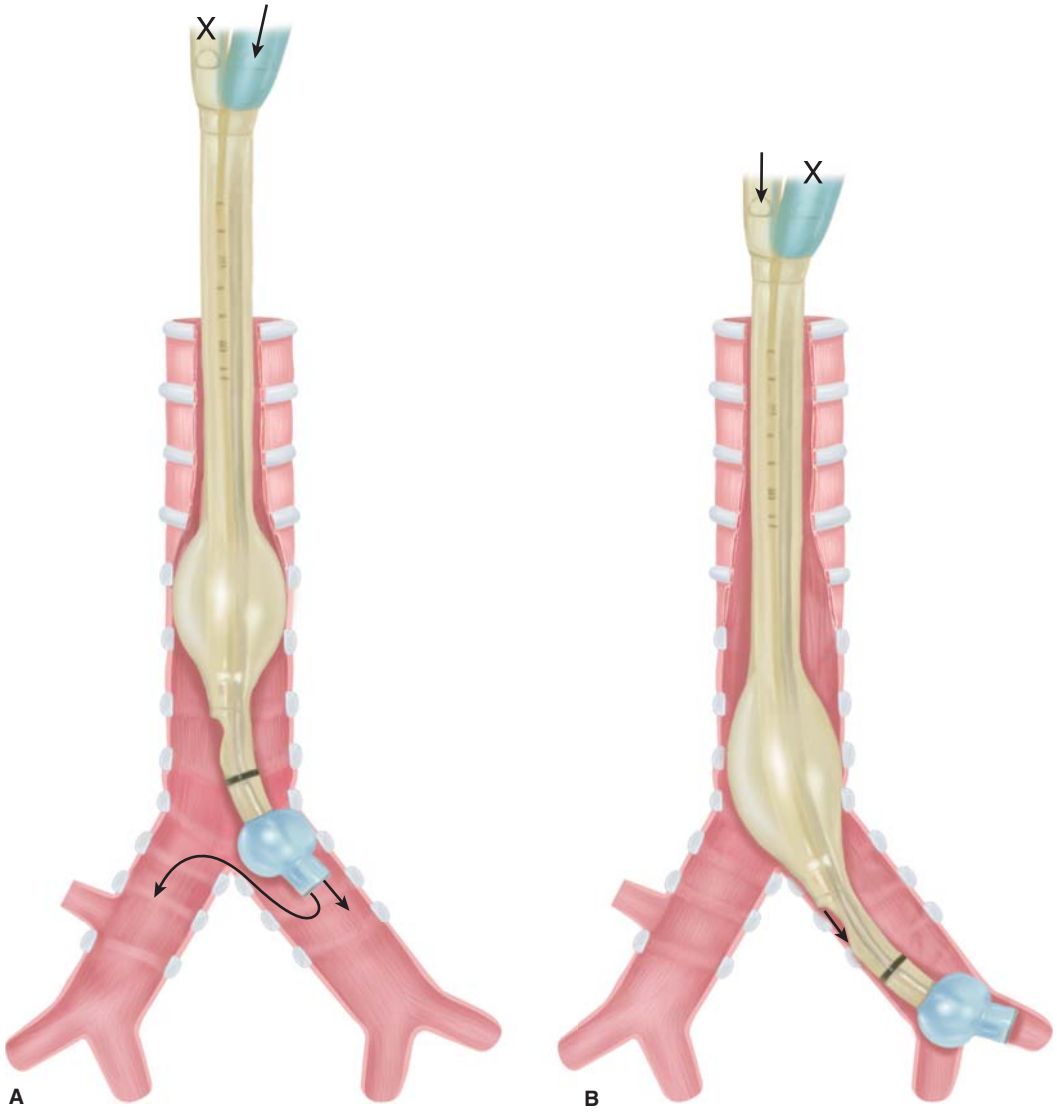

FIGURE 25-2 Flow patterns that may occur during auscultatory verification of a left DLT position (**A**) when DLT is insufficiently inserted and the left lumen is ventilated (right lumen clamped) and (**B**) when DLT is inserted too far and the right lumen is ventilated (left lumen clamped).

position within the airway, however, is still recommended. In addition, the Univent's axial-blocker shaft has a lumen that allows irrigation, suction, O_2 insufflation, CPAP, and high-frequency ventilation.[29] The Arndt endobronchial blocker[24–26] (Fig. 25-5) requires bronchoscopic guidance for placement. The kit comes with an ETT adaptor that allows access for mechanical ventilation, the blocker, and the bronchoscope through separate ports (Fig. 25-5). The bronchoscope is passed into the airway that requires blocking, and the blocker is then guided into that airway via a snare over the bronchoscope (Fig. 25-5A). The bronchoscope then is withdrawn, the balloon is inflated, and its position is confirmed by bronchoscopy before withdrawal (Fig. 25-5B). This has the advantage of being performed via the ETT in situ, thereby avoiding reintubation, provided that the ETT is sufficiently large to admit both the blocker and the available bronchoscope. The Cohen Flexitip Endobronchial Blocker[28] has a flexible tip that can be guided under bronchoscopy but independently of the bronchoscope (Fig. 25-6).

Techniques for Independent Lung Ventilation

A variety of techniques have been reported.

SYNCHRONIZED INDEPENDENT LUNG VENTILATION

Synchronized independent lung ventilation (SILV) consists of synchronous initiation of inspiration into each lung. Each lung must necessarily have the same respiratory

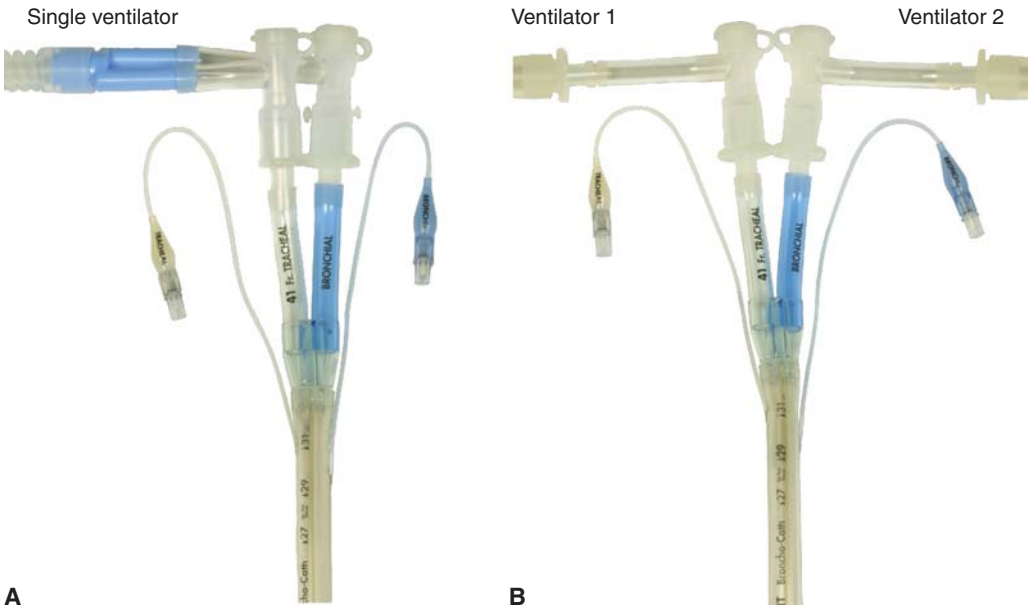

FIGURE 25-3 **A.** Both lumens of a double-lumen tube connected to a single ventilator airway. **B.** Each lumen of a double-lumen tube connected to separate ventilators.

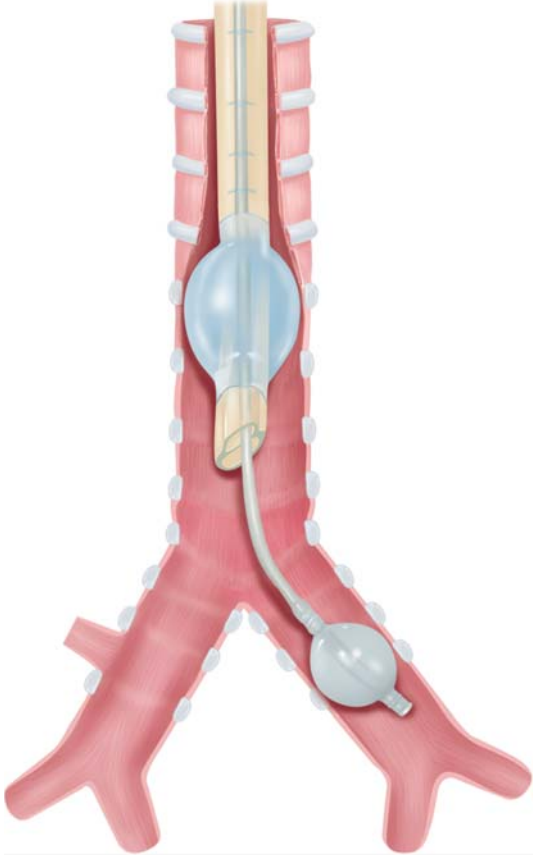

FIGURE 25-4 The Univent tube with the balloon inflated in the left main bronchus.

rate, but may have different tidal volume (V_T), PEEP, and inspiratory flow. SILV may be achieved by a variety of techniques.

1. *Two ventilators of the same type linked to cycle synchronously*. This may be achieved by electronically "slaving" the rate control of a second ventilator to a primary ("master") ventilator,[18,32–40] by electronically synchronizing both to an external control device,[41,42] or by simultaneously resetting the respiratory cycle on paired ventilators and relying on accurate internal timing to maintain synchronization.[43,44] These forms of SILV allow difference in all variables apart from rate—different V_T, PEEP, and inspiratory flow, and hence different inspiratory-to-expiratory time (T_I/T_E) combinations. SILV with two ventilators synchronized 180 degrees out of phase[45,46] has been successful in animals, but appears to have no advantages over other forms of ILV and has not been reported in humans.
2. *A single ventilator linked to a twin circuit with variable resistances in each inspiratory line*[47–49] can create different flows to each lung. The V_T received by each lung will then be determined by both the resistance in the circuit and the impedance in the lung and must be independently measured in each circuit and resistance adjusted accordingly. An alternative to this is flow controllers in both inspiratory lines[50,51] resulting in a fixed V_T to each lung determined by the set flow and inspiratory time and independent of lung impedance. Separate PEEP in each circuit was achieved by expiratory flow controllers. This method allows different V_T and PEEP to each lung, but necessarily must have the same T_I, T_E, and rate.

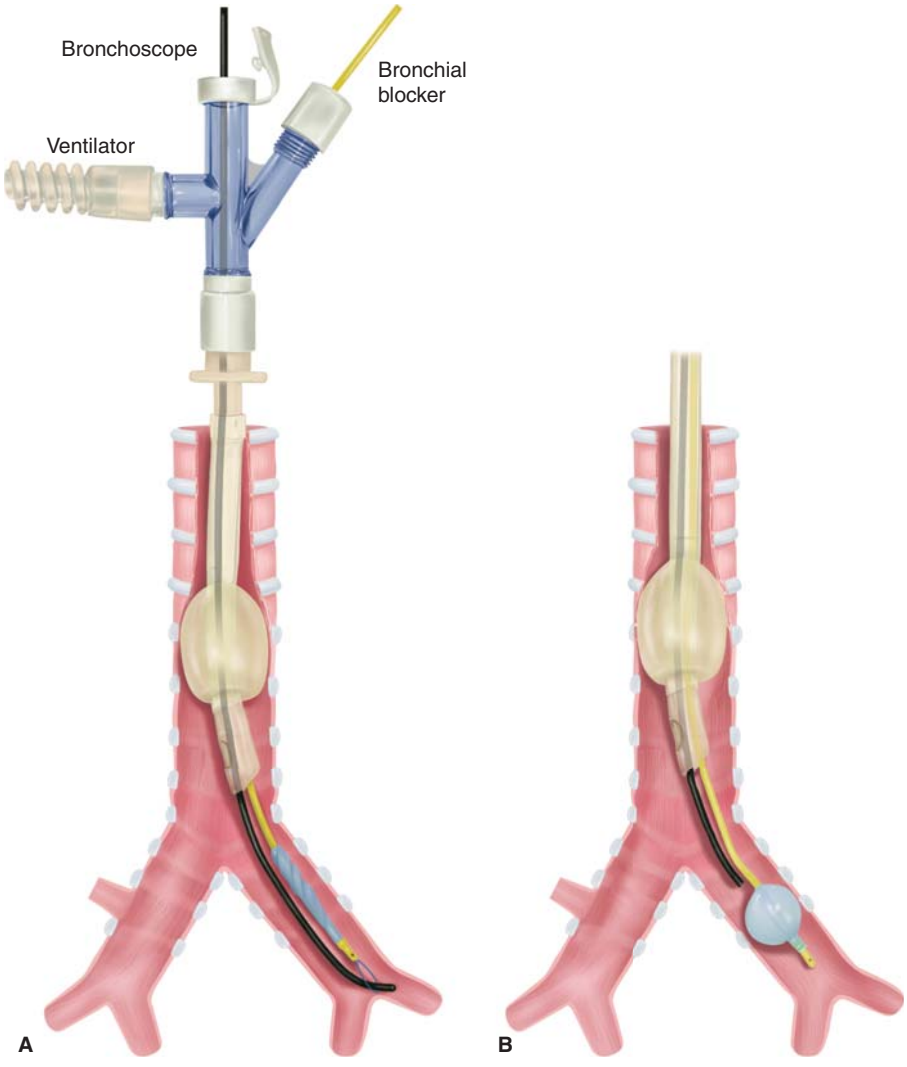

FIGURE 25-5 The Arndt endobronchial blocker shown (**A**) during bronchoscope guidance into the left main bronchus and (**B**) after partial bronchoscope withdrawal and balloon inflation, with the bronchoscope remaining to check balloon position.

3. *A single ventilator linked to two circuits, each with a separate PEEP valve or other PEEP-generating device.*[52,53] This arrangement allows different PEEP to each lung. The division of V_T between the lungs is not controlled independently, being determined by both the relative inherent impedance of each lung and the effect of PEEP on that impedance.
4. *A single ventilator linked to two circuits with no attempt to influence the distribution of ventilation.*[13] This method generally is used during selective airway protection. The division of V_T between the two lungs is determined solely by their relative impedance.

While many indications for ILV are suited to having the same ventilator rate to each lung, there is usually no particular benefit for exact coordination of two ventilators. The only exception may be the uncommon circumstance where patient-triggered ventilation is attempted.

ASYNCHRONOUS INDEPENDENT LUNG VENTILATION

Asynchronous independent lung ventilation (AILV) consists of completely independent ventilator techniques applied to each lung. It requires two separate ventilation devices. Options include:

1. *Controlled* (CMV) *or intermittent mechanical ventilation to both lungs.*[9,54–62]
2. *CMV or intermittent mechanical ventilation to one lung and high-frequency jet ventilation* (HFJV) *to the other.*[57,63–66]
3. *CMV or intermittent mechanical ventilation to one lung and CPAP to the other.*[7,57,58,67]
4. *High-frequency oscillatory ventilation to both lungs.*[68]

AILV permits different rate, V_T, inspiratory flow, and PEEP to each lung. Lack of synchronization between the two lungs offers the greatest flexibility and appears to hold

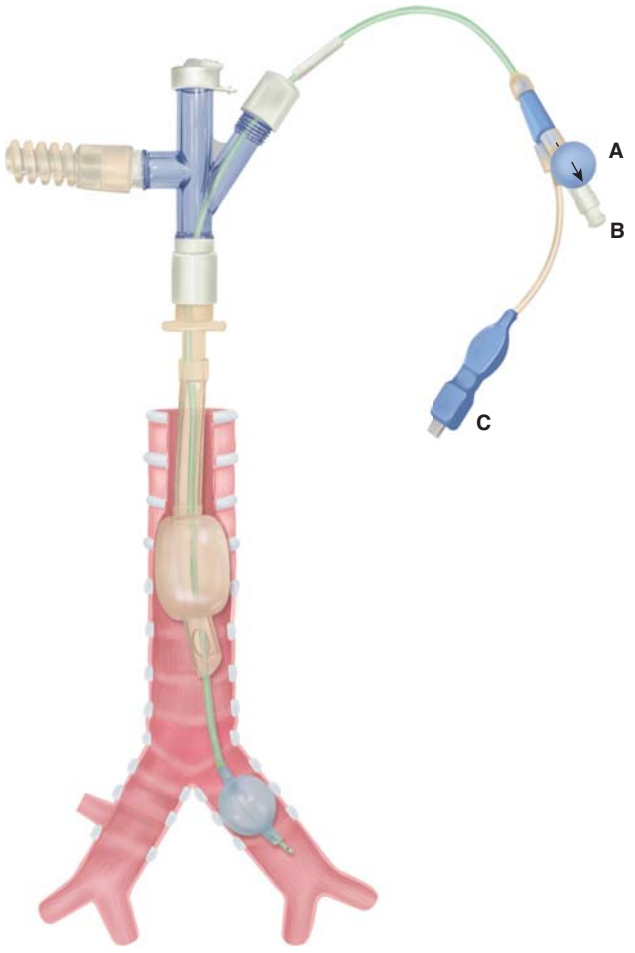

FIGURE 26-6 The Cohen Flexitip Endobronchial Blocker shown with its endotracheal tube attachment. **A** is the knob that controls and locks the tip flexion. **B** is a Luer lock port to the lumen of the Cohen blocker. **C** is the valved insufflation port for the blocker balloon.

no disadvantage and a number of advantages compared with SILV.[55,61]

ONE-LUNG VENTILATION

With OLV, one lung is ventilated mechanically while the other is either occluded or open to atmosphere with an option of spontaneous ventilation. OLV is used mainly in thoracic surgery to keep the lung collapsed and immobile. It also may be used in bronchopleural fistula (BPF) to prevent air leak or for selective airway protection if secretions from the affected lung prevent any useful ventilation (e.g., massive hemoptysis). Options include:

1. *DLT intubation*[11,20,21,69–71] or in infants, two separate uncuffed tracheal tubes of different lengths attached longitudinally (Marraro DLT)[69] with CMV applied to only one lumen.
2. *Endotracheal intubation with a bronchial blocker inserted into one of the major bronchi.* The occlusive balloon excludes that lung from mechanical ventilation and the blocker lumen allows deflation (and inflation) of that lung.[1,21,24–26,30]
3. *Endobronchial intubation with a single lumen tube* (e.g., Mackintosh-Leatherdale left endobronchial tube and Gordon Green right endobronchial tube).[21]

SPONTANEOUS VENTILATION

Spontaneous ventilation with a DLT and differential CPAP applied to each lung was first reported by Venus et al.[72] It has been used in spontaneously breathing patients with unilateral pulmonary contusion and atelectasis with good results.[72,73] It is not recommended because of increased work of breathing through a long narrow tube.

APPLICATIONS OF INDEPENDENT LUNG VENTILATION

Applications of ILV (Table 25-2) fall into five categories.

TABLE 25-2: INDICATIONS FOR INDEPENDENT LUNG VENTILATION

Thoracic Surgery
Pneumonectomy
Some lobectomies
Thoracic aortic surgery
Thoracoscopy
Some esophageal surgery and diaphragmatic surgery
Selective airway protection
Secretions (tuberculosis, bronchiectasis, abscess)
Whole-lung lavage
Massive hemoptysis
Bronchial repair protection
Bronchopleural fistula
Asymmetrical lung disease
Unilateral parenchymal injury
Aspiration
Pulmonary contusion
Pneumonia
Massive pulmonary embolism
Reperfusion edema
Asymmetrical acute respiratory distress syndrome
Asymmetrical pulmonary edema
Atelectasis
Unilateral airflow obstruction
Single lung transplantation for chronic airway obstruction
Unilateral bronchospasm
Severe bilateral lung disease
Acute respiratory distress syndrome
Aspiration
Pneumonia

Thoracic Surgery

A number of thoracic surgical procedures require OLV, usually in the lateral position. Table 25-1 lists the common thoracic surgical indications for OLV.[19,21,69] Although OLV is required during surgery, ILV may be required before, and sometimes after, the surgical procedure.[69,74]

OLV may be achieved with a DLT, bronchial blocker, or endobronchial tube. A DLT has the advantage of enabling ILV, which may be important in alleviating hypoxia, but has the disadvantage of high-resistance airways with more difficult suctioning. An ETT with a bronchial blocker has the advantage of a wide-bore, low-resistance endotracheal lumen with better bronchoscopic and suction access, through which either OLV (bronchial blocker inflated) or double-lung ventilation (bronchial blocker deflated) can be delivered.[30] The narrow lumen in some bronchial blockers can enable lung inflation, deflation, CPAP, or HFJV, but does not allow conventional ILV. OLV may be delivered to either lung, but repositioning of the bronchial blocker is required.[30] When the blocker is an integral part of the ETT (Univent tube, see Fig. 25-4),[29–31] it is easier to insert and it maintains a more stable position compared with an intraluminal or extraluminal blocker that is more subject to movement and dislodgment, especially during suctioning, bronchoscopy, or patient movement.[30] With any bronchial blocker, bronchoscopy is easier and required less frequently.[19,30] A disadvantage is that the inflated blocking balloon near the site of intended bronchial surgery (e.g., pneumonectomy, single lung transplantation) may hamper that procedure, and a DLT placed in the opposite lung may be technically easier.

EFFECTS OF INDEPENDENT LUNG VENTILATION IN THE LATERAL DECUBITUS POSITION

Irrespective of patient position, gravity-induced differences in ventilation and perfusion occur vertically within each lung: between the bases and apices in the erect position, and between the dependent and nondependent lung regions in the supine position.

When a patient is in the erect or supine position, gravitational differences in ventilation and perfusion occur vertically within each lung. In the lateral decubitus position, these gravitational differences occur between the two lungs.[71,75] Up to two-thirds of perfusion shifts to the dependent lung.[75–77] During *spontaneous ventilation,* a smaller increase in ventilation also occurs in the dependent lung in the lateral position, thereby reducing ventilation–perfusion mismatch.[71,75] When the patient is anesthetized and *mechanically ventilated* in the lateral decubitus position, however, reduced diaphragmatic activity allows the weight of abdominal contents to retard expansion of the dependent lung,[71,75] and most ventilation is diverted to the nondependent lung. In this situation, the nondependent lung may receive up to two-thirds of ventilation.[36,40,76] Opening the nondependent thorax further reduces ventilation to the dependent lung by facilitating expansion of the nondependent lung.[77,78] The net effect of these changes is overperfusion relative to ventilation (or shunting) in the dependent lung and overventilation relative to perfusion (or dead space ventilation) in the nondependent lung with adverse effects on gas exchange.

Left thoracotomy achieves a higher partial pressure of arterial oxygen (Pa_{O_2}) during OLV than does right thoracotomy because the left lung normally receives 10% less cardiac output than the right lung.[70] The presence of chronic airway obstruction (CAO) is associated with better Pa_{O_2} during OLV possibly because of dynamic hyperinflation in the dependent lung.[70] Pa_{O_2} during double-lung ventilation is also predictive of Pa_{O_2} during OLV.

Some forms of ILV cannot be applied when the nondependent lung is immobile, deflated, or removed, yet ILV has been shown to improve many of these abnormalities. Application of PEEP to both lungs improves dependent-lung ventilation and oxygenation.[76] SILV (see "Techniques for Independent Lung Ventilation" above) with delivery of equal V_T to both lungs,[39] or PEEP to the dependent lung,[37,38,40,79,80] or both,[38] improves oxygenation when compared with double-lung ventilation or generalized PEEP.

When OLV is undertaken and the nondependent lung is excluded from ventilation, the reduction in ventilation to the dependent lung is eliminated, but all perfusion through the nondependent lung constitutes a shunt. In this situation, the amount of perfusion of the nondependent lung is a major determinant of hypoxia. Hypoxic vasoconstriction (not opposed by anesthetic agents), lung collapse, and surgical occlusion of blood flow (pneumonectomy) to the nondependent lung all have the potential to reduce shunt and improve Pa_{O_2} in OLV.

PEEP in the dependent lung may be beneficial by increasing functional residual capacity and improving distribution of ventilation or be detrimental by increasing alveolar pressure and diverting blood flow to the nonventilated lung.[71,81–86] Consequently, PEEP to the dependent lung during OLV may improve Pa_{O_2},[81,86] decrease Pa_{O_2},[81,82,86] or cause no change.[84–86] During OLV, Cohen et al[79] compared PEEP (10 cm H_2O) to the dependent lung, CPAP (10 cm H_2O) to the nondependent lung, and both. All three maneuvers increased Pa_{O_2} compared with OLV alone. PEEP caused the smallest (nonsignificant) increase in Pa_{O_2}. CPAP and PEEP + CPAP caused larger (significant) increases in Pa_{O_2}, whereas PEEP + CPAP reduced cardiac output and oxygen (O_2) delivery significantly, which CPAP alone did not. Cohen et al[28] concluded that CPAP alone (to the nondependent lung) had the most beneficial effect by diverting blood flow to the dependent lung without reducing cardiac output. More recently, PEEP has been shown to benefit oxygenation during OLV to the dependent lung during thoracotomy.[87]

Because of these variable effects, it has been recommended that CPAP (5 to 10 cm H_2O) be applied to the nondependent lung, combined with no, low, or high PEEP (5 to 15 cm H_2O) to the dependent lung, depending on patient response.

Although function of the two lungs commonly differs after thoracotomy, conventional mechanical ventilation or spontaneous ventilation are usually resumed after surgery. ILV is required occasionally in the postoperative period for marked asymmetry of lung function with hypoxia,[7,8,55] BPF,[47,58,63,66,88] or following esophagectomy.[74] Pawar et al[69] reported successful use of the Marraro pediatric double-lumen tube[89] (two separate uncuffed tracheal tubes of different lengths attached longitudinally) in seventeen children, ages 1 day to 3 years (2.7 to 12 kg) who required OLV during cardiothoracic surgery. Of these, six children required ILV up to 48 hours postoperatively. All children survived. Ito et al[90] reported ILV with a separate bronchial cannula in each main bronchus, combined with bilateral HFJV, the repair of tracheal stenosis in a 2-year-old infant.

Selective Airway Protection

WHOLE-LUNG LAVAGE

Pulmonary alveolar proteinosis is the most common indication for whole-lung lavage. This condition was first described in 1958,[91] and soon after, bronchopulmonary lavage became established as the main treatment.[92–100]

Pulmonary alveolar proteinosis is most often acquired (90%) but may be congenital or secondary to conditions such as acute silicosis and other inhalational syndromes, immunodeficiency disorders, malignancies, hematopoietic disorders, and lysinuric protein intolerance.[101] It has also been reported following prolonged cotton dust exposure.[102] Recent studies suggest that acquired pulmonary alveolar proteinosis may be caused by deficiency of granulocyte-macrophage colony-stimulating factor,[101,103] and administration of this factor is of value in approximately 50% of patients. Despite these advances, lavage remains the most effective therapy.[101,103]

The clinical course is variable: increasing dyspnea progressing to respiratory insufficiency, static disease with minimal symptoms, asymptomatic disease, and spontaneous resolution in some patients.[101,104] Because the course is variable, the decision to undertake bronchopulmonary lavage is based on disease progression and symptoms.

Whole-lung lavage has been used for asthma,[105,106] chronic bronchitis, and cystic fibrosis,[11,98,105–111] but with doubtful benefit; it is no longer recommended. Radioactive dust inhalation is another indication.[112]

Procedure for Whole-Lung Lavage. To minimize hypoxia during the procedure, the worst lung should be lavaged first. The worst lung can be identified by chest radiograph, ventilation–perfusion scan, or oxygenation[3,113,114] during OLV to each lung before the procedure.

The procedure usually is performed with anesthesia, neuromuscular paralysis,[11,105,115] and a left DLT in the supine position. The supine position is chosen to balance the risk between hypoxia and fluid spillage[11] (see "Basic Principles of Independent Lung Ventilation" above).

Complete lung isolation to prevent spillage of fluid from the lavaged lung into the ventilated lung is essential. Correct DLT position should be established using both bronchoscopy and leak testing (as above) up to plateau pressures of 40 to 50 cm H_2O.[11,19] Both lungs should be preoxygenated with 100% O_2 to maximize gas exchange and eliminate nitrogen, which may prevent full access of lavage fluid to the lung to be lavaged.

Isotonic saline, warmed to body temperature, then should be infused through wide-bore tubing into the lung to be lavaged from a gravitational height 30 cm above the midaxillary line.[11] This infusion pressure of 30 cm H_2O usually results in infusion volumes of 500 to 1000 mL depending on the compliance of the lung. Efflux of fluid may be commenced as soon as fluid influx is complete; the drainage tube is placed below the patient, assisted by head-down posturing, and percussion and vibration of the hemithorax.[11,115] Fluid flow may be achieved using separate clamped inlet and outlet lines or a single line that is elevated for fluid influx and lowered for fluid efflux. Total fluid exchange may range from 10 to 50 L and should be continued until efflux fluid is relatively clear.

When fluid influx into the lavaged lung is complete, the alveolar pressure usually exceeds the pulmonary capillary pressure, minimizing shunt through this lung and maximizing arterial oxygenation at this stage of the procedure.[105,115–118] When the lavaged lung is emptied of fluid, blood flow returns, and significant hypoxemia can occur (Fig. 25-7).[11,105,115–117]

On conclusion of the lavage, double-lung ventilation should be recommenced with the DLT in situ using a single ventilator and a bifurcated circuit. If oxygenation is satisfactory, the patient may be weaned and extubated or reintubated with a regular ETT and later weaned. If oxygenation is unsatisfactory, ILV may need to be recommenced. Up to 1000 mL of saline may be retained in the lavaged lung;[115] although this is absorbed rapidly, lung function may not improve for hours or days. The procedure is repeated on the second lung after an interval of 1 to 3 days.

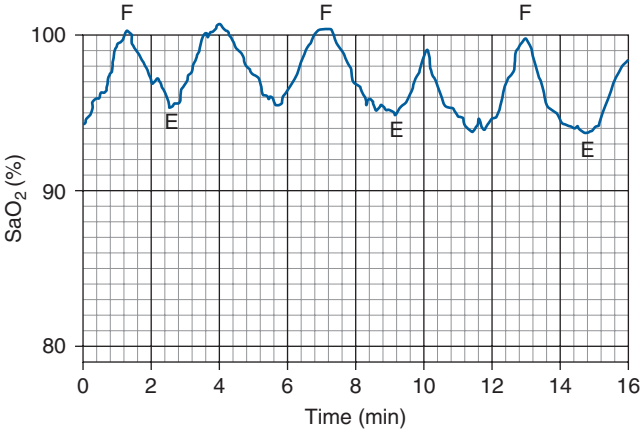

FIGURE 25-7 Variations in arterial oxygen saturation (SaO_2) during the influx (**F**) and efflux (**E**) phases of whole-lung lavage. (Modified, with permission, from Claypool et al.[115])

Leakage of fluid into the ventilated lung may be recognized by desaturation, crepitations, and rhonchi in the ventilated lung; fluid in the tubing to the ventilated lung; or air bubbles in the fluid from the lavaged lung.[11] If this occurs, lavage should be ceased, and the patient should be placed in the lateral decubitus position with the lavaged lung dependent and the head down to facilitate drainage from both lungs. Active suctioning of both lungs should be undertaken. If the leak is only minor and adequate oxygenation is restored, the correct DLT position may be reestablished, lung isolation rechecked, and the procedure continued. With a major leak and failure to restore adequate oxygenation once fluid removal is complete, double-lung ventilation with PEEP should be resumed and further lavage delayed until hypoxia has improved.

Hypoxemia during the procedure is common. Some patients with severe lung disease are too hypoxemic before the procedure to tolerate OLV. Several options exist for such patients. Extracorporeal membrane oxygenation (ECMO) may be instituted before lavaging the first lung.[11,119–123] ECMO may or may not be required for lavage of the second lung, depending on the effect of the first lung lavage on subsequent oxygenation. Cohen et al[121] reported successful lavage of both lungs with ECMO during a single session, avoiding the need for a second procedure. Because of the complexity and limited availability of ECMO, an alternative is to perform limited bronchoalveolar lavage using a fiberoptic bronchoscope,[124,125] with or without an inflatable cuff on the bronchoscope, under local anesthesia. This may be undertaken in a spontaneously breathing patient or during CMV through a single-lumen ETT. Limiting lavage to a lobe or several subsegments necessitates multiple procedures but minimizes hypoxemia. Nadeau et al[126] reported that the combination of inhaled nitric oxide and inflation of a balloon in the right pulmonary artery during right whole-lung lavage improved oxygenation sufficiently to avoid ECMO.

Randomized studies of whole-lung lavage for pulmonary alveolar proteinosis have not been undertaken. Seymour and Presneill[101] analyzed survival of 231 patients in multiple reports; 5-year actuarial survival from diagnosis was 94% ± 2% in patients who underwent whole-lung lavage ($n = 146$) compared with 85% ± 5% for patients who did not ($n = 85$). In fifty-five patients in whom duration of benefit was reported,[101] median duration of benefit from lavage was 15 months; fewer than 20% of patients followed beyond 3 years remained symptom-free. In a series of twenty-one patients followed prospectively after whole-lung lavage, Beccaria et al[127] found that more than 70% remained free from recurrent pulmonary alveolar proteinosis at 7 years. Although whole-lung lavage is labor-intensive, these data suggest that it is worthwhile.

MASSIVE HEMOPTYSIS

Massive hemoptysis carries a high mortality[128–130] and requires prompt intervention. Common causes include tuberculosis, bronchiectasis, lung abscess, mycetoma, pulmonary carcinoma, cystic fibrosis, arteriovenous malformations, and trauma.[104,128,131–133] The source of bleeding is the bronchial arterial system in 90% of patients.[134] Iatrogenic causes are uncommon but include pulmonary artery rupture by a pulmonary artery catheter[128,135,136] and transbronchial lung biopsy. Death results from acute asphyxia and is related to the rate and volume of blood loss and the underlying condition.[13,128,129,137,138] Factors increasing mortality include preexisting pulmonary insufficiency, obtundation from any cause, poor cough, and coagulopathy.[129,137,139,140]

Management consists of general measures, diagnosing the site of bleeding, isolating the bleeding lung, and controlling the bleeding. The patient should be given 100% O_2, placed in the head-down lateral-decubitus position, bleeding side down, clotting studies performed, blood typed, wide-bore intravenous access established, and cough suppressed with an opiate, and resuscitation and suction equipment should be in close proximity. Chest radiography and computed tomography scanning should be done when appropriate.

A number of alternatives exist for the localization, isolation, and control of the bleeding:

1. Fiberoptic bronchoscopy and placement of an endobronchial blocker (Fogarty catheter or Arndt endobronchial blocker) in the bleeding lung or segment should be done.[25,26,141–143] This can be performed in a patient who is not intubated but is easier in one who is. Fiberoptic bronchoscopy is limited by the narrow suction channel and rapid visual loss secondary to occlusion of the lens by blood.[140] Fiberoptic bronchoscopy, however, can allow accurate localization of bleeding,[104,128,140,144,145] catheter placement in a bronchial segment,[128,141,146] and lavage with iced isotonic saline or epinephrine.[128,146]
2. Rigid bronchoscopy has advantages over fiberoptic bronchoscopy when blood loss is massive because of better suction, visual access, and airway control.[137,139,140,144,147,148] It allows easier placement of endobronchial blockers and iced saline or epinephrine lavage. It also allows diathermy, laser therapy, and cryotherapy,[130] as well as placement of endobronchial tampons soaked in vasoconstrictor drugs.[137] As use of embolization increases, rigid bronchoscopy is required less, although it still has a place.[144,147]
3. Endotracheal intubation may be required where bleeding is sufficient to compromise oxygenation, particularly if mentation is depressed or cough is inadequate. If bleeding is so rapid that acute asphyxia arrest is imminent despite intubation,[128] the ETT can be advanced beyond the carina (usually into the right main bronchus) and OLV commenced.[128,149] If blood does not flow out of the ETT (implying blood loss from the contralateral side), the cuff is inflated and the ETT left in situ. If bleeding continues through the ETT, a Fogarty or Foley catheter is passed, the main bronchus is occluded, and the ETT is withdrawn to the trachea to ventilate the contralateral side.
4. Selective intubation is performed with a small (6 to 7 mm) ETT, with or without fiberoptic bronchoscope guidance, or a selective left or right endobronchial tube.[128,137] Selective intubation must be preceded by accurate bronchoscopic localization of bleeding because it excludes one lung from ventilation. Selective intubation has the

advantage of reliable protection of the nonbleeding lung[137,140] but the disadvantage of permitting OLV only and excluding the bleeding lung from endobronchial procedures and suctioning. Bleeding then must be controlled by tamponade, bronchial angiography, and embolization or surgery.

5. DLT insertion is an alternative that isolates the lungs but preserves access to both. In the past, DLTs were not recommended as an early alternative[128,137] to control bleeding. Problems included difficulties with insertion under adverse circumstances, requirement for an experienced operator, difficulties with suction and bronchoscopy access, and easy blockage of DLT lumen with clot. More recently, use of PVC DLTs has been successful.[13,131,150] DLT enables lateralizing of the bleeding, protects the nonbleeding lung, allows ILV, and allows therapeutic procedures to address the bleeding lung without compromise of the healthy lung.[13,150] A left DLT is the tube of choice.[13,131,137,150] Most commonly, a single ventilator with a Y connection to the DLT lumens is used[13] with distribution of ventilation according to the relative impedance of the two lungs (see "Lung Separation" above). If there is risk of blood overflowing to the nonbleeding lung, or if differential ventilation is required, a second ventilator with AILV should be used. OLV must be present during bronchial blockade or endobronchial intubation and may be required during iced saline lavage or massive blood loss.
6. Embolization. Because 90% of major hemoptyses arise from bronchial arteries,[134] once bleeding has been localized, bronchial artery embolization has a high success rate.[104,134,145,151–153] Once the bleeding lung or segment has been isolated, the bleeding must be controlled.
7. Emergency surgery. Urgent surgical resection is undertaken if bleeding overwhelms airway control or fails to respond to other measures. Resection is associated with a low mortality in many series.[104,129,140,144,152,154] It should not be unduly delayed if bleeding is not readily controlled.

The choice of these alternatives depends on the intubation status of the patient, the rate of bleeding, and whether the site of bleeding is known (Table 25-3). The choice is also affected by the availability of the technique and the skills of the personnel involved. In an unintubated patient who remains stable despite moderate hemoptysis, bleeding may settle with correction of clotting abnormalities and general measures (above) or angiographic embolization (Table 25-3). An obtunded patient with a decompensating respiratory or circulatory state requires intubation combined with a plan to confine the bleeding to one lung (Table 25-3). This can include a primary choice of specialized tubes, such as the Univent or a DLT. A patient who is already intubated will usually have control attempted primarily by a blocker or manipulation of the ETT in situ (Table 25-3).

In reported series of patients with major hemoptysis, localization of bleeding is usually achieved by history, fiberoptic bronchoscopy, or radiology (chest radiograph, computed tomography scan, or angiography). Bleeding is controlled by conservative measures, embolization, or surgery.[104,145,152] The relative requirement for these three treatments varies widely,[104,145,152] depending on cause, amount of bleeding, and local expertise. Supportive care, correction of coagulopathy, and time as the only measure ranged from 13% to 87% of patients with major hemoptysis. Embolization was used in 7% to 51% with success rates of more than 80%. Surgery was required in 6% to 50%.

LUNG PROTECTION FROM SECRETIONS

Spread of purulent secretions from a lung abscess, empyema, bronchiectasis, cavitating tuberculosis, or cavitating malignant disease to the dependent normal lung during chest

TABLE 25-3: FACTORS INFLUENCING CHOICE OF PROCEDURES IN PATIENTS WITH MODERATE TO MASSIVE HEMOPTYSIS

	Intubation	Severity	Side of Bleed	Management Options
A	Not required	Moderate		Conservative only Angiogram and embolization Elective intubation and blocker
B	Required	Moderate or massive Massive Massive	 Known Known left Unknown	ETT + blocker[a] ± bronchoscopic guidance Univent tube ± bronchoscopic guidance or DLT ETT advanced into R main bronchus DLT or ETT to right main ± blocker[a] and withdraw ETT[b]
C	Already present	Moderate Massive		Blocker[a] ± bronchoscopic guidance ETT to right main ± blocker and withdraw ETT[b]

[a]In an emergency, the blocker may be any suitable device with and inflatable balloon—Arndt, Cohen, Swan-Ganz catheter, balloon-tipped cardiac pacing wire, Fogarty catheter.

[b]If the site of bleeding is known, directed balloon placement can be done before bronchoscopy. If the site of bleeding is unknown, bronchoscopy may be required first to guide blocker placement.

surgery is associated with considerable risk.[1,2,5,6,155] A DLT not only allowed thoracic surgery but provided an important protective role for the dependent normal lung[1,66,155] and allowed perioperative ILV if required.[1,66,155]

Although these conditions have become less common, the requirement for ILV for lung protection, during or outside thoracic surgery, occurs occasionally.[156] Essential during thoracic surgery, it is problematic outside that setting because viscous or tenacious secretions drain poorly through the narrower lumen of a DLT. Appropriate antibiotic therapy, postural drainage, and a standard ETT may be preferable.

BRONCHIAL REPAIR PROTECTION

Mainstem bronchi and lower trachea (near the carina) can be ruptured by severe blunt chest trauma, resulting in tension pneumothoraces, massive air leak, and the need for urgent surgical repair. Selective airway intubation usually is required for the repair and ILV has been used postoperatively to protect the anastomoses.[157–160] Pizov et al[160] used one-lung high-frequency ventilation in the management of traumatic tear of the bronchus in a child. After a right mainstem bronchial rupture, Moerer et al[157] used a left DLT with bilevel ventilation to the left lung and CPAP alone to the right lung for 48 hours before switching to CMV. In three patients with lower tracheal rupture (near the carina), Wichert[158] reported that standard DLTs position the cuff too close to the site of carinal injury and used bronchoscopy-guided selective endobronchial intubation with two tubes to undertake the repairs. After repair, the tubes were reintroduced via tracheostomy, and ILV was performed for 9 to 14 days to allow recovery from respiratory and other complications.

Bronchopleural Fistula

BPFs can result from trauma, necrotizing pneumonia, lung abscess, tuberculosis, acute respiratory distress syndrome (ARDS), thoracic surgery, overinflation from mechanical ventilation, central venous catheter insertion, and intercostal catheters. Persisting BPF often leads to infection of the pleural space.[161] If massive air leak from a BPF occurs during mechanical ventilation, the consequences include respiratory insufficiency and sometimes tension pneumothorax. Persisting failure of lung expansion can occur despite intercostal catheters if the rate of air leak exceeds the rate of drainage through the catheters. BPFs are estimated to occur in 2% of ventilated patients.[162] Mortality depends on the size of the leak[162] and the cause and is reported to be 18% to 67%.[161,162]

Management includes antibiotics, pleural sclerosing agents, surgical control of air leaks at thoracotomy, intercostal catheter insertion, underwater seal drainage with suction, conventional ventilation strategies to reduce air leak, patient positioning,[161] positive pleural pressure during inspiration,[161,163] HFJV, a variety of bronchoscopic occlusion techniques, and ILV. ILV is usually employed when massive air leak persists despite conservative measures and results in respiratory insufficiency. Before instigating ILV, conservative measures should be optimized.

Inadequate drainage can occur despite actively bubbling intercostal catheters and can lead to failure of lung expansion and respiratory insufficiency. Intercostal catheters must be adequate in number and diameter; their patency must be visualized and demonstrated by active bubbling. Underwater-seal drainage systems and wall-suction units must have an adequate maximum flow capacity. Air-filter patency must be checked. High resistances and low maximum flow rates in either the drainage system or wall-suction unit actually can retard thoracic drainage and increase pneumothorax size. Ideally, maximum flow capacity should approximate or exceed the percentage of V_T lost to the BPF multiplied by the inspiratory flow rate. Drainage devices vary widely in maximum flow capacity but rarely exceed a capacity of 35 L/min. Increased bubbling or radiologic improvement after suction disconnection suggests retardation by the device. Persisting negative pressure on a wall-suction unit after disconnection suggests an occluded air filter. With massive air leaks, more than one underwater-seal drainage system may be required.

The conventional ventilator strategy for a BPF has three goals: reduce air-leak rate (to facilitate healing), reduce pneumothorax size, and maintain adequate gas exchange. These goals often have conflicting needs. The usual strategy is directed toward lowering alveolar and airway pressure to reduce air leak. V_T and PEEP should be minimized and the rate reduced, especially if dynamic hyperinflation is present, although these steps may impair gas exchange. Inspiratory flow is controversial. Increasing flow may decrease air leak by decreasing inspiratory time or increase proximal air leak by increasing peak airway pressure. The impact of any change on all three goals must be assessed.

HFJV without ILV appears to benefit patients with a proximal BPF and otherwise relatively normal lungs.[161,164] Reported success of HFJV in patients with parenchymal lung disease, whose BPFs usually are peripheral, is variable.[161] ILV has been used in many patients with a BPF.[35,47,56–58,60,62–64,66,88,162,164–174] Conditions in which ILV has been used for BPF include pneumonia with and without CAO,[174] ARDS,[168] trauma,[57,63,162,166,167] pulmonary contusion or large airway trauma,[62,133,164,166,171] emphysema, asthma,[165] staphylococcal pneumatoceles,[173] and thoracic surgery.[47,58,63,66,88] Most patients had air leaks exceeding 50% of V_T, lung collapse despite multiple intercostal catheter insertions, and hypercapnic acidosis and hypoxia despite attempts at optimizing mechanical ventilation.

The most common form of ILV for BPF is AILV using two ventilators[56–58,60,66] with low V_T, low rates, and low or no PEEP for the lung with the BPF. The BPF lung also has been ventilated with SILV with low V_T, PEEP, and inspiratory flow;[35,88,170–173] HFJV;[63,64] and high-frequency oscillation[168] or excluded from ventilation by a Fogarty catheter passed through a DLT after failing to respond to both CPAP and jet

ventilation.[174] Successful use of a DLT with a single ventilator and a variable-resistance valve in the inspiratory circuit to the BPF lung has been reported in an animal model[48] and in one patient[47] with a large BPF.

Almost all authors report reduction in air leak with improvement in gas exchange. ILV was continued from 2 hours[66] up to 10 days[58] in some patients before CMV could be resumed. Improvement was reported in most patients with ILV. Overall survival was approximately 50%, although a large BPF is as a poor prognostic factor.[161] Outcome mainly was related to the prognosis of the underlying condition.

Asymmetrical Lung Disease

ILV has been used for a variety of unilateral or asymmetric lung diseases (see Table 25-1). Three main indications are unilateral pulmonary parenchymal injury, unilateral atelectasis, and unilateral airflow obstruction.

UNILATERAL PARENCHYMAL INJURY

Patients who receive ILV for asymmetric pulmonary injury have poor compliance on the affected side, hypoxemia refractory to high O_2 concentrations and high levels of PEEP. Under these circumstances, PEEP may cause hyperinflation of the unaffected lung, collapse of the affected lung,[41,50] barotrauma,[41,50,175,176] and worsening of hypoxemia[41] consequent to increased pulmonary vascular resistance in the unaffected lung (diverting blood flow to the injured lung). This hyperinflation also can elevate intrathoracic pressure, reduce arterial pressure and cardiac output,[41,50,169,170] and, combined with arterial desaturation, reduce O_2 delivery.[51,71,169,170,177–181]

The prime objective of ILV under these circumstances is differential PEEP, although different ventilator patterns have been applied to achieve a similar effect and optimize gas exchange and minimize barotrauma. ILV allows lung recruitment maneuvers and high PEEP to the affected lung, permitting maximum benefit to that lung without adverse effects on the contralateral lung, intrathoracic pressure, cardiac output, and the distribution of ventilation between the two lungs. PEEP applied to the diseased lung can improve oxygenation by alveolar recruitment and diverting blood flow to the more normal lung. Low or no PEEP in the more normal lung avoids hyperinflation and the adverse effects of high intrathoracic pressure.

ILV has been used in various unilateral or asymmetric lung diseases (see Table 26-1). The most common indication has been *pulmonary contusion*. Of forty-five patients who received ILV for asymmetric lung injury,[9,41,50,63,73,133,166,175,176,182,183] three received SILV,[41,50] but most received AILV.[9,166,175,176,182,184] Two patients received no mechanical ventilation and breathed spontaneously through a DLT with different levels of CPAP applied to the expired limb of each circuit.[73] All methods improved gas exchange, and overall mortality was only 10%. In twelve trauma patients with unilateral contusion requiring ILV, Cinnella et al[182] monitored end-tidal CO_2 and static compliance in each lung and reverted to conventional ventilation when these became similar in the two lungs.

ILV has been reported in patients with *aspiration*[55,56,169,170] and *pneumonia* or *consolidation*.[9,32,35,43,53,59,68,169,170,184–186] As with contusion, a mixture of AILV and SILV has been used. In one patient, high-frequency oscillatory ventilation was used with a higher mean airway pressure to the affected lung.[68] SILV has been used in patients with unilateral consolidation on a background of congenital heart disease with asymmetric lung blood supply.[32,185] Mortality was 48%.

SILV has been reported in patients with asymmetric ARDS secondary to trauma and sepsis (56% mortality[34]), asymmetric acute pulmonary edema,[32,169,187] and massive pulmonary embolism.[188] In a patient with a single-lung transplant, it enabled weaning from ECMO.[187]

All patients received differential PEEP: 0 to 10 cm H_2O on the unaffected side and 7 to 25 cm H_2O on the affected side. In all cases, higher PEEP was used on the affected side. V_T values to the two lungs were equal in some studies, smaller to the affected lung in some, and larger in one study.[50] In two studies,[34,169] PEEP administered to each affected lung was carefully adjusted to the compliance response of that lung. Carlon et al[169] increased PEEP in the affected lung until its compliance was similar to that of the unaffected lung. Siegal et al[34] found that increasing PEEP in the affected lung initially improved compliance, but then it decreased secondary to overinflation. They set PEEP at the level that achieved maximum compliance. Both methods improved oxygenation, shunt fraction, and cardiac output. The duration of ILV ranged from 1 hour[50] to 12 days.[176]

From these reports, several factors emerge as requirements for ILV:

1. *Differential PEEP* with a higher level applied to the affected lung is a key factor. PEEP may be applied to the affected lung until gas exchange improves, to an inflection point[34] on a compliance curve, until lung compliance is equal on the two sides,[169] or based on CO_2 excretion. PEEP most commonly is 10 to 20 cm H_2O. A recruitment maneuver and PEEP level that maximizes arterial oxygenation can be recommended.[189] PEEP may or may not be required in the contralateral lung.
2. *Equal* V_T to both lungs was used most commonly and was most likely to maximize gas exchange[36,39,40] compared to smaller or larger V_T values to the affected lung. Maintenance of plateau pressure below 30 cm H_2O is an important goal.[190,191]
3. *AILV* or *SILV* is equally acceptable because there is no requirement for a different respiratory rate. AILV holds no disadvantages when compared with SILV[55,61] and is simpler and more flexible.

The primary goal of ILV and differential PEEP or CPAP is improvement in gas exchange and hemodynamics and physical expansion of collapsed lung regions.

UNILATERAL ATELECTASIS

Unilateral atelectasis that has failed to respond to either standard ventilator support, bronchoscopy, or both[7,50,51,55,59,65,67,150,169,170,192–194] is another indication for ILV. High PEEP, CPAP, HFJV, or high-frequency oscillation have been applied to the atelectatic lung for the purpose of reinflation without the risk of overinflating the contralateral lung and generalized elevation of intrathoracic pressure.

In some studies,[42,51,59,67,169,170] high PEEP was applied to the atelectatic lung during AILV or SILV with mechanical ventilation of both lungs. The collapsed lung received 10 to 30 cm H_2O of PEEP, whereas the unaffected side received 0 to 10 cm H_2O of PEEP. In other studies, the collapsed lung received transient CPAP alone[7,65,67,150,193] (20 to 80 cm H_2O) without mechanical ventilation, or 30 cm H_2O CPAP followed by HFJV with 25 cm H_2O PEEP,[65] or 80 cm H_2O CPAP followed by AILV,[67] or unilateral high-frequency oscillation with a mean airway pressures of 28 to 30 cm H_2O.[192,194] Millen et al[193] transiently applied 60 to 70 cm H_2O of CPAP to individual lungs in two nonintubated, spontaneously breathing patients via a cuffed fiberoptic bronchoscope with good results. There was no report of lung injury despite transient application of very high inflation pressures, and there were only two deaths in this group of eighteen patients with atelectasis.[7,42,51,55,59,65,67,150,169,192,194]

These reports demonstrate success with a range of recruitment maneuvers. Application of CPAP up to 50 to 60 cm H_2O to both lungs for a few minutes has no prolonged consequences of raised intrathoracic pressure and is recommended for lung collapse.[189] In unilateral atelectasis, recruitment maneuvers should be undertaken routinely during double-lung ventilation (unless contraindicated by a problem in the nonatelectatic lung) before attempting ILV and may prevent the need for ILV in many patients.

UNILATERAL AIRFLOW OBSTRUCTION

Unilateral airflow obstruction occurs most commonly following single lung transplantation (SLT) but may occur with a mechanical or chemical insult to one lung in a patient with asthma or partial occlusion of a major bronchus. Under these circumstances, standard ventilation can cause dynamic hyperinflation and high intrinsic PEEP in the obstructed lung. This can elevate intrathoracic pressure, reduce cardiac output, and compress the contralateral lung.

To achieve hypoventilation of the obstructed lung, SILV can be used with a much lower V_T to the obstructed lung. It is better achieved with AILV using reduced rate and V_T (or CPAP alone) to the obstructed lung.[54,67]

Single Lung Transplantation. Early reports suggested that SLT was contraindicated in chronic obstructive pulmonary disease because of the risk of dynamic hyperinflation in the native lung with mediastinal shift.[122,195] Initial experience supported these concerns.[196–199] Subsequent series[10,195,200–209] combined with 210 SLTs at our institution[10] result in a total of 733 patients. Overall early mortality is 18% and only 13% when the primary diagnosis is CAO (emphysema, α_1-antitryspin deficiency, lymphangioleiomyomatosis) (Table 25-4). Thirty-day mortality varies widely (0%[203] to 50%[200]). Small series reveal that early mortality[195,200,207,208] ranges from being slightly lower with SLT than with

bilateral lung transplant[195,207,208] to higher with SLT.[200] Larger series suggest lower mortality with bilateral lung transplantation,[210–213] although selection criteria such as age may have contributed.[210]

Although SLT is becoming less popular, it remains an alternative to bilateral lung transplantation, especially in patients older than 50 years of age with nonsuppurative lung disease. SLT is technically easier than bilateral lung transplantation and benefits more recipients when donor availability is a limiting factor. The most common indication for SLT is some form of CAO, which accounts for 77% of SLTs.[195,200–209] Although lung function is better after bilateral lung transplantation, SLT substantially improves quality of life[195,207] and achieves equivalent maximum work capacity and maximum O_2 consumption.[214]

More than thirty reports[10,27,54,67,187,195–209,215–226] plus experience from our institution provide information on 768 patients receiving SLTs, 601 for CAO. ILV was required almost exclusively in patients who received SLT for CAO.[10,27,54,200,202–204,208,209,215,217–219,221,223] There are few reports of patients requiring ILV after bilateral lung transplantation for any reason, nor after SLT for restrictive lung disease. In one patient,[223] ILV was required for a large, unresolving BPF arising in the native lung after SLT that eventually necessitated pneumonectomy of the native lung. In another patient,[187] ILV was required for reperfusion edema after SLT for primary pulmonary hypertension. Use of ILV in SLT series for CAO (see Table 25-4) varies widely: 0%[195,201,205–207] to 43%,[200] with an overall frequency of 9%.[10,195,200–209]

The phenomenon leading to use of ILV has been termed *acute native lung hyperinflation* (ANLH), which is defined as radiologic mediastinal shift with flattening of the ipsilateral hemidiaphragm (Fig. 25-8A) associated with signs of hemodynamic instability or respiratory dysfunction.[10,200,203,204] Evolution of this phenomenon can be divided into three stages:

1. *Asymptomatic ANLH*. Dynamic hyperinflation of the native lung with mediastinal shift is seen commonly in the postoperative period without transplanted lung collapse, hypoxia, or hypotension, and without the need for ILV.[10,195,225] This phenomenon arises because of asymmetry of lung disease following transplantation. The native lung with severe airflow obstruction undergoes dynamic hyperinflation during CMV, just as both lungs would do during CMV before transplantation.[227] A healthy transplanted lung with normal compliance and airflow resistance will receive most of the blood flow and ventilation, thereby reducing the degree of dynamic hyperinflation that would have occurred if both lungs received the same ventilation. Nevertheless, the transplanted lung does not have a "balancing" degree of dynamic hyperinflation, and mediastinal shift occurs commonly. The occurrence of asymptomatic ANLH is reported infrequently (Table 25-5). Weill et al[203] reported asymptomatic ANLH in sixteen of fifty-one patients (31%), although smaller series have reported symptomatic ANLH in 44%[204] and 64%[200] of SLTs for CAO. In our institution, mediastinal shift (shift of right-heart border relative to the spine by 1 cm or greater toward the transplanted lung) occurred in seventy-eight of ninety-five consecutively evaluated SLTs (82%) for CAO (Table 25-5).[10] The asymmetry usually improves or resolves over time, but it persists indefinitely in some patients. In some patients it can arise weeks or months after transplant.[200]

Abbreviations: ANLH, acute native lung hyperinflation; *NS*, nonsignificant; *SLT*, single lung transplantation.

2. *Transplanted lung dysfunction*. Any dysfunction in the transplanted lung, whether parenchymal (e.g., reperfusion edema, contusion, rejection, pneumonia, or collapse) or airway (e.g., anastomosis narrowing or sputum obstruction), impedes ventilation in the transplanted lung and redistributes ventilation to the native lung, especially during volume-controlled ventilation. This necessarily increases dynamic hyperinflation in the native lung and increases mediastinal shift and collapse and further impairs gas exchange in the transplanted lung. A vicious cycle results, redistributing more ventilation to the native lung with greater dynamic hyperinflation and mediastinal shift. Primary dysfunction of the transplanted lung,[219] severe postimplantation syndrome,[10,218] or ARDS have been identified as major contributors to native lung hyperinflation and mediastinal shift[10,27,208,209,218,219,221] usually resulting in hypotension, collapse of the transplanted lung with hypoxia, or both. Progressive compromise of the transplant lung can lead to refractory hypoxia and hypercapnia, whereas dynamic hyperinflation, mediastinal shift, and pulmonary vessel compression can lead to circulatory compromise with hypotension (see Fig. 25-8A). This has been termed *symptomatic ANLH*[203,204] (see Table 25-5). Almost all such problems have occurred only during mechanical ventilation, in the immediate or early postoperative period.
3. *Mechanical ventilation response*. The typical response to a lung collapse with worsening hypoxemia and hypercapnia includes increasing PEEP, increasing rate, and/or increasing V_T. Each response increases dynamic hyperinflation in the native lung,[227,228] which can worsen gas exchange, precipitate circulatory collapse, and necessitate ILV. Although the requirement for ILV usually is attributed to transplant dysfunction (see previous paragraph), the precipitant often is the failure to improve (or deterioration) with mechanical ventilation. In addition to transplanted lung injury (see previous paragraph), factors that increase the risk of this problem include the severity of airflow obstruction in the native lung, the size of the transplanted lung, and the side of the transplantation (see Table 25-5). Yonan et al[204] found that patients who developed ANLH had higher pulmonary artery pressures, higher residual volumes, and lower forced expiratory volumes in 1 second (FEV_1) than did patients who did not develop symptomatic ANLH. Weill et al[203] suspected more symptomatic ANLH in patients with bullous emphysema, but lung function and pulmonary artery pressure were equivalent among patients with and without symptomatic ANLH. We found that patients who required ILV had a greater degree of preoperative airflow limitation and preoperative hyperinflation, and lower postoperative Pa_{O_2}/FI_{O_2} ratios, more radiologic mediastinal shift, and more transplanted lung infiltrate on the postoperative chest radiograph.[10] Severity of airflow obstruction directly affects the degree of dynamic hyperinflation.[227,228] The size of the donor lung[195,209,218] is an important factor. A donor's predicted vital capacity that approximates[209] or is smaller than[218] the recipient's predicted vital capacity is associated with the need for ILV. A donor-to-recipient predicted vital capacity ratio of 1.4[209] or a donor-lung predicted vital capacity exceeding recipient-lung predicted vital capacity by 2 L[195] is associated with the absence of

mediastinal shift following SLT. Others have found no difference as a consequence donor size.[203]

Several reports have suggested a higher incidence of ANLH with left SLTs (see Table 25-5). Weill et al[203] found radiographic ANLH in 37% of left SLTs and 25% of right SLTs and no difference in symptomatic ANLH (see Table 25-4). Angles et al[200] did not report radiographic ANLH but found symptomatic ANLH in 83% of left SLTs and 50% of right SLTs. We[10] found no difference in mediastinal shift between left and right SLTs for CAO, but ILV was required twice as often with left SLTs (see Table 25-5).

Severe symptomatic ANLH commonly requires urgent intervention. Options include:

1. *Permissive hypercapnia*.[201] Permissive hypercapnia reduces dynamic hyperinflation in the native lung and may improve mild symptomatic ANLH but is unlikely to be adequate for severe ANLH. Although ILV was not used in this study, four patients required ECMO.
2. *ILV*.[27,54,198,200,202–204,208,209,215,217–219,221,223] Although technically complex, ILV commonly results in immediate resolution or improvement in gas exchange and circulatory problems and provides the most rapidly available and chosen solution (see Fig. 25-8).
3. *ECMO*.[201] ECMO is a complex and invasive solution, but provides an alternative to ILV.
4. *Contralateral lung-reduction surgery*.[202–204] This has been reported recently. It has been undertaken concurrently with SLT, during the postoperative period, and late after SLT. It may offer the best long-term solution to ANLH but is less readily applicable in urgent or life-threatening situations.
5. *Contralateral lung transplantation*.[202,204] After primary SLT, this offers a solution but depends on availability of a donor lung and subjects the recipient to two major surgical procedures and two sets of foreign antigens.
6. *Retransplantation of the SLT*.[204] This has been used for early graft dysfunction associated with ANLH.

The choice of DLT for ILV is different following SLT. A left DLT normally is easier to position correctly. With a left SLT, however, this can compromise the anastomosis and airway distal to the anastomosis, which has a tenuous blood supply in the immediate postoperative period. Thus, a DLT opposite to the side of the SLT normally is chosen in the early postoperative period. If ILV is required for more than 2 to 3 weeks after left SLT when the anastomosis is stable, a left DLT may be used, although a smaller size is chosen in case the anastomosis is narrower than the adjacent airway.

ILV after SLT usually consists of CMV to the transplanted lung and AILV,[208,209,218,219] SILV,[221] bronchial blockade,[27,209] CPAP,[223] or spontaneous ventilation[218] to the native lung. All methods are viable options. The ventilatory requirements of each lung differ so much, however, that AILV is the method of choice primarily because of different rate requirements of the two lungs (Table 25-6). AILV was the method of choice in forty-seven patients in four series.[10,200,202,204] The donor lung

TABLE 25-6: VENTILATOR SETTINGS FOR INDEPENDENT VENTILATION AFTER SINGLE LUNG TRANSPLANTATION FOR AIRFLOW OBSTRUCTION

	Native Lung	Transplanted Lung
Ventilator rate (breaths/min)	2 to 4	14 to 20
Tidal volume (mL/kg)	2 to 3	3 to 4
Plateau pressure (cm H_2O)	<25	<30

PEEP (cm H_2O)	0	10 to 17
Recruitment maneuver (cm H_2O)	No	±35 to 50[a]

[a]Stability of the anastomosis and the presence of air leak need to be considered before undertaking a recruitment maneuver. Lower-than-normal recruitment pressures may be initially chosen.

commonly requires PEEP at a sufficient level to expand collapsed regions and improve oxygenation, a V_T sufficiently low to avoid pressure injury to the lung, and a rate high enough for adequate CO_2 elimination without causing flow limitation. A recruitment maneuver may maximize the benefit from PEEP, provided that it is safe to undertake.[189,229,230] The native lung should be ventilated with a pattern that maximizes its contribution to gas exchange without excessive dynamic hyperinflation. This necessitates low V_T, high inspiratory flow rate, and a very low rate (Table 25-6).[228] The goals of native-lung ventilation are to maintain a low plateau pressure, restore the mediastinum to the midline (see Fig. 25-8B), and allow restoration of circulatory instability (that caused by dynamic hyperinflation). If this is not achieved, rate should be reduced further (even to 0). The goals of SLT ventilation are a safe plateau pressure (Table 25-7) and restoration of adequate SaO_2 and Pa_{CO_2}. If this is not achieved, further recruitment maneuvers and higher PEEP should be explored. The introduction and stabilization of these different ventilator

TABLE 25-7: COMPLICATIONS ASSOCIATED WITH DOUBLE-LUMEN TUBES AND INDEPENDENT VENTILATION

- Trauma to larynx, trachea, and major bronchi during insertion
- DLT malposition resulting in bronchial occlusion, poor oxygenation, ventilation, and secretion clearance
- Incomplete lung isolation resulting in unwanted lavage fluid, blood, or pus in the protected lung
- Retention of secretions as a result of long narrow airways and difficulty with suction
- Tube dislodgement following routine patient position changes
- Complications from prolonged immobility associated with the need for sedation and controlled ventilation
- Airway injury because of prolonged requirement for high cuff pressures to maintain
- Laryngeal injury from the prolonged presence of large diameter tube

strategies to each lung generally necessitate sedation and paralysis during the early stages of ILV. If SaO_2 or circulation is not satisfactory, ECMO may be needed.

Withdrawal of ILV can be initiated when function of the transplanted lung improves and its ventilatory requirements decrease. This can be assessed with a DLT in situ by ventilating both lungs with a single ventilator and a bifurcated ventilator circuit (see Fig. 25-3). Because spontaneous ventilation is difficult with a DLT, patients usually require reintubation with a single-lumen ETT for weaning before extubation. Others experience recurrent dynamic hyperinflation with double-lung ventilation and must wean with the DLT in situ. ILV has been required for as little as 1 day.[209] In most instances, prolonged ILV has been required; periods exceeding 1 month[218,219,221,223] have been reported with eventual resolution and good functional outcome. Patients who require prolonged ILV should undergo a tracheostomy and receive a double-lumen tracheostomy tube(Fig. 25-9).[218,221,231]

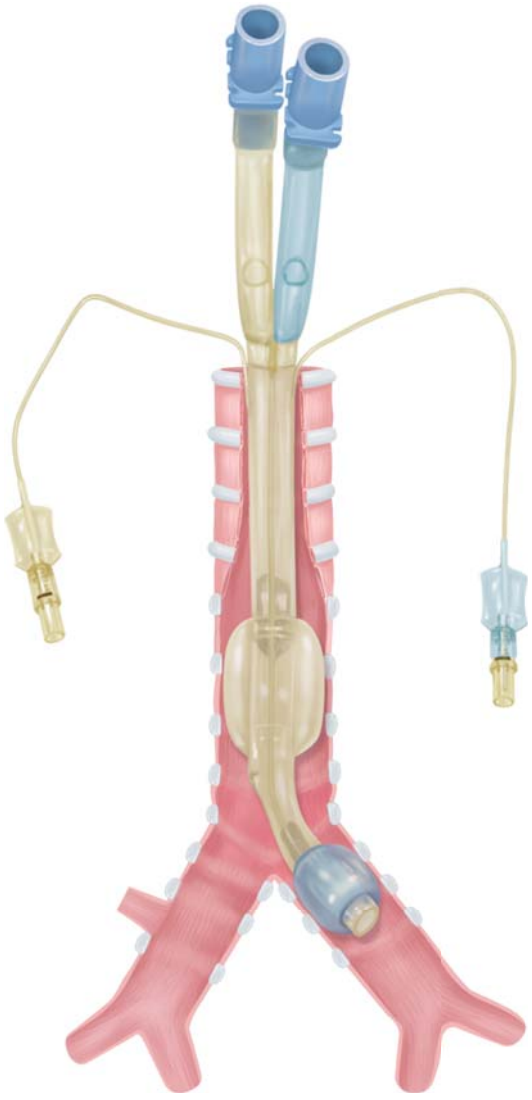

FIGURE 25-9 A double-lumen tracheostomy tube.

Outcome of Acute Native Lung Hyperinflation. Several investigators[10,200,203,204,218,221,231] have reported that patients with symptomatic ANLH have a longer duration of mechanical ventilation, a longer intensive care unit stay and higher mortality: 7% mortality in 213 SLT patients without symptomatic ANLH, and 37% mortality in fifty SLT patients with symptomatic ANLH ($P < 0.05$). Yonan et al[204] reported lower FEV1 values and higher residual volumes after transplantation in ANLH patients, whereas Weill et al,[203] in a larger series, found no differences in long-term lung function.

Outcome of Independent Lung Ventilation. Fifteen papers[10,27,54,198,200,202–204,208,209,215,217–219,221,223] report sixty-three patients with ILV following an SLT for CAO. Overall mortality was 30%. Including only recent case series in which all SLT patients and ILV survival were reported,[10,202–204] ILV patients had higher mortality (fifteen of forty-two patients, or 36% mortality) than non-ILV patients (forty-five of 338 patients, or 13% mortality). This difference is not surprising because ILV patients are sicker and show a higher incidence of graft dysfunction.

In summary, SLT for airflow obstruction poses a risk of ANLH with mediastinal shift. When this is sufficient to compromise gas exchange and/or circulation, ILV is the initial method of choice and may reduce the need for ECMO.

Unilateral Bronchospasm. In patients with asthma, airways respond locally to local stimuli; irritants applied to one lung may create a different degree of bronchospasm in the two lungs.[232] During mechanical ventilation, this can lead to different levels of dynamic hyperinflation and mediastinal shift, and during thoracic surgery, this can lead to difficulty with thoracotomy closure and the need for ILV. Narr et al[67] reported unilateral bronchospasm during unilateral pleurodesis. The pleurodesed lung initially collapsed; following DLT insertion and ILV with 80 cm H_2O of CPAP applied to the collapsed lung, that lung inflated and would not deflate. Low-level CPAP to the affected lung, CMV to the unaffected lung, and aggressive bronchodilator therapy allowed deflation of the affected lung, maintenance of gas exchange, and thoracotomy closure.[67]

Patient Selection for Independent Lung Ventilation in Unilateral Lung Disease. Asymmetric lung disease usually is easy to recognize, but criteria for ILV are not so clear. Not all patients with asymmetric lung disease require ILV. Commonly used criteria are unilateral or clearly asymmetric lung disease, which is evident on chest radiography or known from the patient's condition (e.g., SLT), plus one of the following:

1. Severe hypoxemia despite 100% O_2 and different levels of PEEP.
2. Circulatory failure/hypotension secondary to dynamic hyperinflation.

Factors that suggest that a patient is likely to benefit from ILV include

1. Worsening hypoxemia and/or circulatory status by increasing PEEP, rate, or V_T.
2. Improvement in gas exchange but marked deterioration in circulatory status with increasing PEEP and the opposite when PEEP is reduced.

Bilateral Symmetrical Lung Disease

Acute bilateral lung injury may appear diffuse, uniform, and symmetric on chest radiography but contain significant in homogeneity on computed tomography scan.[233,234] Many of these changes result from a uniformly injured lung collapsing in dependent zones as a result of increased lung weight. Because patients commonly are nursed on their back, collapse occurs in posterior zones and is not apparent on anteroposterior chest radiographs. In this case, no PEEP is required to open alveoli in the least dependent regions, and high PEEP may be required in the most dependent regions. Generalized PEEP may fail to inflate the most dependent regions and may overinflate nondependent regions. There is now increasing evidence that the injury can result from prolonged collapse[235] and repetitive collapse/reexpansion and overexpansion,[236,237] and that lung injury may contribute to multiorgan failure and death.[190,238] Considerable effort has been devoted to ventilator strategies that reduce prolonged collapse, collapse/reexpansion, and overexpansion,[190,191,239] and more recently to reduce prolonged collapse by higher PEEP with or without lung recruitment.[240–243] Although some strategies have been successful, all have the same problem of conflicting pressure requirements within different regions of the same lung.

The application of ILV under these circumstances is based on two principles:

1. Differences in compliance, ventilation–perfusion ratios, and gas exchange between the two lungs may be present and not be suspected from plain X-rays.[34,39,40,169]
2. Placing the patient in the lateral decubitus position will redistribute much of the collapsed (high-PEEP-requiring) lung regions to the dependent lung and the open (low-PEEP-requiring) regions to the nondependent lung.[39,40,244,245]

When a patient with normal lungs is ventilated in the lateral decubitus position, up to two-thirds of perfusion goes to the dependent lung, and up to two-thirds of ventilation goes to the nondependent lung,[36,75] creating significant ventilation–perfusion mismatch and shunt. Application of global PEEP improves distribution of ventilation,[246] but perfusion inequality may be increased and cardiac output reduced[36] with little net benefit.

In acute bilateral lung disease, the changes in ventilation and perfusion and the resulting mismatch in the lateral decubitus position are similar to those seen in patients with normal lungs[37,38] but with redistribution of lung collapse from posterior lung zones to the dependent lung. ILV with equal V_T to each lung and selective PEEP to the dependent lung proved additive in improving shunt fraction, arterial oxygenation, cardiac output, and O_2 delivery compared with CMV in both the supine and lateral positions.[37,38] These maneuvers have been applied on a long-term basis in bilateral lung injury with some early success.[245] Wickerts et al[244] and Diaz-Reganon Valverde et al[33] prospectively studied eleven and forty-five patients, respectively, with severe bilateral ARDS who received ILV. These patients were assessed in the supine position on global PEEP and then reintubated with a DLT and placed in the lateral decubitus position. PEEP was applied to the dependent lung and no PEEP to the nondependent lung. Both groups reported improved oxygenation, and Diaz-Reganon Valverde et al[33] reported a good response in 83% of patients.

ILV is difficult and labor-intensive to apply.[244] Accordingly, it has not gained widespread acceptance for symmetric bilateral lung injury.

COMPLICATIONS WITH INDEPENDENT LUNG VENTILATION

Many of the problems with ILV are related to the DLT. The technique of DLT placement and verifying its correct position is complex, time-consuming, and requires experienced personnel.[15,19,21,23] These considerations can limit the use of DLTs and ILV when required urgently or under adverse circumstances, such as massive hemoptysis.[137,140]

Trauma of the larynx and upper airways was a common problem with red-rubber tubes[19,106] but is uncommon with PVC tubes.[15,247,248] Rare complications have included cardiovascular collapse after a DLT displaced a mediastinal tumor into the mediastinal vessels[249] and exsanguination following inclusion of the DLT in sutures during pneumonectomy with subsequent vessel laceration when the DLT was removed.[250,251]

Placement of right DLTs is critical with respect to right upper-lobe ventilation. Benumof et al[252] estimated a right upper-lobe occlusion rate of 11% with PVC tubes. McKenna et al[18] assessed occlusion of the right upper lobe by bronchoscopy: occlusion was 89% with Mallinckrodt PVC DLTs and only 10% with right Robertshaw red-rubber DLTs. High malposition rates are reported after primary insertion.[22,253] This has become an uncommon problem now that most DLT insertions are assessed routinely by bronchoscopy. Left upper-lobe occlusion also has been reported[254,255] with left PVC DLTs from overinsertion, wedging the tip of the DLT in the left lower-lobe bronchus. Saito et al[256] found 27 ± 6 mm movement of the tip of a left DLT, proximally with neck extension and distally with flexion, with a total potential range of movement of up to 4.5 to 7 cm. This range of movement is sufficient to either occlude the left upper-lobe bronchus or lose lung isolation. Similar problems are more likely with a right DLT, with which tube position is more critical.

High cuff pressures are a significant problem with DLTs. In routinely placed tubes with cuffs inflated to avoid air leak, bronchial cuff pressures were 56 ± 21 mm Hg in left PVC DLTs and 130 ± 41 mm Hg in Carlens tubes.[14,257] This study suggests a considerably lower risk to the airway from PVC tubes, although the pressures required to prevent leaks still were well above safe limits.

Bronchial rupture was reported regularly[248,258–263] and there is one report of bronchial stenosis[183] with red-rubber tubes. Bronchial rupture is uncommon with PVC DLTs, although they are not free of this complication.[248,250,264]

Although lumen diameter has improved considerably with PVC tubes, difficult suction access, retained secretions,[41,43,60,88] and lumen blockage remain a problem and can lead to difficult ventilation, the need for regular bronchoscopic toilet, and the need to change the DLT.[13]

When ILV is continued for some time, several difficulties related to patient care arise. Head movement, patient movement, and routine patient turning all threaten DLT position and can lead to loss of lung isolation and lobe occlusion.[43,60,88,256] Frequent bronchoscopy may be required to maintain DLT position.[43,248] Running two ventilators requires additional space, O_2, air, and suction outlets, and standard patient charts usually are inadequate.[60] There are significant increases in nursing time requirement and workload,[60,265,266] and the patient may find the DLT more uncomfortable and restrictive than normal intubation.[88]

CONCLUSION

ILV has been used in a wide range of conditions (see Table 25-2). Although ILV is infrequently required, it has an established and sometimes lifesaving role for many of conditions and users of mechanical ventilation should be familiar with the complexities of ILV so that it can be instigated promptly and appropriately when the need arises. A ILV can be undertaken with any ventilator and can be used for all indications.

MECHANICAL VENTILATION DURING RESUSCITATION

Holger Herff
Volker Wenzel

Before the arrival of an emergency medical service unit, ventilation given by bystanders must employ techniques that do not require special equipment. Safar, Elam, and Ruben first showed that obstruction of the upper airway by the tongue and soft palate occurs commonly in victims who lose consciousness or muscle tone and that ventilation with manual techniques is markedly reduced or prevented by such obstruction.[1–3] Subsequently, Safar et al[4,5] developed techniques that prevent obstruction by extending the neck and jaw and applied these in conjunction with mouth-to-mouth ventilation. The "gold standard" today for airway maintenance during resuscitation is intubation of the trachea, which provides a route for ventilation with oxygen, allows suctioning of the upper airway, protects the airway from aspiration of gastric contents, and prevents inflation of the stomach.

SPECTRUM OF EMERGENCY CARE SKILLS

Airway management should be mastered by all properly trained prehospital personnel. This involves both airway assessment and airway control. Compromise of the airway may occur suddenly or slowly and progress over time; therefore, continuous assessment of the airway is vitally important. Pulse oximetry is helpful in identifying hypoxia, although hypoxia may be a relatively late sign of airway compromise. It is therefore important to evaluate breathing pattern, level of consciousness, and shortness of breath continuously.

When endotracheal intubation of children was added to paramedic practice, fifteen of 177 (approximately 8%) children were either intubated esophageally or dislodgment of the endotracheal tube were unrecognized; fourteen of these fifteen children subsequently died.[6] Accordingly, invasive pediatric airway equipment was removed from emergency medical service units in Los Angeles County; instead, bag-valve-mask ventilation was recommended. A similarly alarming experience was seen in Orlando, Florida, when the esophagus was intubated in eighteen of 108 (approximately 16%) patients being managed by the emergency medical services.[7] This suggests that the skills and experience of a rescuer performing basic and advanced airway management may determine if these maneuvers achieve effective oxygenation and carbon dioxide elimination or result in extremely serious complications, such as severe neurologic impairment, or even death.[8]

Endotracheal intubation is the "gold standard" for providing emergency ventilation. Thus, every advanced emergency medical service provider must acquire and, especially, maintain intubation skills. Such a goal may be difficult to guarantee because of the large numbers of individuals who require training and/or the infrequent

performance of intubations. This experience is similar to observations of the emergency medical services in Houston, Texas, where airway device-related complications were associated more with training with the devices than with the devices themselves.[9] This confirms that the success rate of airway management interventions depends on three factors: (a) initial training, (b) continuous quality assurance, and (c) actual frequency of performing the specific intervention. For example, when the actual frequency of performing endotracheal intubation is relatively low, as in the case of the Los Angeles County emergency medical services (e.g., 2584 trained individuals performing 420 actual endotracheal intubations over 33 months), it is not surprising that endotracheal intubation performed by paramedics (who were allowed to perform bag-valve-mask ventilation) did not improve survival or neurologic outcome; instead, it caused some catastrophes.[6] In a recent study in Germany, however, trained emergency medical service physicians intubated the esophagus in approximately 7% of all out-of-hospital intubation scenarios.[10] These high incidences of intubation disasters even by highly trained rescuers actually may tip the scales toward supraglottic airway devices or bag-valve-mask ventilation for emergency ventilation of patients with a respiratory or even cardiac arrest performed by emergency medical services personnel without excellent intubation skills. Thus, teaching emergency medical services personnel a limited number or even a single airway procedure may follow the axiom "the simpler, the better" and ensure adequate oxygenation and avoid airway-related catastrophes.

DISTINCTION BETWEEN AIRWAY PROTECTION AND ASSISTED VENTILATION

Discussion of whether health care professionals or lay bystanders should or should not perform mouth-to-mouth ventilation has emotional connotations. The question of whether satisfactory lung ventilation in an unintubated cardiac arrest patient can be achieved, however, is clearly a scientific issue. If it is possible to identify ventilation strategies that are beneficial to patients and not harmful, then resuscitation outcomes may be improved.

The distribution of ventilation volume between lungs and stomach in a patient with an unprotected airway depends on factors such as lower esophageal sphincter pressure, airway resistance, and respiratory system compliance.[11] Of equal importance are specifics of techniques used for basic or advanced airway support, such as head position, tidal volume, inflation flow rate, and duration, all of which determine upper airway pressure.[12,13] The combination of these variables determines gas distribution between the lungs and the esophagus and, subsequently, the stomach. Several fundamental differences exist between respiratory mechanics in a healthy, awake adult, an anesthetized supine patient, and a victim of a cardiac arrest (Table 26-1).

Lower esophageal sphincter pressure is the pressure that prevents regurgitation of stomach contents into the pharynx and insufflation of air into the gastrointestinal tract during ventilation. Sphincter pressure in a healthy adult is approximately 20 to 25 cm H_2O but may be lower in patients with chronic esophageal reflux disease, during induction of anesthesia, and after insertion of a laryngeal mask airway.[14] It is unclear, however, whether these changes in sphincter pressure result from induction of anesthesia. Animal investigations showed that the lower esophageal sphincter pressure deteriorated rapidly from a baseline level of 20 to 5 cm H_2O within 5 minutes of untreated cardiac arrest.[15,16] This decrease in lower esophageal sphincter pressure was also measured in human subjects following cardiac arrest.[17] In a healthy adult, air flows freely from the lips to the alveoli, and therefore, minimal inspiratory pressure is required to move gas during spontaneous ventilation. In a patient with chronic obstructive lung disease, airflow through the respiratory system may be impaired by mucus or airway spasm.[18] Data from clinical studies showed an airway resistance of 2 to 4 cm H_2O/L/s in healthy volunteers, 8 to 15 cm H_2O/L/s in patients with varying degrees of lung disease, and 17 cm H_2O/L/s with positive-pressure bag-valve-mask ventilation in a patient during induction of anesthesia.[19] In a healthy awake adult, 1 cm H_2O of inspiratory pressure moves approximately 100 mL of air into the lungs; compliance decreases to 50 mL in an anesthetized supine adult and may decrease to approximately 20 to 50 mL in a cardiac arrest patient.[20] Many factors can change lung compliance. Pulmonary vascular

TABLE 26-1: RESCUER AND PATIENT VARIABLES AFFECTING RESPIRATORY MECHANICS DURING MOUTH-TO-MOUTH VENTILATION AND BAG-VALVE-MASK VENTILATION

Rescuer	Patient	Conscious	Anesthetized	Cardiac Arrest
Chin support	LESP (cm H_2O)	~20 to 25	~20	5?
Tidal volume	Crs (mL/cm H_2O)	~100 to 150	~50	~20 to 50
Inflation time	Raw (cm H_2O/L/s)	~2 to 4	~15	?
Ventilator setting				
Bag-valve-mask size				

Abbreviations: Crs, compliance of the respiratory system; *LESP*, lower esophageal sphincter pressure; *Raw*, airway resistance.

congestion during cardiac arrest increases the volume of the parenchymal interstitium and reduces compliance. Chest compressions and pulmonary edema secondary to left-ventricular failure also contribute to a reduction in compliance.[21]

Chin support and backward tilt of the head are the two most important maneuvers during rescue ventilation of paralyzed and nonparalyzed patients with an unprotected airway. Moreover, a slight lateral tilt of the head may reduce upper airway obstruction arising from backward relaxation of the tongue and soft tissues.[22] The settings of an automatic ventilator or the technique of bag-valve-mask ventilation governs inflation flow rate, inflation time, and tidal volume, all of which affect peak inflation pressure, assuming that there is no significant upper airway obstruction.[23] The relationship between peak inflation pressure and lower esophageal sphincter pressure determines gas distribution between the stomach and lungs.[24] For example, when peak inflation pressure exceeds sphincter pressure, some air will flow into the stomach; if sphincter pressure is higher than peak inflation pressure, inspiratory air will flow completely into the lungs. The preceding scenario, however, depends on the assumption that the lower esophageal sphincter pressure acts like a mechanical valve, which may not be the case. For example, Safar[25] stated that stomach inflation in healthy volunteers was self-limiting, but lower esophageal sphincter pressure was not reported. This observation implies that the physiology of respiratory mechanics in human subjects may be more complex than has been considered previously. Until a better understanding of these mechanisms is obtained, the goal of ventilation with an unprotected airway is to keep it permanently patent and to keep peak inflation pressure to a minimum at all times to prevent stomach inflation.

Stomach inflation is a complex problem that may cause regurgitation,[26] aspiration,[27] pneumonia,[28] and possibly death.[29] Stomach inflation will increase intragastric pressure,[30] elevate the diaphragm, restrict lung movements, and so reduce respiratory system compliance.[31] A reduced respiratory compliance may direct even more ventilation volume into the stomach when the airway is unprotected,[10] thereby inducing a *vicious cycle with each breath*.[32] The life-threatening complication of stomach inflation, regurgitation, and subsequent aspiration pneumonia (induced by gastric acid) causes a loss of alveolocapillary integrity and pulmonary surfactant. As a result, fluid and proteins pass into the interstitial spaces, alveoli, and bronchi, causing pulmonary edema, decreased pulmonary compliance, increased lung weight, and significant intrapulmonary shunting or ventilation–perfusion mismatching. Consequently, alveolar gas exchange is impaired markedly. Data from an animal model showed that aspiration of more than 0.8 mL/kg of body weight resulted in 50% mortality. Extrapolation of these results to humans suggest a critical aspiration volume of 50 mL at a pH of 1.[33] The results from recent studies of anesthetic practice, however, suggest that the true morbidity from acid aspiration has been exaggerated greatly.[34]

Cricoid Pressure and the Sellick Maneuver

A maneuver for preventing stomach inflation during ventilation with an unprotected airway is to apply cricoid pressure; this is a simple, effective maneuver to prevent stomach inflation[35] that was first described 200 years ago.[36] In a model of human cadavers, an intraesophageal pressure of 75 cm H_2O was required to overcome cricoid pressure, indicating that the Sellick maneuver may be able to prevent gastric distension even when ventilating with a high peak inflation pressure.[37] One study investigating the efficacy and minimum inflation pressure at which gas entered the stomach in pediatric patients found that appropriately applied cricoid pressure was invariably effective in preventing gas insufflation into the stomach in all children with and without paralysis.[38] The value of cricoid pressure, however, has been established based on case report series and cadaver and animal studies, and has never been validated in a large, controlled prospective study. Because of the lack of prospective studies, some authors regard the level of evidence for cricoid pressure as V (expert opinion) and the level of recommendation as D (levels being A to D, with A being the highest recommendation level).[39] The value of cricoid pressure has been further questioned because of the risk of esophageal rupture when vomiting occurs.[40] A further technical limitation is that applying both cricoid pressure and bag-mask ventilation by a single rescuer is nearly impossible and requires a second person to assist.

Moreover, a possible complication of cricoid pressure is airway obstruction.[40,41] In fifty-two anesthetized patients, airway obstruction did not occur without cricoid pressure, occurred in one patient (2%) with cricoid pressure of 30 N (3 kg or approximately 6.6 lb), in twenty-nine patients (56%) with cricoid pressure of 30 N (3 kg or approximately 6.6 lb) applied in an upward and backward direction, and in eighteen (35%) patients with cricoid pressure of 44 N (4.4 kg or approximately 9.7 lb).[40] These findings were validated in a recent study in children.[42] Furthermore, cricoid pressure deforms the larynx and impedes laryngoscopic visibility for intubation and thus may result in more intubation difficulties.[43] Finally, modern magnetic resonance imaging has questioned whether cricoid pressure truly closes the hypopharyngeal space or upper esophagus secondary to lateral displacement of the esophagus.[44] Thus, in regard of all these limitations it is not surprising that the European Resuscitation Council's 2010 cardiopulmonary resuscitation (CPR) guidelines stated: "The routine use of cricoid pressure in cardiac arrest is not recommended. If cricoid pressure is used during cardiac arrest, the pressure should be adjusted, relaxed or released if it impedes ventilation or intubation."[45]

ROLE IN DIFFERENT SETTINGS

Prehospital Care

Securing the airway by tracheal intubation in the prehospital setting may be very difficult. If airway management is difficult in a prehospital patient, maintenance of oxygenation

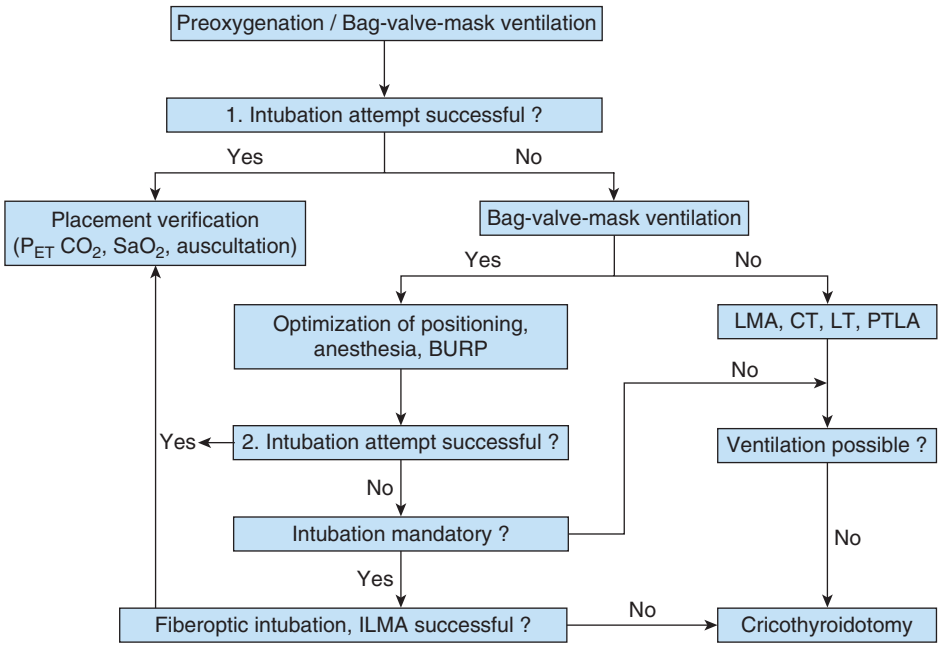

FIGURE 26-1 Algorithm for airway management. *BURP*, backward, upward, rightward pressure maneuver; *CT*, Combitube; *ILMA*, intubating laryngeal mask airway; *LMA*, laryngeal mask airway; *LT*, laryngeal tube; *PTLA*, pharyngotracheal lumen airway; $P_{ET}CO_2$, end-tidal carbon dioxide; SaO_2, arterial oxygen saturation.

can be in doubt despite use of a bag-valve-mask. Definite securing of the airway can be done later in the emergency department with more experienced personnel and equipment. In acute life-threatening situations, however, a standardized procedure, such as an algorithm, may be fast and reliable (Fig. 26-1).

Cardiopulmonary Resuscitation

Outcome after CPR in adults with chest compression alone was similar to that after chest compressions combined with mouth-to-mouth ventilation; Hallstrom et al. concluded that chest compressions alone may be the preferred approach for bystanders inexperienced in CPR.[46] It has been suggested that more lives could be saved if only rapid chest compressions are performed (producing immediate reperfusion of vital organs but with decreased oxygen content) in contrast to the "gold" solution of rapid chest compressions combined with ventilation, which may produce less perfusion but with higher oxygen content.

In a more recent prospective study in Japan, chest-compression-only CPR resulted in increased survival rates in adults.[47] Results, however, have been inconsistent in follow-up studies.[48,49] In a 2011 study, there seemed to be a time-dependent factor with regards to survival rates: The longer CPR was performed by lay rescuers, the more dependent ventilation became. This is rational from a physiologic viewpoint; at the beginning of a cardiac arrest caused by cardiac disease, there is still enough air in the lungs to enable sufficient oxygen uptake as long as chest compressions are able to deliver any circulatory output. Moreover, directly after cardiac arrest gasping may additionally ventilate the patient's lungs if the airway is in a patent state.[50] This reasoning is in accordance with a study in children where compression-only CPR seemed to be less effective. Because pediatric cardiac arrest contrasts with adult cardiac arrest, being more often caused by hypoxemia than cardiac disease, superiority of ventilation CPR is not surprising in pediatric patients.[51] In a metaanalysis, authors detected a potential benefit for compression-only CPR, with a "number needed to treat" of forty-one, based on prospective studies; in contrast, analysis of retrospective studies did not reveal any benefit for chest-compression-only CPR.[52] The 2010 CPR guidelines recommend that trained lay rescuers provide ventilation; untrained or unwilling rescuers should provide chest-compression-only CPR.[53] Chest compressions and ventilation are performed in a 30:2 ratio (thirty compressions to two ventilations) in a cardiac arrest when the airway is not secured.[53] After intubation, ventilation is performed out of synchrony with chest compressions; a respiratory rate of 10 breaths/min is recommended.

One argument that ventilation during CPR could be abandoned is that gasping provides sufficient gas exchange. The value of gasping in human subjects has to be interpreted with caution because fundamental differences in human and animal upper airway anatomy make it difficult to extrapolate results from laboratory studies, where gasping was beneficial. The human upper airway is kinked and is subject to rapid occlusion by the tongue and/or head position in the supine position, whereas the upper airway in swine, dogs, and rats is straight and may not be occluded by the

tongue or head position in the supine position.[54] In addition, animal studies were performed in fasting animals that, as a consequence of fasting, are extremely unlikely to aspirate gastric contents. Furthermore, it is unknown if humans gasp as frequently or as deeply as animals during cardiac arrest. Whether gasping in humans results in effective gas exchange has not been studied, and for ethical reasons, such a study would be extremely difficult to perform. If a patient is gasping and the rescuer is unwilling or unable to perform mouth-to-mouth ventilation during basic life-support CPR, one strategy is to keep the airway open and perform chest compressions alone until emergency medical services arrive so as to provide a minimum of ventilation.[53] In the absence of a dedicated airway, extending the head by placing a pillow under the shoulder or gently tilting it laterally could reduce the acute pharyngeal obstruction from the tongue falling backward over the palate.

Ventilation consumes time during CPR that could be devoted to chest compressions.[53] Because only rapid chest compressions are effective, some argue that time spent for ventilation should be decreased and the time for chest compressions increased. Because cardiac output during CPR is at best approximately 25% of normal, some argue that the low cardiac output does not need to be accompanied with a normal minute ventilation. This argument has yet to be proven in a clinical study. Until evidence is available, assisted ventilation should be performed during CPR whenever possible, although the rate of chest compressions should not be decreased critically by ventilation attempts.

Another method, first being described in the late 1990s, is to decrease intrapulmonary pressure by intermittent airway occlusion during the chest-decompression phase. Therefore, a special impedance-threshold valve was designed that is adjusted to a tracheal tube and occludes the airway in the decompression phase.[55] This occlusion results in decreased intrapulmonary pressure that enhances venous return to the heart and subsequently increases cardiac output with the next chest compression, improving oxygen transport to vital organs in cardiac arrest. The impedance-threshold valve is especially effective when intrapulmonary pressure is further reduced by active chest decompression using special suction cups attached to the sternum.[55] In a clinical study, use of such an impedance-threshold device significantly increased the proportion of patients that "survived to hospital discharge with favorable neurological function" (from 6% to 9%).[56] It should be noted, however, that active ventilation is mandatory using the impedance-threshold device, because continuous airway occlusion may otherwise result in atelectasis compromising pulmonary function.[57]

Trauma

The underlying principle for care of trauma patients is the ABCs (*a*irway, *b*reathing, *c*irculation) of resuscitation. Initial priorities after trauma are the same for the field and the hospital, but field providers usually have only limited equipment and limited assistance. They also provide care in the least-controlled circumstances, such as the roadside. Airway management is the highest priority and should occur as early as possible; in severe cases, it may be necessary in the field. Physical examination may reveal subcutaneous emphysema, absent breath sounds, and unilateral hyperresonance, identifying a tension pneumothorax, which can be decompressed. Progressive clouding of consciousness indicates nearly always a loss of airway protection, risking aspiration; endotracheal intubation is required. Oral intubation is the most common method because adequately sized tubes can be placed under direct vision. Nasal intubation requires significant expertise, especially when performed blind, and may exacerbate agitation; it is contraindicated in patients with midface fractures. Laryngoscopy in an awake patient nearly always worsens agitation; in these instances, rapid-sequence intubation (RSI) is advised.

RSI involves administration of a sedative followed by a short-acting muscle relaxant, typically succinylcholine. If endotracheal intubation fails, however, the patient must be ventilated with a bag-valve-mask device until short-term paralysis resolves. A retrospective analysis of trauma patients revealed that RSI in the field and in hospital were equally successful (97.9% vs. 98.5%) and safe.[58] Other studies reported success rates of 84% to 90.5% for field intubations, suggesting that training and experience are the major determinants of success.[59] Failed intubation was associated mainly with inadequate relaxation and difficult anatomy (i.e., morbid obesity or inability to visualize the vocal cords). Although the length of hospital stay and mortality were comparable, pneumonia occurred more frequently with RSI in the field than in hospital.[60] In a prospective study of severely injured trauma patients who were intubated in the field via RSI or immediately intubated on admission to the hospital, total out-of-hospital times were twice as high for the field group versus the hospital group (26 vs. 13 minutes).[59,61] Patients intubated in the field versus in the hospital had more ventilator, hospital, and intensive care unit days, higher mortality (23% vs. 12.4%), and a 1.5-fold increased risk of nosocomial pneumonia.[62] These data argue against spending extra time in the field with severely or even moderately injured patients (injury severity score 15 to 25).[63] Even in recently published studies, conducted several years after the problems of high failure rates in out-of-hospital emergency airway management had been identified, the rate of failed intubations is still unacceptably high.[64]

The high failure rate may indicate that although proper ventilation and perfect intubation skills in the field had been identified as being of utmost importance, it is not possible to achieve in all cases. Rescue personnel must recognize the importance of skill retention. Thus, before intubation attempts, a risk-to-benefit assessment is needed to prevent harm with multiple failed attempts. For example, if conditions are difficult (morbid obesity or midface fractures), it may be prudent to use a bag-valve-mask device and subsequently intubate immediately after arrival in the emergency

department. Health care personnel, however, must understand that bag-valve-mask ventilation needs to be performed carefully. In laboratory shock models, excessive ventilation with a bag-valve-mask caused increasing positive intrathoracic pressure, inhibition of venous return, decreased coronary perfusion, and thereby decreased survival.[65,66] In contrast, reduced intrapulmonary pressure resulted in better venous return in severe hemorrhagic shock and thus improved blood flow in an animal model comparable to CPR.[67] In contrast to the impedance-threshold device during CPR, however, large prospective studies determining the effect of decreased intrapulmonary pressure in shock patients are still lacking.

Cervical Spine Injury

Cervical spine injuries occur in 2% to 5% of blunt trauma patients,[68] and approximately 10% of these are unstable.[69] The most common fracture was C2, accounting for 24% of fractures. Dislocations are most common at C5-6 and C6-7.[70] Missed cervical spine injury can have disastrous consequences. The incidence of missed or delayed diagnosis is 1% to 5%, and up to 30% of these patients develop secondary neurologic damage.[71] The primary objective when managing the airway of such a patient is to minimize neck movement while the airway is secured rapidly and efficiently. Flight paramedics had only a 52% success rate with blind nasal intubation in spontaneously breathing patients in an out-of-hospital setting but were successful with this procedure in fourteen of fifteen patients in the hospital.[72] Traumatologists working in a prehospital environment used RSI with a success rate of 97% to 99%.[73] When emergency physicians were compared with anesthesiologists using RSI in an out-of-hospital environment, the nonanesthesiologists were twice as likely to fail to intubate and needed to undertake a surgical airway.[74]

During normal direct laryngoscopy and oral intubation, significant extension occurs between the occiput and C1 and between C1 and C2.[75] In an emergency department, the most common approach to intubating the multiple-injury patient with a potential cervical spine injury is RSI while maintaining cricoid pressure and manual inline neck stabilization. Manual inline neck stabilization is provided by an assistant who holds the patient's mastoid processes firmly down, opposing the upward forces generated during laryngoscopy.[76] In anesthetized patients, this maneuver reduced head extension by 50% and should increase the safety of direct laryngoscopy.[77] Axial traction must be avoided because excessive distraction may injure the spinal cord. The view at laryngoscopy is better with manual inline neck stabilization than with rigid-collar immobilization[78]; if a cervical collar is left on during laryngoscopy, the view will be often grade 3 or 4.[79] Once manual inline neck stabilization has been applied, the rigid collar should be removed and then reapplied when successful placement of the tracheal tube has been confirmed. Direct laryngoscopy and oral intubation are the quickest method for securing the airway in a patient with potential cervical spine injury.

Many clinicians advocate awake intubation as the safest approach in a patient with a cervical spine injury. It is thought that preservation of muscle tone provides protection, and spinal integrity can be monitored during airway manipulation.[80] Prolonged hypotension or malposition after intubation is at least as likely to cause neurologic injury as the intubation itself.[81] Awake techniques are particularly favored when the need for intubation is not urgent. Awake intubation is slower than RSI. In the acute trauma patient, it may increase the risk of aspiration and can increase intracranial pressure. Awake techniques, such as blind nasal, blind oral, and fiberoptic intubation, require considerable training and the patient has to be cooperative. Of the awake techniques, fiberoptic intubation is best in the patient with a cervical spine injury. The laryngeal mask airway (LMA), intubating LMA, and ProSeal LMA are useful alternatives if tracheal intubation is not possible. The LMA can be inserted easily in the neutral position and is an option in patients with cervical spine instability.[82] The standard LMA and intubating LMA cause temporary pressures of greater than 250 cm H_2O against the posterior pharyngeal wall during insertion in cadavers. This pressure is sufficient to induce up to 2 mm of displacement of C3.[83] During insertion, the intubating LMA causes some movement of the upper cervical spine, but it is less than that produced during direct laryngoscopy.[84] Neck stabilization methods make insertion of the LMA and intubating LMA more difficult, although the effect on the intubating LMA is less.[85]

Open Penetrating Chest Wounds and Tension Pneumothorax

An open penetrating chest wound is a challenging injury that is potentially associated with life-threatening airway compromise requiring complicated emergency airway management.[86] Intubation is challenging because preoxygenation may be less effective than usual; furthermore, if mask ventilation is attempted, air may be forced into the subcutaneous tissue, further distorting the anatomy.[87] In one study of thoracic trauma, approximately 20% of the patients suffered a pneumothorax and/or hemothorax, injuries were penetrating in approximately 10%, and only approximately 3% required a thoracotomy.[88] Dyspnea, hemoptysis, subcutaneous emphysema, pneumomediastinum, and pneumothorax are found commonly in patients with open, penetrating chest wounds (secondary to blunt trauma). Such a difficult airway needs to be secured; alternative airway techniques have been recommended as first-line approach, in particular, fiberoptic laryngoscopy. Fiberoptic intubation is the "gold standard" whenever the airway is expected to be difficult; direct airway injury can be diagnosed definitively, and an endotracheal tube can be placed into one of the bronchi if there is a major injury of the opposite side.[89] The patient should breathe spontaneously for as long as possible and ideally undergo

a gas induction of anesthesia followed by bronchoscopy; a rigid scope may be useful if there is blood or copious secretions in the pharynx.

Traumatic Brain Injury

Outcome of traumatic brain injury depends heavily on initial and admission Glasgow Coma Scale score and age.[90] Direct trauma-related destruction of brain structures (primary lesion) cannot be saved therapeutically. Secondary brain injury, however, defined as the damage to neurons owing to a systemic physiologic response to the initial injury, can be influenced. Hypotension and hypoxia are major causes of secondary brain injury.[91] One of the first tasks of trauma resuscitation is airway management. Approximately 50% of traumatic brain injury patients are reported to be hypoxic in the field, a finding associated with increased mortality.[92] Indications for intubation include an inability to maintain and to protect the airway but also may include inadequate ventilation, need to hyperventilate, hemodynamic instability, and need for radiographic imaging and subsequent surgery. The common coexistence of cervical spine injury requires vigilance. Early orotracheal intubation is recommended if the Glasgow Coma Scale score is 8 or less, although retrospective studies revealed increased mortality with field intubation.[93,94] Intubation usually can be accomplished without sedation and pharmacologic paralysis. Sedation and neuromuscular blockade can be useful in optimizing transport of the head-injured patient, but they interfere with neurologic examination and influence initial evaluation and management.[95] Hemodynamic stability similarly is ranked as a priority before and after intubation. These priorities should not be compromised in an attempt to prevent an increase in intracranial pressure.

Intracranial hypertension itself is not harmful unless it causes cerebral perfusion pressure to fall below a critical value. Cerebral ischemia leads to neuronal injury and cerebral edema, which further increases intracranial pressure, progressing to irreversible neurologic damage. Proper maintenance of gas exchange is more important than pharmacotherapy aimed at intracranial pressure control. Hyperventilation reduces intracranial pressure by causing cerebral vasoconstriction with a subsequent reduction in cerebral blood flow. Long-term hyperventilation is no longer recommended because outcome is worse than with normocapnia[96,97]; initial target partial pressure of arterial carbon dioxide (Pa_{CO_2}) should be 35 to 40 mm Hg.[98] Short-term hyperventilation, however, may have a role in reducing intracranial pressure in patients who are deteriorating rapidly before other measures can be instituted.[99] The lowest level of positive end-expiratory pressure that maintains adequate oxygenation and prevents end-expiratory alveolar collapse should be used.[92] Hemodynamic stability has particular importance in serious traumatic brain injury patients because outcome is worse with systolic pressures of less than 90 mm Hg[100] and cerebral perfusion pressures of less than 70 mm Hg. Thus, anaesthesia for intubation has to be performed as cautiously as possible maintaining a stable blood pressure.[101]

Burns

In a burn patient, airway and respiratory complications remain a common cause of morbidity and mortality. Multiple variables have an impact on resuscitation, including delay in its initiation, inhalation injury, and the depth and vapor-transmission characteristics of the wound itself. Inaccurate volume administration causes substantial airway, respiratory, and other morbidity; thus, burn resuscitations must be guided by hourly evaluation of resuscitation end points.[102] Constricting circumferential or near-circumferential torso wounds can reduce chest wall compliance as soft tissues swell beneath the inelastic eschar. Improvement in ventilation is common after escharotomy of the chest and abdomen.

In the initial evaluation and resuscitation phase, the key point of airway management is assessment of airway patency and inhalation injury. The latter results from aspiration of superheated gases, steam, or noxious products of incomplete combustion. Inhalation injury adversely affects gas exchange and hemodynamics. It also profoundly influences mortality from that predicted by age and burn size.[103] Physical signs of particular importance are singed nasal hair, facial burns, and soot in the mouth and between the teeth. Stridor mandates rapid intubation. In questionable cases, direct laryngoscopy and fiberoptic bronchoscopy can be very helpful; the bronchoscope can serve as a stylet for intubation. Patients at risk for progressive edema should be observed closely and intubated early. After securing the airway, the following require close attention: bronchospasm, small airway obstruction, carbon monoxide poisoning, and respiratory failure. If massive edema is associated with burn resuscitation, reintubation after unplanned extubation can be especially difficult; prevention by endotracheal tube security is the best approach, such as securing the endotracheal tube with an umbilical tie harness. Adjunctive techniques in case of difficult intubation, such as laryngeal mask airway or a needle or open cricothyroidotomy, can be lifesaving.

Drowning

Worldwide, 3.5 deaths per 100,000 population are caused by drowning accidents. Death by submersion is the second most common cause of accidental death in children.[104] Victims of drowning accidents usually show an initial phase of panic and swimming movements. Apnea and breath holding often are followed by swallowing of large amounts of fluid with subsequent vomiting, gasping, and fluid aspiration. Ultimately, severe hypoxia leads to unconsciousness, loss of airway reflexes, and further movement of water into the lungs. Aspirated hypotonic or hypertonic fluids result in

bronchospasm, leading to an increase in relative shunt and alveolar edema.[105] These events cause hypoxemia, decreased lung compliance, and increased work of breathing. Up to 70% of drowning victims aspirate foreign material such as mud, algae, and vomitus. Patients usually develop acute lung injury followed by acute respiratory distress syndrome within a very short time. Because hypoxia is the major cause of death, the primary goal is to restore oxygen delivery. Immediate rescue out of the water is critical. After initial resuscitation, continuing heat loss must be prevented by adequate insulation against the environment.[106] Patients presenting awake or somnolent but with clinical signs of respiratory distress should receive oxygen at a high concentration using a tight-fitting mask and a reservoir bag. In the case of progressive deterioration of respiratory or neurologic function, RSI has to be performed and ventilation with positive end-expiratory pressure and 100% oxygen initiated without delay. A nasogastric tube will decompress a full stomach and aid ventilation in these patients. Asystole and ventricular fibrillation warrant aggressive CPR because the prognosis is dismal; unfortunately, CPR is underused in drowning victims.[107] In an investigation of unwitnessed out-of-hospital cardiac arrest, near-drowning was an independent predictor of survival.[108]

ADJUNCTS FOR OXYGENATION, VENTILATION, AND AIRWAY CONTROL

Use of Oxygen

During resuscitation, 100% inspired oxygen ($FI_{O_2} = 1$) should be used as soon as possible. Exhaled air contains approximately 17% oxygen and approximately 4% carbon dioxide.[109,110] Ventilation with such a gas mixture of 17% oxygen and 4% carbon dioxide in animals[111] and healthy, conscious volunteers resulted in insufficient oxygenation and ventilation.[112] Short-term therapy with pure oxygen is beneficial and not toxic. Oxygen toxicity occurs only during prolonged therapy with a high FI_{O_2}. During bag-valve-mask ventilation using room air (21% oxygen) and a normal cardiac output, tidal volumes of 700 to 1000 mL (approximately 8.5 mL/kg) were required to maintain adequate oxygenation.[113,114]

Careful preoxygenation is essential to increase safety before induction of anesthesia and intubation in emergency settings such as trauma victims. Completely preoxygenated lungs can provide a supply of oxygen for up to 10 minutes by resorption of oxygen out of functional residual capacity.[115] This time can be further extended secondary to diffusion respiration.[116] Hemoglobin streaming through the pulmonary vessels continuously absorbs oxygen out of the functional residual capacity of the lungs (approximately 200 mL/min), whereas carbon dioxide remains (because of its high solubility) mainly in the bloodstream and only a small amount diffuses into the lungs (approximately 40 mL/min). Because the balance constitutes a negative amount of approximately 160 mL of gas per minute in the lungs, a subatmospheric pressure develops, which suctions gas into the lungs from the upper airways. If oxygen is administered continuously, for example, over a nasopharyngeal tube, partial alveolar oxygen pressure may be maintained at levels sufficient for arterial oxygenation; hypercarbia is generally well tolerated (unless brain injury or pulmonary hypertension).[115] Thus, oxygenation of the body had been maintained for up to 1 hour in animal settings and, in clinical settings, apnea times of up to 15 minutes have been reported.[115,117] Of note, in acute shock states in animal experiments, apnea times were dramatically shorter until oxygen saturation in the blood dropped[118]; nevertheless, the better preoxygenated are the lungs of a patient, the more reserve is available for apnea time.[115,118]

Ventilation Devices

BAG-VALVE-MASK VENTILATION

A simple, portable bag-valve-mask device usually is available in hospital wards and in every emergency medical service. Proper bag-valve-mask ventilation is a fundamental skill of resuscitation and should receive a high priority in training. Unfortunately, these skills are poorly performed even after retraining, and inadvertent hyperventilation is detrimental to morbidity and mortality. With an unprotected airway, the risk of stomach inflation and aspiration is high using standard bag-valve-mask resuscitators. Short inspiratory times, high flow rates, and high airway pressures, caused by squeezing the bag too hard and too fast, are the main causes of stomach inflation. Reduced expiratory times produced by inadvertent hyperventilation stacks air in the lungs, creating decreased cardiac refill and decreased coronary perfusion pressure. A small self-inflatable bag was advantageous over a large one when paramedics undertook bag-valve-mask ventilation with a pediatric versus an adult-sized self-inflatable bag using an in vitro model of ventilation with an unprotected airway. Pulmonary ventilation was similar with both bags, but stomach inflation was much less with the pediatric bag.[119,120]

Depending on lung compliance, different tidal volumes caused stomach inflation in patients, but most often at a peak inflation pressure of greater than 20 cm H_2O. Data from an in vitro model of an unprotected airway confirmed that longer inflation times produced increased lung ventilation and reduced stomach inflation, especially when intrapulmonary airway resistance was high. Although the bag-valve mask is the simplest and most-cost-effective ventilation device available, its efficacy is diminished by lack of skill of the user, the "incident stress" associated with treating a patient in cardiac arrest, and the subsequent inadvertent hyperventilation that these issues cause. A relatively new bag-valve-mask technology exists that assists rescuers in ventilating correctly by responding to squeeze and release of the bag and controlling the flow of gas from the bag, reducing airway pressure, increasing inspiratory times, and reducing the risk of stomach insufflations even in the hand of less-well-trained rescue personnel.[121]

AUTOMATIC TRANSPORT VENTILATORS

In prehospital care, mechanically powered devices are as effective as other devices for ventilating intubated patients. In unintubated patients, it depends on the mode of power; that is, in pressure-cycled devices, because these device must achieve a relatively high airway pressure (usually greater than the reported lower esophageal sphincter pressure) to turn off the flow and cycle to an exhalation, they create large amounts of stomach inflation, especially as the airway resistance increases or lung compliance decreases. The guidelines for resuscitation recommend avoiding these devices. On the other hand, tidal volume should be restricted in volume- and time-cycled ventilators. In an in vitro model of an unprotected airway, significantly less stomach inflation was found when applying a tidal volume of approximately 500 mL versus approximately 1000 mL.[122] Controlling inflation time, flow rate, and flow waveform with a mechanical ventilator may be the best solution to control and limit peak inflation pressure for a given tidal volume, but these variables are not controlled easily during manual ventilation.

Airway Control Devices

OROPHARYNGEAL AND NASOPHARYNGEAL AIRWAYS

These airway adjuncts can be used in unintubated patients requiring ventilation. The oropharyngeal airway should be inserted only in unconscious patients; otherwise, gagging and vomiting can be evoked. The nasopharyngeal airway is better tolerated in somnolent patients. The devices should be inserted carefully by trained personnel; lubricants ease insertion.

ENDOTRACHEAL TUBE

As early as possible during resuscitation, trained personnel should intubate the trachea. Before commencing intubation, the patient should be preoxygenated either by spontaneously breathing pure oxygen or by controlled bag-valve-mask ventilation with a high inspired concentration of oxygen. Preoxygenation increases the alveolar pressure of oxygen; elimination of nitrogen increases the reservoir of oxygen fivefold and generates a grace period of several minutes before a patient becomes hypoxic. The grace period depends on the alveolar volume, shunts, oxygen consumption, and oxygen-carrying capacity. The interruption of ventilation should be as brief as possible, and adequate ventilation and oxygenation must be provided if more than one intubation attempt is necessary. To facilitate intubation, the sniffing position and hyperextension of the head at the atlantooccipital joint is beneficial. A stylet, which should not extend over the distal end, can be used to provide some stiffness to the tube and makes control during insertion easier. When the cuff of the tracheal tube is inflated and the airway thus secured, cricoid pressure can be removed. Tube placement is confirmed by chest excursion and auscultation; over the epigastrium, no stomach gurgling should be heard during inspiration. These clinical signs are not always reliable[123]; unrecognized misplacement of the endotracheal tube occurred in up to 25% of intubated patients in the field.[6,7] Verification by direct visualization of the tube passing through the vocal cords and use of end-tidal carbon dioxide monitoring also are recommended.[124,125] Clinical assessment and esophageal detector devices may be used but are not reliable in all patients.

LARYNGEAL MASK AIRWAY

The LMA is now used widely for managing failed intubations or difficult airways.[126,127] It should be considered first among the alternative airway devices. Placement and use of an LMA are simpler than tracheal intubation because laryngoscopy and visualization of the vocal cords are unnecessary. The LMA is introduced into the hypopharynx, and the cuff seals the larynx after inflation. While the arrow is positioned at the upper esophageal sphincter without sealing it, the distal opening of the tube is just above the glottis, providing ventilation and oxygenation. The main limitation of the LMA is a lack of protection against aspiration,[128] although regurgitation is less likely than with bag-valve-mask ventilation.[129]

A recently developed ProSeal LMA has an additional lumen to introduce a nasogastric tube to drain the stomach or regurgitated fluids[130] away from the respiratory tract.[131] The bowl of the mask is deeper than that of a standard LMA, with an additional cuff on the dorsal side. Because of these modifications, the airway sealing pressures achievable with the ProSeal LMA are at least 10 cm H_2O higher than with the standard LMA. As with the standard LMA, the ProSeal LMA can be inserted in the neutral position, making it attractive in potential cervical spine injury. Another limitation of the LMA is the relatively low leak pressure, 19 to 22 cm H_2O,[132] which may decrease tidal volume and increase stomach inflation.[133]

The intubating LMA is a modified conventional LMA; once inserted, it allows passage of a tracheal tube, either blindly or by fiberoptic bronchoscopy. Standard insertion requires a neutral position; manipulation of the head and neck is not needed. In a recent study in Bordeaux, France, "senior emergency physicians" achieved a nearly 100% success rate in advanced out-of-hospital airway management applying the intubating LMA as a first-choice alternative to conventional intubation.[134] Again, this study indicates that it is not only a question of which airway device is applied but which airway device is applied by which rescuer.

COMBITUBE

The Combitube is essentially a double-lumen tube that is inserted blindly through the mouth and is more likely to pass into the esophagus (approximately 95%) than into the trachea (approximately 5%). The esophageal lumen is closed distally and perforated at the hypopharyngeal level with several small openings; the tracheal lumen is open distally. First, the proximal large pharyngeal balloon is inflated, thereby

filling the space between the base of the tongue and the soft palate. Second, the distal cuff is inflated. These cuffs provide a good seal of the hypopharynx from the oropharynx and stability in the trachea or esophagus, respectively. The most common reason for failure to ventilate is placing the Combitube too deeply; the entire perforated pharyngeal section enters the esophagus. Pulling the Combitube back 3 to 4 cm usually resolves the problem. The success of insertion and ventilation with the Combitube is comparable with that of other upper airway devices[135] and is 100% in an urban environment where trauma patients receive care.[136] The Combitube, however, is not well tolerated by patients with a persistent, strong gag reflex. It should be exchanged to an alternative airway as early as possible. Advantageously, the Combitube can be a routine device in emergency medicine[137] and in "cannot ventilate, cannot intubate" situations.[138] The Combitube has the same limitations as the LMA. Thus, it may be unsuitable in patients with hypopharyngeal pathology or preexisting esophageal pathology, such as a malignancy or esophageal varices.[139]

LARYNGEAL TUBE

The recently introduced single-lumen laryngeal tube can be inserted orally without additional equipment and is effective for ventilating and oxygenating patients who experience a respiratory arrest during induction of anesthesia.[140] Thus, the laryngeal tube may be used as an alternative airway device during routine or emergency airway management. Handling of the laryngeal tube has been simplified by blocking two cuffs with one instead of two catheters; the first secures inflation of the oropharyngeal cuff, and the second secures inflation of the esophageal cuff because of different resistance characteristics of the connected tubing. Given its design, the laryngeal tube may not be the best device for spontaneously breathing patients.[141] The blind ending in the esophageal inlet also may cause esophageal rupture in the case of vomiting.[142] Accordingly, the laryngeal tube has been fitted with a second lumen for suctioning and free stomach drainage (laryngeal tube S) but not for ventilation, as with the Combitube. In contrast to the Combitube, the laryngeal tube S has only one adapter, which may be connected with a ventilation device, whereas the remaining connector can only be connected to a suction adapter. This may achieve additional patient safety; it prevents an inexperienced user from inadvertently attaching a ventilator or bag-valve-mask device to the esophageal tubing, which could result in stomach inflation and subsequent ventilation-related complications.

VIDEOLARYNGOSCOPY

In the past, patients' tracheas were being intubated either by direct laryngoscopy or by awake fiberoptic access in expected difficult airway scenarios. In the last years, different portable laryngoscopes with integrated fiberoptic systems have been developed. These systems enable an indirect view of the glottis from the tip of the laryngoscope, and transmit that picture via a special monitor. Thus, the view of the glottis is often dramatically improved, enabling successful intubation as compared with conventional direct laryngoscopy.[143,144] It is noteworthy that the view of the glottis via a videolaryngoscope does not automatically signify that intubation will be successful. The human airway is kinked and often it may be necessary to compensate for this through use of a preformed stylet in order to place the tip of the tube into the glottic area during application of videolaryngoscopy.[145] The learning curve for these indirect videolaryngoscopic devices, however, is flat, and rescuers are often able to provide successful intubation after less than a dozen intubation attempts.[143,144,146,147] Thus, employment of videolaryngoscopy may increase in emergency intubation settings within the next years, even in the field, because of high intubation-success rates.

TRACHEOSTOMY AND CRICOTHYROIDOTOMY

When the airway is compromised by trauma, or when massive oropharyngeal or hypopharyngeal pathology is present, emergency access may be possible only through an emergency tracheostomy or cricothyroidotomy. Emergency tracheostomy usually is performed via a vertical incision from the cricoid cartilage down in the direction of the sternal notch. A skilled operator can insert a small, cuffed endotracheal tube rapidly.

Emergency cricothyroidotomy is a valid alternative for a less-skilled operator. The cricothyroid membrane, palpable directly under the skin, is incised in its inferior third to minimize the possibility of bleeding. The cricothyroid membrane is not always easy to appreciate (in obese patients or those with short necks). Cricothyroidotomy is performed infrequently; in inexperienced hands, success is only 60% to 70%.[148] The main advantage of this technique is the blunt dissection of the subcutaneous tissues all the way to the cricoid membrane. An airway catheter is then introduced over a dilator threaded over the guidewire.[149] This technique allows the ultimate insertion of an airway that is considerably larger than the initial needle or catheter. Its internal diameter often is sufficient to allow ventilation with conventional ventilation devices, suctioning, and spontaneous ventilation.

Needle cricothyroidotomy is another alternative, regardless of whether it is surgical or percutaneous. Needle cricothyroidotomy always requires the use of a jet device to provide ventilation. It is associated with a high incidence of complications, such as massive subcutaneous emphysema, barotrauma with pneumothorax or tension pneumothorax, and air trapping with severe hemodynamic instability.

CONCLUSION

The goal of ventilation strategy during resuscitation is to optimize oxygenation and carbon dioxide elimination. This can be achieved in an unprotected airway with techniques

such as mouth-to-mouth ventilation, but preferably with bag-valve-mask ventilation. Because ventilation of an unprotected airway may result in stomach inflation and subsequent severe complications, securing the airway with an endotracheal tube is the "gold standard"; however, poorly performed intubation can result in esophageal intubation and disaster. Thus, and importantly, airway-device complications are more related to training than to the devices themselves. Excellent success in emergency ventilation depends on initial training, retraining, and actual frequency of performing a given procedure on the job. Rescue personnel with less experience in advanced airway management should step back and try to avoid anesthesia induction and intubation when patients can be oxygenated by spontaneous breathing. If artificial ventilation is unavoidable, for example, during CPR, less-experienced rescuers can apply extraglottic airway devices or retreat to bag-valve-mask ventilation with high $F_{I_{O_2}}$. Success in out-of-hospital airway management is often less a question of the "right-tools" than one of the "the right tools in the right hands at the right time."[150]

TRANSPORT OF THE VENTILATOR-SUPPORTED PATIENT

Richard D. Branson
Phillip E. Mason
Jay A. Johannigman

Mechanical ventilation of the critically ill patient is best practiced in the safe confines of the intensive care unit (ICU). Transport of ventilated patients, however, remains a frequent challenge. Successful transport requires effective communication, appropriate planning, key personnel, and compact, rugged equipment. Clinicians should be aware of the physiologic effects of transport, frequency of adverse events, and methods to prevent complications.

INTRAHOSPITAL TRANSPORT

Mechanically ventilated patients are moved frequently within the hospital. The most common destinations for patients transported from the ICU are computed tomography (CT) and the operating room with other radiologic modalities also being common.[1–15] Most transports between the ICU and non–operating room destinations last 40 to

90 minutes.[2,5–7,10,12–14] More recently, portable scanners have been used to perform CT scans in patients with traumatic brain injury to reduce the uncertainties of transport.

Magnetic resonance imaging is an increasingly common destination for the critically ill ventilated patient. Safe transport is more challenging in this setting because of limited patient access and the need for nonferrous equipment.

INTERHOSPITAL TRANSPORT

Interfacility transport has increased in recent years owing to the regionalization of specialty care in neonatology, respiratory failure, trauma, transplantation, stroke, and cardiac disorders. The growth of hospital systems with acute and chronic care facilities represents another reason for interhospital transport as patients travel back and forth based on acuity. The current military operations in Iraq and Afghanistan have generated thousands of long distance interhospital transports requiring mechanical ventilation.

Interhospital transport can be accomplished using ground or air transport. Ground transport is the most readily available and least expensive, while also the least influenced by weather. There are few restrictions on weight and patient access can be quite good. Helicopters offer a significant improvement in speed but are expensive to operate. Patient care is made more difficult by weight limitations and a cramped, noisy cabin. Fixed-wing transport is the only viable option when critical patients must be moved over long distances.

PREPARATION AND PLANNING

The American College of Critical Care Medicine suggests that all hospitals have a formalized plan addressing pretransport coordination and communication, composition of transport team, transport equipment, monitoring during transport, and documentation.[16] Many adverse events associated with transport can be avoided with preparation and communication.[14,15,17–21] Patients having to wait at their destination can be particularly problematic and can be avoided with proper coordination.[8]

An experienced critical care nurse and respiratory therapist should accompany all mechanically ventilated patients during transport.[16,22] The need for physician presence has been evaluated in pediatric transports but has not been clearly elucidated.[23–25] The American College of Critical Care Medicine recommends a physician competent in airway management, advanced cardiac life support, and critical care medicine accompany all unstable patients.[16] The American Association for Respiratory Care does not opine on physician presence, but does suggest that team members be skilled in airway equipment operation and troubleshooting.[22]

RISKS AND BENEFITS OF TRANSPORT

Considerable effort has been expended to catalog the risks of transport.[3–8,10–15,17,18,26,27] The costs associated with transport include transport equipment, personnel, and managing complications of transport. Benefits may include discovering new pathology that changes treatment, intervention to address disease processes, or, in the case of interhospital transport, receiving care not available at the sending facility. Several investigations have noted that in two-thirds of transports to radiology, the patient's treatment course is unaltered.[5,6] Head CT is least likely to result in a change in therapy, whereas abdominal CT is most likely to result in new findings and guide intervention.

PHYSIOLOGIC EFFECTS AND COMPLICATIONS OF TRANSPORT

Transporting ventilated patients requires transitioning to portable equipment, repositioning the patient, and transfer from the ICU bed. Patients are often transported in the supine position, which changes respiratory mechanics and may alter hemodynamics. Many intrahospital destinations are distant from the ICU, located in facilities never designed to house critically ill patients. Both remote locations and poor physical plants may contribute to complications and untoward outcomes. Complications of intrahospital transport are frequently recalled as "the catastrophe in radiology." During interhospital transport, patients must be cared for in the suboptimal confines of a transport vehicle. Transport complications range from minor changes in heart rate to cardiac arrest. Table 27-1 lists common complications. The true complication rate is difficult to ascertain because of inconsistent definitions in existing studies.

Cardiovascular Complications

Cardiovascular events are the most frequent complication during intrahospital and interhospital transport, and are reported in up to 50% of cases.[4–7,11,13,14,17,28–33] An increase in heart rate is seen frequently as a result of anxiety, pain, and activity. Arrhythmias are common during the transport of high-risk cardiac patients, a finding complicated by the fact that routine lead II monitoring may be unable to detect early changes.[34,35] Acute respiratory alkalosis resulting from hyperventilation alters myocardial irritability, leading to dysrhythmias.[4,36–39] This finding commonly is associated with unmonitored manual ventilation but can occur with a ventilator when minute ventilation is unreliable.[39]

Hypotension during transport may result from loss of intravenous access, interruption of vasoactive agents, pneumothorax, or bleeding. Alkalemia associated with

  - Increased anxiety
- **Other**
  - Increased risk of ventilator-associated pneumonia
  - Bleeding or hemorrhage
  - Hypothermia
  - Effects of altitude on physiology[a]
    - Hypoxic hypoxemia
    - Expansion of trapped gases (endotracheal tube, pneumothorax, ears, gastrointestinal tract)
- **Equipment Failure or Mishaps**
  - Airway obstruction
  - Extubation
  - Intubation of right mainstem bronchus
  - Gastric aspiration around endotracheal tube cuff
  - Loss of battery power to monitoring equipment or ventilator
  - Damage to equipment as a result of mishandling or falls
  - Loss of oxygen supply
  - Failure to reproduce ICU ventilation parameters with a portable ventilator or manual ventilator (loss of positive end-expiratory pressure, failure to trigger, inappropriate tidal volume or frequency)
  - Effects of altitude on equipment performance[a]
  - Loss of venous access/indwelling vascular catheters
  - Interruption of medications—continuous and intermittent
  - Inadequate chest tube drainage

[a]Unique to air transport.

hyperventilation likewise can cause hypotension.[4,39,40] Excessive hyperventilation is associated with increased intrathoracic pressure, reduced venous return, and reduced cardiac output. During cardiopulmonary resuscitation, excessive ventilation reduces the efficiency of cardiopulmonary resuscitation and is referred to as "death by ventilation." Hypertension can result from stress and anxiety, as well as from patient movement that encounters "bumps" in the transport path and jostling of patients that causes pain.[3,5,6,41] Cardiac arrest has been reported during transport, but patient movement per se has not been directly implicated.[17,31,32]

Respiratory Complications

Hypoxemia is a well-documented transport complication.[2,4–6,14,30,32,33,40,42,43] It may result from loss of positive end-expiratory pressure (PEEP), changes in patient position, impaired secretion removal, equipment malfunction, and failure to reproduce ventilator settings adequately. During transport of adult patients, high inspired oxygen concentrations (FI_{O_2}) are used commonly as a matter of convenience.[18,44] Elevated FI_{O_2}, however, may mask deterioration in lung function and contribute to absorption atelectasis. Patients requiring PEEP of more than 10 cm H_2O are vulnerable to deterioration in oxygenation during transport that lasts up to 24 hours.[3]

Hyperventilation is frequent with manual ventilation[4,39,42,45] and with poor control of minute ventilation by portable ventilators.[42] Sudden respiratory alkalosis can result in changes in cardiovascular function. Hyperventilation increases intrathoracic pressure, produces air trapping, reduces cardiac output, shifts the oxyhemoglobin dissociation curve to the left (hindering oxygen unloading), and causes cerebral and myocardial vasoconstriction. These combined effects may adversely affect patient outcome.[46]

Hypoventilation is reported less frequently and generally is better tolerated.[3–6,8,10–13,26,27] Decreased tidal volume contributes to atelectasis and acute respiratory acidosis, which may compromise cardiac function. Sedation and neuromuscular blocking agents may also contribute to hypoventilation.

Unplanned extubation is an infrequent but potentially catastrophic complication.[17,30] Inability to establish an adequate airway is associated with hypoxemia and poor outcome in head-injured patients.[19,47] Unintubated patients with marginal airway control may benefit from intubation before transport. Radiologic procedures requiring the patient to remain supine may compromise the tenuous airway.

Other Complications

Increases in intracranial pressure have been reported during transport and are associated with supine positioning, changes in ventilation, airway compromise, and hypoxemia.[3,19,47]

Hypothermia during transport occurs because hallways, examination areas, and transport vehicles have imprecise environmental controls.[10] Exposure of skin surfaces for adequate radiologic examinations and use of skin preparations for procedures further contribute to temperature loss. Blood loss has been reported during movement of patients with unstable fractures.[10] Transport from the ICU is an independent predictor for the development of pneumonia, although a causative role cannot be definitively established.[9,48] Table 27-2 lists studies evaluating complications of transport.

SPECIAL CONSIDERATIONS FOR AEROMEDICAL TRANSPORT

Air transport subjects patients to altitude-induced physiologic alterations. Fixed-wing aircraft commonly pressurize to a cabin altitude of 8000 feet (barometric pressure of 565 mm Hg). Rotor-wing aircraft do not have pressurized cabins, leaving the patients and crew exposed to ambient barometric pressure. Flight altitudes are typically much lower in fixed-wing flight, but may reach physiologic significance when flying over high terrain.

The most relevant alterations in the hypobaric environment are hypoxemic hypoxia and expansion of gases. A change in altitude from sea level to 8000 feet is associated with hypoxemia in patients with normal and abnormal pulmonary function.[49,50] At similar altitude changes, gases expand in volume by 30%. This may cause injurious pressure increases in endotracheal tube cuffs during ascent.[51–53] Inconsequential volumes of trapped gases at sea level may cause significant physiologic effects at altitude, most dramatically in the setting of untreated pneumothorax. Less severe, but important, effects for patient comfort include ear pain secondary to pressure changes and expansion of gas in the gastrointestinal tract.

Ventilator performance can be adversely affected by changes in barometric pressure. Pneumatically operated devices will have alterations in tidal volume, frequency, and inspiratory time as altitude increases. Even sophisticated transport ventilators may deliver excessive tidal volumes in hypobaric environments.[54] Some newer ventilators automatically compensate for hypobaric effects on gas density.

CONTRAINDICATIONS TO TRANSPORT

There are few absolute contraindications to transport. Transport of the ventilated patient is best considered as transferring the ICU with the patient, not transferring the patient from the ICU. Patients occasionally are deemed too sick to transport. The specific contraindications to transport are (a) inability to maintain acceptable hemodynamic status, (b) inability to establish an adequate airway, (c) inadequate personnel, (d) inability to maintain adequate gas exchange, and (e) inability to monitor patient status effectively. Rescue therapies for acute respiratory distress syndrome are a relative contraindication to transport. If transport is required for potentially lifesaving therapy, then it should be considered. Safe transport with aggressive rescue therapies, including inhaled nitric oxide, prone ventilation, inhaled prostacyclin, and high-frequency percussive ventilation, has been described.[55–59]

EQUIPMENT AND MONITORING DURING TRANSPORT

Appropriate equipment and monitoring are important to maintaining homeostasis and ensuring safety (Table 27-3). Monitoring during transport should emulate the ICU. Minimum requirements include electrocardiographic monitoring of heart rhythm and rate, invasive or noninvasive blood pressure monitoring, and pulse oximetry. Continuous capnography greatly enhances safety by immediately detecting inadvertent extubation, circuit disconnection, or ventilator failure. Its importance cannot be overstated. Monitoring should adapt to the needs of the patient and include additional pressure monitoring if intracranial pressure or central venous pressure catheters are present. Battery-powered intravenous pumps for medication delivery also are required.

Equipment for transport should be rugged, lightweight, reliable, and operate from battery power for at least 1 hour. Required equipment for all transports includes a physiologic monitor; pulse oximeter; ventilator; manual resuscitator with a PEEP valve and mask; oxygen supply with sufficient reserve; stethoscope; and emergency airway-management equipment. Sedative, analgesic, and neuromuscular blocking agents, as well as resuscitation drugs and fluids should be readily available during transport. Some means to humidify inspired gases and suction the airway should be available for interhospital and long intrahospital transports. A spirometer to monitor tidal volume is useful with ventilators that fail to provide a reliable tidal

TABLE 27-3: MONITORING AND LIFE-SUPPORT EQUIPMENT FOR TRANSPORT OF THE VENTILATOR-DEPENDENT PATIENT

Monitoring
- ECG monitoring (rate and rhythm)
- Arterial blood pressure monitoring (invasive or noninvasive)
- Pulse oximetry
- Additional pressure monitoring (e.g., pulmonary artery, intracranial)
- Stethoscope
- End-tidal CO_2 monitor
- Portable spirometer (if not integral to ventilator)

Support equipment
- Portable ventilator capable of providing required mode, tidal volume, and PEEP
- Airway maintenance (should include a difficult airway kit)
- Manual resuscitator and mask
- Oxygen supplies (one or two cylinders)
- Drug box (emergency drugs, patient-specific drugs, sedatives, IV fluids)
- Infusion pumps (battery-operated)
- Defibrillator (optional)
- Portable suction (optional)

volume and during the use of pressure ventilation. Airway carbon dioxide monitoring can be helpful when sedation reduces minute ventilation.

A dedicated transport cart or trolley may simplify transport but is an inefficient use of resources.[6,34,45,60,61] The advantage of the cart is immediate availability of required devices. The disadvantages are cumbersome size and cost. A dedicated trolley for transport perhaps is best suited for interhospital transport.[59]

EQUIPMENT MALFUNCTION AND/OR MISHAPS

Mishaps range from benign to catastrophic. The frequency of mishaps varies widely with the definition. Using a broad definition of mishap, up to one-half of patients suffer a mishap during transport, most of which are minor and do not cause adverse effects.[8,14,15,17] Common mishaps include loss of vascular access or intravascular monitoring devices, disconnection from oxygen supply, disconnection from the ventilator, and improper care of chest tubes.[4,6,8,13–15,17,30,31,41]

Equipment failure remains a common mishap during transport, frequently attributed to poor planning and carelessness.[13,41] Reported failures include depletion of battery power of ventilator or monitoring equipment, exhaustion of portable oxygen supplies, ventilator failure, and damage to devices resulting from falls to the floor.[4–6,8,13–15,17,26,30,31] Exhaustion of a compressed oxygen supply during use of a pneumatically powered ventilator terminates ventilation and can be a life-threatening mishap. Table 27-2 provides a comparison of studies evaluating complications and mishaps in intrahospital transport of critically ill patients.

Rationale for Use of a Portable Ventilator

Manual ventilation is commonly used during transport. It is inexpensive, simple, and requires only human power. During manual ventilation, however, the volume, frequency, and pressure applied are unknown. Several investigators have noted hyperventilation and acute respiratory alkalosis during manual ventilation resulting in cardiovascular complications.[34,39,40,42,43,45–47] Aggressive manual ventilation can result in excessive airway pressures, causing barotrauma or volutrauma and worsening air trapping.[62]

Manual ventilation can be successful in the hands of a skilled clinician with additional volume-monitoring and pressure-monitoring capabilities.[10,13] Monitoring end-tidal CO_2 also may prove helpful in preventing hyperventilation.[40] Simple reasoning, however, dictates that manual ventilation cannot replicate the tidal volume, frequency, FI_{O_2}, PEEP, and mode of ventilation with the consistency and precision of a ventilator. Maintaining constant PEEP with a manual resuscitator is difficult and failure to do so can lead to hypoxemia.[2,18,43] Finally, manual resuscitators cause excessive work of breathing when spontaneous ventilations are present.[63,64]

Comparisons of manual ventilation with a transport ventilator uniformly support the use of a ventilator to preserve normal gas exchange.[4,39,42] A mechanical ventilator also allows monitoring and alarms. Modern transport ventilators provide the most commonly used ventilator modes, flow triggering, and constant FI_{O_2} and PEEP.

Portable ventilators are more expensive than manual resuscitators, and many require a high-pressure (50 pounds per square inch gauge [psig]) gas supply. Although manual ventilation of the postoperative patient with normal lungs during transport to the recovery room is safe, ventilation of the patient requiring PEEP, elevated FI_{O_2}, and constant volume is best accomplished by a ventilator.

TRANSPORT VENTILATORS

Technically, any ventilator that operates from a battery and either an internal gas source or a compressed gas cylinder could be considered a transport ventilator. Because of the demands of patient transport, however, these simple criteria are inadequate. Using performance to discriminate transport ventilators yields three categories: automatic resuscitators, pneumatically powered transport ventilators, and sophisticated transport ventilators.

Automatic Resuscitator

Automatic resuscitators provide ventilation at a set pressure. The user has limited control over respiratory parameters, and some do not allow any control of respiratory rate or tidal volume. The ability to apply PEEP is limited or nonexistent. As a function of pressure cycling, the respiratory rate and tidal volume vary with lung compliance. When compliance is low, tidal volume is small and frequency rapid; when compliance is high, tidal volume is high and frequency slow. These devices are powered pneumatically (requiring no electricity), and have only a mechanical, audible high-pressure alarm, and disposable pressure manometers. Spontaneous ventilation requires entrainment of ambient air, which reduces FI_{O_2}. Spontaneous respirations will cause dyssynchrony and increased work of breathing because of limited inspiratory flow rate and difficulty triggering. Automatic resuscitators are designed for use in the prehospital setting by personnel with limited expertise in mechanical ventilation.

The Vortran and Oxylator EM-100 are inexpensive examples of automatic resuscitators (Fig. 27-1). The Vortran has proven unreliable when the orientation is changed, failing to cycle.[65,66] In the presence of a leak, if the set peak pressure cannot be reached, both devices will remain stuck in inspiration. Despite these limitations, successful use of the Vortran in intubated, closely monitored subjects has been reported.[67]

FIGURE 27-1 Examples of automatic resuscitators, the Vortran (left) and Oxylator (right).

Our experience with the Vortran, however, suggests it is unsuitable for transport of patients with even minor lung disease.

Simple Transport Ventilator

The simplest transport ventilators provide mechanical ventilation at a specified rate and volume and include a pressure-relief valve with an audible mechanical alarm. Most are powered and controlled pneumatically. In some instances, a battery allows for simple low-presure and high-pressure alarms, as well as monitoring and display of airway pressure. Simple transport ventilators also are used primarily in prehospital settings by personnel with some training in mechanical ventilation. More complex than automatic resuscitators, they offer respiratory rate and tidal volume adjustment and can be used with spontaneously breathing patients.

EXAMPLES OF SIMPLE TRANSPORT VENTILATORS

The AutoVent 2000 (Fig. 27-2) and 3000 are pneumatically powered transport ventilators operating in the intermittent mandatory ventilation mode. FI_{O_2} is 100% and cannot be adjusted, and PEEP is not available. Mandatory breaths are time-triggered, flow-limited or pressure-limited, and time-cycled, while spontaneous breaths are pressure-triggered, pressure-limited, and pressure-cycled. During spontaneous breaths, the patient breathes from the demand valve at

FIGURE 27-2 The AutoVent 2000 simple transport ventilator.

48 L/min. If patient demand exceeds 48 L/min, ambient air is drawn into the valve, diluting the FI_{O_2}. There is no monitoring. An audible alarm sounds if airway pressure exceeds 50 cm H_2O.

The AutoVent 2000 is designed for adults and allows control of breath rate and tidal volume. The AutoVent 3000 is designed for adults and children and allows the user to control inspiratory time. The AutoVent 4000 offers additional alarms, manometer, adjustable airway pressure relief valve, and continuous positive airway pressure (CPAP) mode; it allows selection of FI_{O_2} 0.65 or 1. The ability of the AutoVent 4000 to provide a consistent FI_{O_2} is altered by reduced compliance. As the lung becomes stiffer, the venture mechanism reduces air entrainment and FI_{O_2} increases while tidal volume falls.

The AutoVent ventilators consume approximately 0.5 L/min of gas to operate the logic. The higher the frequency setting, the higher is the gas consumption. The inspiratory flow is fixed at 48 L/min. In patients with an active respiratory drive, the flow capabilities of the AutoVent devices may result in flow starvation, increased work of breathing, and asynchrony.

The Uni-Vent 706 (Fig. 27-3) is a pneumatically powered, electronically controlled ventilator delivering an FI_{O_2} of 1. Controls set inspiratory flow and a series of rate, inspiratory time, and inspiratory-to-expiratory timing (I:E) ratio combinations appropriate for adult and pediatric ventilation. Inspiratory flow is limited from 0 to 90 L/min, and a high-pressure limit can be set (60 or 80 cm H_2O) at the patient valve, which activates an audible alarm when exceeded. Prehospital use of the Uni-Vent 706 by paramedics during cardiopulmonary resuscitation of intubated victims has proven successful.[68]

Sophisticated Transport Ventilator

A sophisticated transport ventilator is capable of performance comparable to an ICU ventilator. These devices may have built-in compressors or turbines to generate positive

FIGURE 27-3 The Uni-Vent 706 simple transport ventilator.

pressure without compressed gas and contain an air–oxygen blender. Most offer extensive control of ventilator parameters and comprehensive alarms. Sophisticated transport ventilators are intended for interhospital or intrahospital transport of critically ill patients. These devices should be capable of ventilating the sickest patients.

EXAMPLES OF SOPHISTICATED TRANSPORT VENTILATORS

The IC-2A is a flow controller that can be triggered by pressure or time or manually; it is also pressure- or flow-limited and time-cycled (Fig. 27-4). It requires a compressed-gas source for delivery to the patient, as well as for the fluidic logic circuit. The IC-2A delivers an FI_{O_2} of 1. Controls include the mode of ventilation, inspiratory and expiratory time, inspiratory flow, sensitivity, and PEEP/CPAP level. Airway pressure is displayed on an aneroid pressure gauge. The IC-2A is often used for ventilation in the magnetic resonance imaging scanner because it has no ferrous components. The excessive gas consumption should be considered when gas supplies are limited. The IC-2A operation during synchronized intermittent mandatory ventilation limits the flow delivered to the set flow on the ventilator, potentially increasing the work of breathing. Our experience with this ventilator suggests most patients have to be sedated to tolerate the operational limitations.

The LTV 1200 offers the performance of a critical care ventilator at a size and weight appropriate for a transport ventilator (Fig. 27-5). It provides synchronized intermittent mandatory ventilation, controlled mechanical ventilation, pressure support, and CPAP modes. Pressure-controlled and volume-controlled breaths are possible. The integral turbine

FIGURE 27-4 The MRI compatible IC-2A.

FIGURE 27-5 The LTV 1200 sophisticated transport ventilator.

permits mechanical ventilation without a compressed gas source. Oxygen can be supplied from a low-flow or compressed-gas source. The user has extensive control of ventilator parameters. Airway pressure, total breath rate, exhaled tidal volume, total minute volume, I:E ratio, calculated peak flow, and patient effort are monitored and displayed. The bias flow during exhalation (10 L/min) increases gas consumption and should be considered when planning transports. The LTV 1200 offers additional features, including ventilator presets, and an oxygen conservation feature to decrease gas consumption during transport. The LTV 1200 also utilizes an electronic control of PEEP, compared to the a spring-loaded valve used with the LTV 1000. This allows the LTV 1200 to apply pressure breaths relative to baseline pressure.

The Uni-Vent 754 is an electrically powered flow or pressure controller offering controlled mechanical ventilation, synchronized intermittent mandatory ventilation, and CPAP modes of ventilation. The internal compressor allows use without a compressed gas source. The operator can set mode of ventilation, breath rate, inspiratory time, tidal volume, sensitivity, PEEP, FI_{O_2}, and peak inspiratory pressure limit. Airway pressure is displayed, as well as the airway pressure waveform, ventilator breath rate, inspiratory time, I:E ratio, tidal volume, FI_{O_2}, mean airway pressure, and baseline airway pressure. A full set of alarms is present. Inspiratory flow is limited to 60 L/min, which can cause dyssynchrony in spontaneously breathing patients. The inability to provide pressure-limited breaths is a minor limitation. The Uni-Vent 754 has a proven track record in transporting ventilated military casualties by U.S. Air Force critical care, air transport teams.

The Uni-Vent 731 transport ventilator (Fig. 27-6) is the next generation of Impact ventilators and is an electrically powered device that offers multiple improvements over the Uni-Vent 754. Most notable is the ability to provide pressure-limited breaths, integral pulse oximeter, and a 10-hour battery life. The peak flow in volume ventilation has also been increased to 100 L/min. The 731 has the capability to provide closed-loop control of inspired oxygen concentration using the pulse oximeter input. The target arterial oxyhemoglobin saturation (SpO_2) can be set between 92% and 99%. If SpO_2 falls below 88%, the FI_{O_2} is increased rapidly to alleviate hypoxemia. This system has potential important advantages during transport when physiologic changes occur quickly and access to the patient may be limited. At the time of writing, this system is not available in the United States.

FIGURE 27-6 The Impact 731 sophisticated transport ventilator.

ATTRIBUTES COMMON TO ALL TRANSPORT VENTILATORS

Weight

These devices must be person-portable and able to be mounted on a variety of platforms. In our mind, portable means that a respiratory therapist can carry the device to and from destinations. In our opinion, ICU ventilators that can be mounted on the ICU bed are in reality not portable. A maximum weight of 8 kg facilitates these requirements.

Durability

These devices should be compact, simple to operate, durable, and unaffected by extremes of heat, cold, or vibration. Proper shielding is required to limit emission of unacceptable levels of electromagnetic energy. Automatic resuscitators in particular should function properly after prolonged storage with minimal maintenance.

Power Requirements

Automatic resuscitators are pneumatically powered, negating the need for batteries. Simple and sophisticated transport ventilators often are powered electrically and pneumatically.

Transport ventilators use a variety of battery supplies. Sealed lead-acid batteries have a low energy density but are durable and inexpensive. Sealed lead-acid batteries hold a charge even when stored for long periods of time. Nickel-cadmium (NiCad) batteries have a higher energy density but are more expensive. Nickel-metal hydride batteries have even a higher energy density than NiCad batteries and are more expensive. Lithium-ion batteries have the

highest energy density and are the most expensive. NiCad, and to a lesser extent nickel-metal hydride, batteries (but not sealed lead-acid or lithium-ion batteries) can suffer from voltage memory and should be stored in the discharged state. Both lithium-ion and NiCad batteries will self-discharge during storage. Duration of ventilator operation on battery is significantly impacted by ventilator settings in all devices.

Oxygen consumption should be less than 5 L/min, keeping in mind that oxygen consumption varies with ventilation mode and the use of PEEP. The device should have the capability of generating flow without a compressed-gas source and offer a means of enriching the inspired-gas mixture with oxygen from a low-pressure source such as a concentrator.

Controls

Controls should be large and not easily adjusted accidentally. Any display should be viewable from an angle and in variable ambient light.

Safety

Automatic resuscitators and simple transport ventilators have basic safety features, whereas sophisticated transport ventilators possess safety features comparable with those of critical care ventilators. A pressure-relief valve that vents gas to the atmosphere at a preselected peak inspiratory pressure is essential. Violation of the high-pressure limit should be signaled by a visual or audible alarm. An antiasphyxia valve that allows the patient to breathe from ambient air in the event of power source failure is desirable.[69] Battery-powered ventilators should be equipped with a "low battery" alarm as the battery nears depletion. If the compressed-gas source falls below operating pressure of the ventilator or is empty or disconnected, an audible or visual alarm should sound. Visual alarms are critical when ventilators are used in environments with high levels of ambient noise such as aircraft.

Assembly and Disassembly

These devices should be designed so that incorrect circuit installation is impossible. Typically, there is a single-limb circuit with an external expiratory valve. Patient valves located at the endotracheal tube should be cleared of secretions easily.

PERFORMANCE ISSUES RELEVANT TO ALL TYPES OF TRANSPORT VENTILATORS

Delivered Tidal Volume

Several investigators have demonstrated unreliable tidal volume delivery with transport ventilators, encouraging monitoring with a portable spirometer.[54,70–76] This includes low tidal volumes in the face of low lung compliance and excessive tidal volume under normal loads and at altitude.

Imposed Work of Breathing

Transport and home-care ventilators often used for transport have been shown to have an unacceptable imposed work of breathing.[74–76] Recent studies of new devices show a wide range of capabilities among transport ventilators.[70,76,77] Transport ventilators with flow triggering and PEEP compensation consistently offer the least imposed work of breathing.

Battery Life

Exhaustion of equipment batteries, including transport ventilators, has been reported in multiple studies of critical care transport.[8,14,15,17,30] The consequences of ventilator battery exhaustion can be catastrophic during long transport of patients requiring advanced mechanical ventilation. The battery life among common transport ventilators varies greatly and may differ from values in the user's manual.[78–80] Use of PEEP, pressure-control ventilation, and increasing FI_{O_2} will shorten battery life in electrically powered ventilators while having little effect on pneumatically driven models.[79,80] Battery life should be considered when planning transport. Provisions should be made for extra batteries or use of AC power if the transport duration exceeds battery life.

Oxygen Consumption

It is critical to estimate expected oxygen consumption to plan for a safe transport. It is intuitive that high FI_{O_2} will increase oxygen consumption, but accounting for bias flow, leaks, changes in patient condition, and variability between ventilators is more difficult. A study of military patients found oxygen consumption was 1.6 to 10.2 L/min using the Uni-Vent 754, with a broad range of mechanical ventilation parameters.[80] The LTV 1000 and LTV 1200 offer a cylinder-duration calculator that slightly underestimates cylinder duration.[81] The Dräger portable ventilators and Impact 731 have a continuous display of oxygen consumption on the front panel display. Continuous assessment of oxygen consumption will allow early identification of consumption exceeding estimates, which should prompt a search for leaks, increase efforts to conserve oxygen, and take steps to terminate or divert the transport as needed.

Operation in a Hazardous Environment

Worldwide concern over terrorist events and natural disasters has led manufacturers and investigators to consider use of portable ventilators in hazardous environments. This includes following radiation exposure and airborne biologic

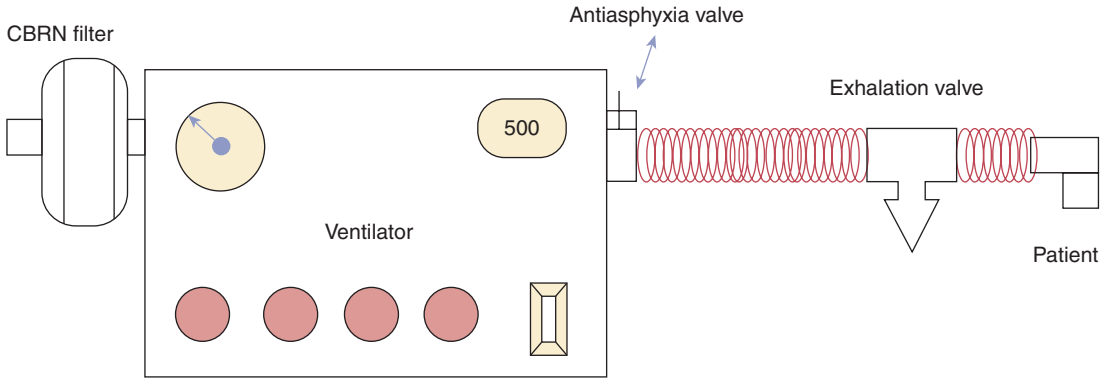

FIGURE 27-7 Placement of the chemical-biologic-radiologic-nuclear (*CBRN*) filter on the ventilator and position of the antiasphyxia valve. Under normal conditions, if patient demand exceeds ventilator output (flow), room air is entrained, which allows contamination of the patient gas and reduces FI_{O_2}.

hazards (anthrax, botulism, nerve agents). A chemical-biologic-radiologic-nuclear filter can be placed on the inlet of the compressor of the ventilator to protect the gas delivered to the patient. A recent study demonstrates that most portable ventilators fail to isolate the patient from ambient air during normal operation.[77] In ICU ventilators, the antiasphyxia valve is kept closed by an electric circuit. The antiasphyxia valve is only opened in the instance of ventilator failure. Portable ventilators typically use a one-way leaf valve in the inspiratory limb between the ventilator outlet and the patient (Fig. 27-7). If patient demand exceeds ventilator output under normal conditions, gas can enter the circuit. This not only exposes the patient to any ambient agents, but reduces FI_{O_2}. Only the Impact 731 routes all gas, including gas via the antiasphyxia valve, through the chemical-biologic-radiologic-nuclear filter. Breathing through the antiasphyxia valve prevents contamination of inspired gas, but does so at the cost of increased work of breathing for the patient secondary to increased resistance.

ANCILLARY EQUIPMENT FOR TRANSPORT

Oxygen Supply

All ventilators require an oxygen supply source. Both compressed-gas cylinders and liquid systems can fulfill this need. Intrahospital transport usually is accomplished with an E cylinder or two E cylinders yoked together. These provide 630 and 1260 liters of gas, respectively. An H cylinder contains 6900 liters and may be required for longer transports. The H cylinder is 152 cm in height, weighs 68 kg, and requires its own attendant.

Liquid-oxygen systems can provide 860 cubic feet of gaseous oxygen for every liquid cubic foot. Most liquid systems, however, cannot operate at 50 psig.

Oxygen concentrators designed for home and ambulatory use have recently been investigated for use during mechanical ventilation.[82] Their utility has not been fully defined, but the concept is theoretically very promising.

Humidification

A passive humidification device, or "artificial nose," is ideal for transport. Use of an artificial nose may result in a progressive increase in breathing circuit resistance, and the patient should be monitored for signs of expiratory–flow restriction. Dead space should be accounted for during low-volume ventilation. Premoistening an artificial nose is inadvisable, does not improve efficiency, and only serves to further increase flow resistance.

SUMMARY

Safe transport of the mechanically ventilated patient requires effective communication, appropriate planning, the presence of key personnel, and compact, rugged equipment. Equipment should meet the demands of patient acuity, and personnel should have the requisite skills and training for the task at hand. Clinicians should be aware of the most frequent complications of transport along with methods of prevention and treatment. The nuances of individual ventilators from battery life and oxygen consumption to imposed work of breathing must be appreciated.

HOME MECHANICAL VENTILATION

Wolfram Windisch

Over the last three decades, home mechanical ventilation (HMV) has become a widely accepted treatment option for patients with chronic hypercapnic respiratory failure that arises from different etiologies such as chronic obstructive pulmonary disease (COPD), restrictive thoracic disorders, neuromuscular disorders, and obesity hypoventilation syndrome.[1,2] There is increasing evidence that HMV is capable of improving symptoms, health-related quality of life (HRQL), and long-term survival in most of these patients,[1–3] although the impact of HMV on survival in patients with COPD is still a matter of debate.[4,5] Thus, HMV should be considered in every patient presenting with symptomatic chronic hypercapnic respiratory failure.

In principle, HMV can be delivered by the application of long-term invasive mechanical ventilation, which requires the insertion of a tracheal tube following tracheostomy. Alternatively, noninvasive ventilation can be used to implement HMV via two possible routes. First, by application of negative pressure ventilation, which achieved international renown in the days when iron-lung ventilation was the preferred method for treating poliomyelitis; nowadays, this technique is seldom used.[2] Second, noninvasive positive-pressure ventilation (NPPV) can be delivered by connecting the natural airways of a patient and the artificial airways of the ventilator system by the use of face masks, which cover either the nose alone (nasal masks) or both the mouth and nose (oronasal masks).[6] Mouthpiece ventilation is an additional option, particularly for neuromuscular patients.[7]

According to a large European epidemiologic study covering more than 21,000 HMV patients from sixteen different countries (Eurovent survey), the overall prevalence of HMV reportedly was 6.6 per 100,000 inhabitants.[8] Substantial variation, however, has been identified among countries in terms of (a) prevalence, (b) the relative proportions of specific patient groups receiving HMV, and (c) HMV techniques. Nevertheless, the number of HMV patients is steadily increasing,[9] and the Eurovent survey only refers to the time span of 2001 to 2002.[8] Moreover, the survey was confined to selected HMV centers that were invited to participate, whereas HMV is increasingly being implemented by many hospitals that are not officially known as HMV centers. Thus, the prevalence of HMV varies substantially between different countries and is at present much higher, at least in some Western countries, than what was estimated by the Eurovent study. Of similar importance is the fact that the pattern of

different conditions underlying chronic respiratory failure is changing over time, with patients suffering from COPD and obesity hypoventilation syndrome experiencing the largest increase in prevalence.[9]

The Eurovent study also identified 13% of the survey population as recipients of invasive ventilation, with the highest percentage comprising patients with neuromuscular disorders (24%). Most patients received NPPV and only 0.005% received other forms unlike positive-pressure ventilation. Thus, NPPV has become the predominant means of delivering HMV.

RATIONALE

The Respiratory System

The respiratory system consists of two independent parts, each of which can be selectively impaired by different pathologies (Fig. 28-1):[10] (a) the lungs, which are responsible for gas exchange, and (b) the respiratory pump, which regulates mechanical movements to ventilate the lungs.

Basically, pulmonary insufficiency leads to hypoxemic respiratory failure, indicating impaired gas exchange; here, oxygen is primarily affected because of its poorer diffusion capacities compared to carbon dioxide. In contrast, ventilatory insufficiency primarily leads to hypercapnia, indicating reduced alveolar ventilation, although hypoxemia also occurs as a result of hypoventilation. This is most often the result of increased load on the respiratory muscles, decreased respiratory muscle capacity, or both, although it can also result from decreased respiratory drive.[10,11]

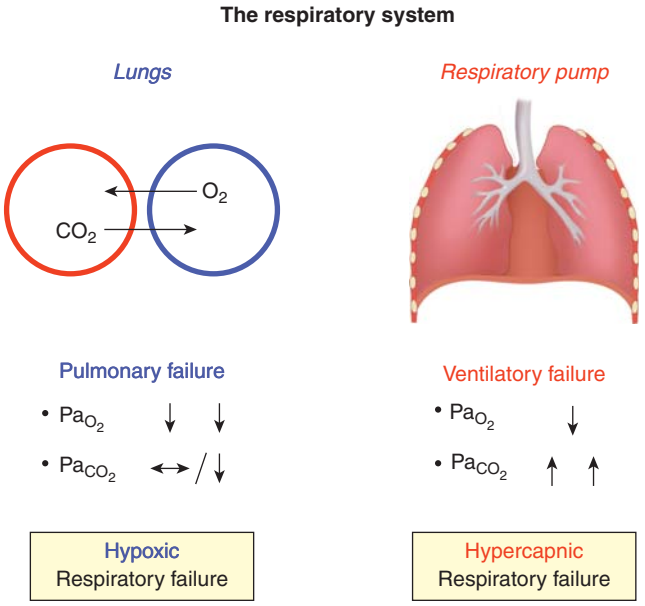

FIGURE 28-1 The two components of the respiratory system. In the lungs, oxygen (O_2) diffuses from the alveolus (*blue*) into the capillary (*red*), while carbon dioxide (CO_2) diffuses from the capillary into the alveolus. The respiratory muscles (*right panel:* diaphragm, intercostal muscles and accessory muscles) are essential for sufficient respiratory pump function. Pa_{O_2}, partial pressure of oxygen; Pa_{CO_2}, partial pressure of carbon dioxide.

The Respiratory Pump

Treatment of chronic respiratory failure primarily depends on which part of the respiratory system is impaired. Chronic pulmonary failure is a well-justified basis for long-term oxygen treatment, with documented improvements in long-term survival in patients with COPD.[12,13] In contrast, chronic failure of the respiratory pump coupled with reduced alveolar ventilation requires artificial augmentation of alveolar ventilation, which can only be achieved by long-term mechanical ventilation, that is, HMV. The indications for HMV are heterogeneous, in accordance with the complexity of the respiratory pump (Fig. 28-2).

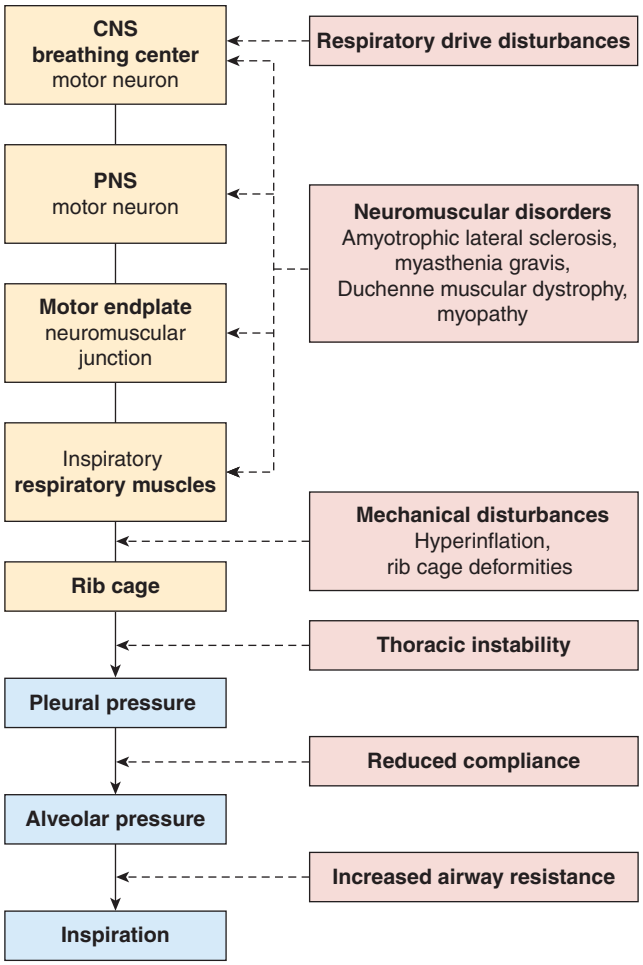

FIGURE 28-2 Primary components of the respiratory pump and the main conditions responsible for impairment, according to anatomical location. *CNS,* central nervous system; *PNS,* peripheral nervous system.

Mechanisms of Home Mechanical Ventilation

Several trials have established that in most patient groups, NPPV used for HMV is capable of improving physiologic variables, the most important of these being blood gases.[1–4,9,14–20] Conflicting results in patients with COPD have been published; the effect of NPPV on blood gases was negligible in some trials,[5,21–23] but a positive effect was clearly documented in other trials.[3,4,24–27] NPPV improves blood gases not only during the time of application, but also during subsequent spontaneous breathing. This benefit has been attributed to an improved breathing pattern with increased tidal volume at an unchanged respiratory rate.[18]

Although the mechanisms by which intermittent NPPV improves subsequent spontaneous breathing remain unclear, three theories have been advanced: (a) respiratory muscle resting; (b) resetting of CO_2 sensitivity in the central breathing center; and (c) changes in pulmonary mechanics.[1,2,20,28,29] The mechanisms are considered complementary rather than contradictory.[1,2] It is, however, still unclear if these mechanisms are unique to all conditions leading to chronic ventilatory failure or are disease related. More recent research suggests that the principal mechanism in patients with restrictive thoracic disorders is an increased ventilatory response to CO_2.[20]

Regarding the assessment of respiratory muscle strength, there is a lack of reliable methodology available. Volitional tests such as the widely used maximal inspiratory pressure method are highly dependent on the patient making a truly maximal effort.[30] In addition, normal values rely greatly on the study cohort and on several methodological aspects; this has resulted in contradictory regression equations for calculating normal values for maximal inspiratory pressure.[31] Thus, this technique is not suitable for physiologic studies. In studies using nonvolitional gold-standard techniques, however, no changes in diaphragmatic muscle strength—as assessed by transdiaphragmatic twitch pressures following magnetic phrenic nerve stimulation—could be observed following initiation of HMV in restrictive thoracic disorders[20] and in COPD.[32]

Another theory for improved spontaneous breathing stems from reports of improved lung function in patients with COPD in whom a substantial reduction in partial pressure of arterial carbon dioxide (Pa_{CO_2}) could be achieved.[3,4,25,26] It has been speculated that the improvement results from a reduction in airway edema.[25,33] Edema is a common finding in patients with COPD and might be related to *cor pulmonale* or possibly volume overload secondary to activation of sodium-retaining mechanisms. This, in turn, is thought to result from a reduction in effective circulating volume, secondary to a fall in total peripheral vascular resistance caused by hypercapnia-induced dilation of the precapillary sphincters.[34] A decrease in hypercapnia by means of HMV would then reverse dilation of the precapillary sphincters and thereby impact positively on the edema, which could improve respiratory mechanics in patients with airway edema.

SELECTION OF PATIENTS

Prerequisites for Home Mechanical Ventilation

There are three mandatory conditions for commencing HMV:[1,2,35] (a) presence of an underlying condition or disease that potentially causes impairment of the respiratory pump and ultimately chronic ventilatory failure; (b) typical symptoms accompanying chronic ventilatory failure, despite optimal treatment; and (c) evidence of a chronically decompensated respiratory pump with reduced alveolar ventilation.

UNDERLYING CONDITION AND/OR DISEASE

Before the commencement of HMV, the cause of the chronic respiratory pump failure needs to be identified and all appropriate treatment strategies instituted. It is necessary to bear in mind that more than one condition can be responsible for the development of chronic ventilatory failure in some patients. Chronic ventilatory failure from the combination of COPD and obesity is especially common. All diseases affecting the respiratory pump may warrant HMV treatment, and the most frequently reported conditions are listed in Table 28-1.

SYMPTOMS AND CLINICAL SIGNS OF CHRONIC VENTILATORY FAILURE

No specific set of symptoms is reliably associated with chronic ventilatory failure because many occur in other conditions. In addition, symptoms (Table 28-2) depend on the underlying disease, its time course, comorbidities, and several other factors, such as medication and symptom perception. Some symptoms, however, are often falsely attributed to other conditions, leaving chronic ventilatory failure undiagnosed. Because one major goal of HMV is to alleviate symptoms, patients should be carefully screened for these symptoms both before and after the commencement of HMV (Table 28-2).

EVIDENCE OF CHRONICALLY REDUCED ALVEOLAR VENTILATION

The most important indicator of reduced alveolar ventilation is an elevated level of partial pressure of carbon dioxide (P_{CO_2}), which can be detected by arterial or capillary blood gas analysis, end-tidal recording, or transcutaneous measurement (Table 28-3).

Although arterial measurement is regarded as the reference standard, transcutaneous measurements are increasingly recognized as being reliable. This has been attributed to technical refinements, which include the prevention and correction of measurement drifts.[36,37] The advantage of transcutaneous measurements is that they enable noninvasive and continuous assessment. The technique is especially attractive

TABLE 28-1: CONDITIONS MOST COMMONLY MANAGED BY HOME MECHANICAL VENTILATION

Obstructive disorders

- Chronic obstructive pulmonary disease
- Cystic fibrosis
- Bronchiectasis
- Bronchiolitis obliterans

Restrictive thoracic disorders

- Kyphoscoliosis
- Posttuberculosis sequelae
- Thoracoplasty
- Restrictive pleural disease
- Bechterew disease
- Severe kyphosis

Neuromuscular disorders

- Amyotrophic lateral sclerosis
- Muscular dystrophy (Duchenne and others)
- Critical illness polyneuropathy and myopathy
- Paraplegia
- Phrenic nerve paralysis
- Postpoliomyelitis
- Myopathy (congenital, metabolic)
- Spinal muscular atrophy
- Myasthenia gravis
- Curschmann-Steinert disease

Obesity-hypoventilation syndrome

Central respiratory drive disturbances

- Primary: Ondine's Curse
- Secondary: brainstem alterations

TABLE 28-2: KEY SYMPTOMS AND CLINICAL SIGNS RELATED TO CHRONIC RESPIRATORY FAILURE

Symptoms and signs of the underlying disease

Symptoms and signs of the mechanical imbalance

Dyspnea
Tachypnea
Pathologic breathing pattern (depending on the underlying disease)

Symptoms and signs related to sleep disordered breathing

Tiredness
Daytime sleepiness
Nonrestful sleep
Poor concentration
Mental alterations

Symptoms and signs related to hypercapnia-induced vasodilation

Vasodilation in the eyes
Headache (particularly in morning)
Peripheral (airway) edema

TABLE 28-3: P_{CO_2} MONITORING

Method	Advantages	Disadvantages
Arterial (Pa_{CO_2})	• Reference standard • Other parameters coeval	• Invasive and painful • Selective
End-tidal ($P_{ET}CO_2$)	• Continuous • Noninvasive	• Unreliable in case of leakage • Unreliable in $\dot{V}/\dot{Q}$ mismatch
Transcutaneous ($PtcCO_2$)	• Continuous • Noninvasive	• Drift of values over time • Problematic in skin abnormalities

Abbreviations: Pa_{CO_2}, arterial partial pressure of carbon dioxide; $P_{ET}CO_2$, end-tidal partial pressure of carbon dioxide; $PtcCO_2$, transcutaneous partial pressure of carbon dioxide; $\dot{V}/\dot{Q}$, ratio of ventilation and perfusion.

during sleep, because sleep is not disturbed by an invasive procedure and it also captures any variations in alveolar ventilation (Fig. 28-3.)

Indications for Home Mechanical Ventilation

HYPERCAPNIA

Initially, hypercapnia typically occurs during the night, and the patient may still be normocapnic during the day. Therefore, nocturnal measurements of P_{CO_2} are required to avoid overlooking the onset of chronic ventilatory failure. There are, however, no established cutoff values for nocturnal or daytime P_{CO_2} that would reliably indicate the need for HMV. Previous international recommendations have provided P_{CO_2} cutoff values for specific disease groups, but these recommendations are based on expert consensus rather than reliable research[1]; moreover, this report only refers to NPPV, thus excluding invasive mechanical ventilation. The report[1] recommends long-term NPPV for restrictive patients when Pa_{CO_2} is equal to or higher than 45 mm Hg, while a Pa_{CO_2} equal to or higher than 55 mm Hg is recommended in patients with COPD. In cases where nocturnal desaturations occur, despite oxygen treatment, or in cases with recurrent hospitalizations in order to manage acute hypercapnic respiratory failure, a Pa_{CO_2} reading of 50 to 54 mm Hg warrants long-term NPPV.[1] Although detailed criteria are provided in the recently published German guidelines for HMV,[35] and a Canadian guideline is in preparation (personal communication), an international consensus on when to start HMV has not been reached. However, HMV needs to be carefully considered, not just in terms of Pa_{CO_2} levels. Patients should be severely symptomatic with reduced quality of life, and should also be very likely to benefit from the therapy. This is particularly important for patients with COPD in whom clear improvements in long-term survival have yet not been scientifically

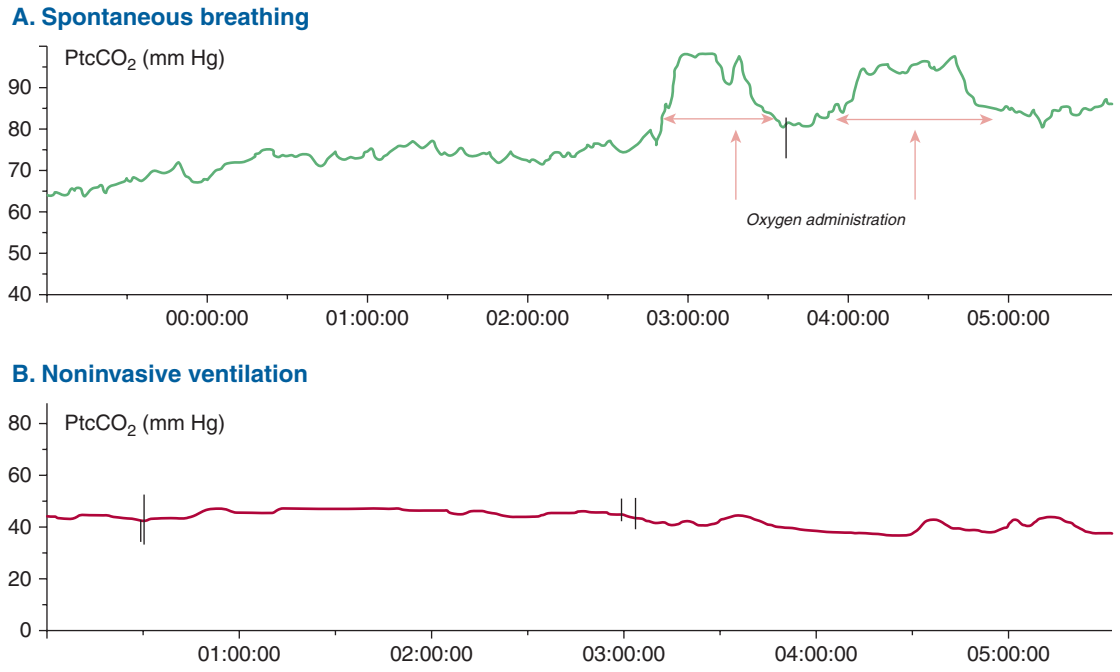

FIGURE 28-3 Transcutaneous carbon dioxide tension ($PtcCO_2$) monitoring in a 49-year-old patient with chronic ventilatory failure secondary to amyotrophic lateral sclerosis. **A.** $PtcCO_2$ starts with values of 65 mm Hg during spontaneous breathing and progressively increases during sleep. Administration of oxygen produces an increase in $PtcCO_2$, likely caused by reduced alveolar ventilation. **B.** Home mechanical ventilation by means of noninvasive ventilation produces normalization of $PtcCO_2$.

established.[5,22,23] Nevertheless, the use of HMV for preventive purposes in nonhypercapnic patients should be avoided.[38]

For the commencement of HMV, chronic hypercapnic failure with normal pH (resulting from bicarbonate retention) should be established and distinguished from acute hypercapnic respiratory acidosis (Table 28-4).

NONINVASIVE VERSUS INVASIVE LONG-TERM MECHANICAL VENTILATION

In general, NPPV should be used in preference to invasive mechanical ventilation, which is used more often in neuromuscular patients following tracheostomy than in other disease groups.[8] In particular, tracheostomy is indicated for the following conditions[39–43]: lack of mask fitting; intolerance of, or claustrophobia with, mask ventilation; ineffective ventilation; impaired bulbar function with recurrent episodes of aspiration; insufficient noninvasive management of secretions requiring suction via a tracheal cannula; and failure to wean off invasive mechanical ventilation following intubation.

It is extremely important to comprehensively inform the patient and the family members about tracheostomy and its consequences. Patients' self-determination is a top priority, and decision making should be based not only on objective circumstances but also on the subjective perspective of the patient.

ORGANIZATION

Specialized Center for Home Mechanical Ventilation

Patients receiving HMV should be managed in a specialized center that is familiar with the specific circumstances and problems occurring in such patients.[35] Here, high-quality, individually customized care is paramount, and it is essential that the treatment plan can be readily adapted to any necessary changes in the ventilator mode, settings, and interface, as well as in the duration, of mechanical ventilation. In all cases where the proposed treatment is

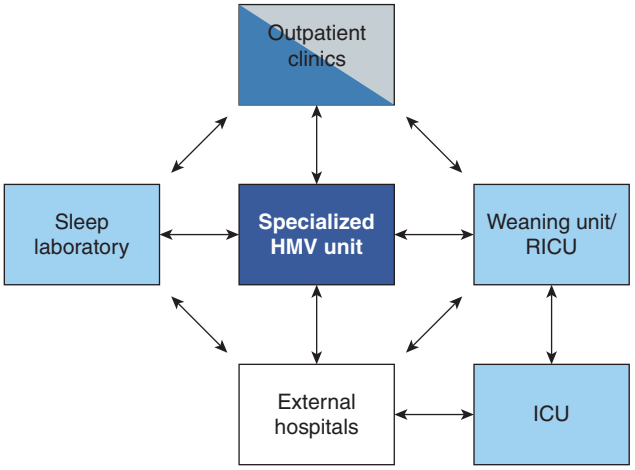

FIGURE 28-4 Specialized center for home mechanical ventilation. Patients are usually transferred to the HMV unit from other units within the specialized center, such as the sleep laboratory and weaning unit (*light blue*), or from external facilities (*white*) including outpatient clinics and external, nonspecialized hospitals. Return transfer should be facilitated at all times, according to patient's needs. *ICU,* intensive care unit; *RICU,* respiratory intensive care unit.

subject to alteration, the patient, together with relatives and all associated therapists, must be included in the decision-making process, which must include close consultation and good organization between all participating individuals.

It is well recognized that the organizational structures vary considerably among countries and regions.[8] Preferably, a specialized unit is set up exclusively for HMV and integrated into a network of specific units qualified for treating patients with mechanical ventilation (Fig. 28-4). Patients are usually admitted to the HMV unit from different sites within the same center, or from external sites (Fig. 28-4). Because many patients have sleep-disordered breathing, the center should provide easy access to full polysomnography, preferably within an in-house sleep laboratory. Many patients, particularly those with obesity hypoventilation syndrome, are primarily admitted to a sleep laboratory for diagnosis of sleep disturbances. In this case, sleep-related hypoventilation with deteriorating hypercapnia must not be overlooked, thus requiring close monitoring of nocturnal P_{CO_2} and the transfer to the HMV unit where appropriate.

Especially confounding is the fact that HMV candidates are not always patients electively admitted to hospital: Some patients may also present with weaning failure consequent to ventilator management for acute respiratory failure (see Fig. 28-4). These patients are usually transferred from the intensive care unit to the HMV unit via a weaning unit ("step-down").[43] With the marked increase in the number of severely ill weaning-failure patients being admitted to a weaning unit,[44] close cooperation between the weaning and the HMV units is mandatory, because many weaning-failure patients are ultimately established on HMV.[43,44]

Staffing and Training

Hospital staffing requirements depend on the type and severity of a patient's underlying disorder. Staffing also relies on the local conditions of the center, such as experience, size, and country-specific organization of health care.[8] Accordingly, great variation in staffing demands exists amongst different centers. Nevertheless, the global standards for staff include satisfactory training in mechanical ventilation techniques that covers both invasive and noninvasive ventilation. The team must be familiar with specific treatment modalities, such as airway clearance techniques, management of acute respiratory failure, and disease-specific issues.[45,46] It is the responsibility of the center to provide sufficient staff training for all professionals involved, which may include: nurse, physician, physiotherapist, equipment provider, psychotherapist, respiratory therapist, and social worker.

In addition, a speech therapist, a nutritionist, or other therapist may be necessary at some point during the treatment of patients with HMV.

Transferring patients from hospital-based to home-based treatment is always a challenge.[35,45–48] The challenge results from the necessity of replacing the in-hospital care team with an out-of-hospital care team, which may also include lay helpers, most importantly relatives. Training of all people caring for HMV patients in the home environment is essential.[35,45,46] In addition, the specialized center and the provider should always be contactable for solving medical and technical problems, respectively.[35,45,49]

Discharge from the Center and Transfer to Home Mechanical Ventilation

Both the underlying and secondary illnesses need to be in a stable condition before discharge.[50] If an optimal level of function and performance is not yet reached, (early) rehabilitative measures should be considered.[35,45] In addition, the fulfilment of costs and provision of the necessary equipment, resources, and materials need to be ascertained in advance.[35] Individual requirements for patient discharge and subsequent setup of the home-ventilation station vary significantly from patient to patient. Table 28-5 is a checklist of the minimal requirements.[35]

Control Visits

Control visits include the collection of data on compliance, side effects, ventilation techniques, and daytime respiratory function, and also on nocturnal diagnostics, particularly nocturnal assessment of alveolar ventilation. Preferably, this should be performed in the specialized center where the patient has been initially treated. The first control examination after commencement of HMV should take place 4 to 8 weeks after discharge.[35,47,51] Subsequent

TABLE 28-5: CHECKLIST OF MINIMAL REQUIREMENTS FOR PATIENT DISCHARGE AND SUBSEQUENT SETUP OF A HOME VENTILATION STATION

Full technical installation of the ventilator machinery and surveillance systems
Surveillance standards in terms of personnel (nurse attendance time)
Time schedule and content of nursing procedures
Type of ventilation interface and the corresponding cleaning and exchange intervals
Detailed description of ventilator mode and associated parameters
Duration of assisted ventilation and, if applicable, phases of spontaneous ventilation
Oxygen flow rates during assisted and spontaneous ventilation
Procedures for managing secretions
Application of inhaled medication
Planning for nutritional needs
Psychosocial care of the patient and, if applicable, the relatives
Additional therapeutic and educative measures
Additional resources (e.g., rollator, therapeutic bed, communication aids)

Based on Windisch et al.[35]

control visits typically occur once or twice a year and are carried out on an individual basis, depending on the type and progression of the underlying disease.

SPECIFIC ASPECTS OF NONINVASIVE VENTILATION UNIQUE TO HOME MECHANICAL VENTILATION

Impact of Ventilator Modes and Settings

VOLUME-LIMITED VERSUS PRESSURE-LIMITED NONINVASIVE POSITIVE-PRESSURE VENTILATION

Volume-limited NPPV initially served as the primary mode for HMV, but pressure-limited NPPV has become the dominant mode,[8,9] probably because constant peak inspiratory pressures (provided by pressure preset) are better tolerated than varying peak inspiratory pressures (provided by volume preset). In addition, ventilators providing pressure-limited ventilation are cheaper. According to the Eurovent study, volume-limited forms of mechanical ventilation were used in only 15% of patients with chronic lung diseases and in 28% of patients with restrictive thoracic disorders, although in a relatively higher number (42%) of patients with neuromuscular disorders.[8]

Physiologic studies show that leak-compensation capabilities, that is, increases in inspiratory flow in the event of air leakage, are only available for pressure-limited ventilator modes, and this holds true for both in vitro[52] and in vivo[53] conditions. Early comparative trials revealed conflicting results, but interpretation of the findings is hindered by short observational periods, uncontrolled study design, and the lack of concomitant sleep studies.[54–57] Two randomized, controlled, crossover trials, however, confirmed that the two modes were, on average, equally effective in improving alveolar ventilation during sleep, both in a mixed cohort that included patients with COPD[17] and in a group of patients with restrictive thoracic disorders.[58] The first trial also indicated that pressure preset is better tolerated secondary to less gastrointestinal side effects,[17] while the second trial suggested that switching from one mode to the other mode can provide individual benefits in terms of gas exchange.[58] Thus, there is no clear global advantage for one or the other mode, although changing the mode might be worthwhile for individual patients.

TARGET VOLUME

Most of the new-generation HMV ventilators provide the opportunity to set a so-called target volume. This expression describes a feature, in which the advantages of pressure preset (better tolerance because of less variation in peak inspiratory pressures) and volume preset (volume stability) are combined. Primarily, a pressure-limited mode is used, but instead of a fixed peak inspiratory pressure, a pressure range with minimal and maximal pressure is set at the ventilator. In accordance with the automatic calculations and adjustments of the ventilator, the pressure is thereby changed within a range so as to reach the preset target volume. Nomenclature and algorithms used for pressure adaption vary considerably among different types of ventilators.

Despite target volume being increasingly implemented in HMV ventilators, evidence supporting this new feature is sparse and long-term trials are nonexistent. The first randomized, controlled, crossover trial demonstrated that after 6 weeks of HMV using target volume settings, bi-level positive airway pressure ventilation was more effective, in comparison to settings without target volume, in improving gas exchange in patients with obesity hypoventilation syndrome; moreover, quality of life and polysomnographic sleep quality showed a comparable improvement following HMV.[59] Two further studies predominantly in patients with obesity-related chronic ventilatory failure revealed improvements in respiratory function through use of target volume settings[60,61]; in one study, however, this occurred at the expense of objective and subjective sleep quality and comfort during ventilation.[61] Finally, a randomized, controlled, crossover study on patients with COPD showed comparable results after 8 weeks of HMV.[62]

HIGH-INTENSITY NONINVASIVE POSITIVE-PRESSURE VENTILATION

High-intensity NPPV has been described as a new approach in patients with COPD (Table 28-6).[4,18,25–27,36,53,63,64] In an attempt to decrease elevated Pa_{CO_2} values, controlled ventilation with high inspiratory pressures (range: 20 to 40 cm H_2O) is implemented in the hospital setting and subsequently

TABLE 28-6: HIGH-INTENSITY NONINVASIVE POSITIVE-PRESSURE VENTILATION IN PATIENTS WITH CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Definition	• NPPV aimed at maximally reducing elevated Pa_{CO_2} values with the major goal of achieving normocapnia or minimal Pa_{CO_2} values using high ventilator settings, as maximally tolerated or necessary.
Procedure	• Mode: assisted or controlled, preferably pressure-limited, NPPV. • Use daytime NPPV first, with the primary aim of establishing tolerance, but also with control of blood gases and vital parameters. • Start with lowest backup respiratory rate and most sensitive trigger threshold (assisted NPPV); use low IPAP levels, typically ranging from 12 to 16 cm H_2O, and the lowest EPAP levels. • Then, carefully increase IPAP in a stepwise approach until maximal tolerance is reached, usually up to 30 (range: 20 to 40) cm H_2O. • Then, increase the respiratory rate just beyond the spontaneous rate to establish controlled ventilation. • Then, set EPAP so as to avoid dynamic hyperinflation according to subjective comfort (usually 3 and 6 cm H_2O), and similarly, set the I:E ratio to 1:2 or lower. • Once daytime tolerance is acceptable, apply nocturnal NPPV. • Adjustments to ventilator settings are made according to subjective tolerance and nocturnal monitoring of blood gases.
Pitfalls and practical advice	• Tolerance of higher IPAP levels can last from minutes to several days; individual adjustment is inevitable. • In cases of coexisting upper airway obstruction, higher EPAP levels are required. On the other hand, higher EPAP reduces the effective IPAP (which is IPAP minus EPAP); thus, avoid high EPAP levels if not required. • For controlled NPPV (final aim), respiratory rates are typically set to 1 breath/min higher than during spontaneous breathing; thus, avoid excessively high respiratory rates, although try to establish controlled ventilation. • Try out several masks: for nocturnal NPPV, use oronasal masks because of potentially substantial leakage; for daytime NPPV, a nasal mask is often better tolerated. Again, individual adjustment is mandatory. • Several days in hospital are usually necessary to establish high-intensity NPPV. • Use humidification in cases of dry mucous membrane. • Leakage is unavoidable, but should be kept as low as possible. • Gastrointestinal side effects can be managed by medication, positioning, and adjustment (reduction) of ventilator settings.
Physiologic effects	• Improvement in blood gases during NPPV.[4,18,26,27] • Improvement in blood gases during subsequent spontaneous breathing.[3,4,18,25–27] • Improvement in breathing pattern during spontaneous breathing.[18] • Improvement in lung function.[3,4,25,26] • Improvement in global inspiratory muscle strength.[18] • Increases in hematocrit in anaemic patients.[25] • Reduces hematocrit in patients with polyglobulia.[25] • Superior to low-intensity NPPV using assisted ventilation with low IPAP regarding the improvement of blood gases.[4,63]
Clinical effects	• Improvement in health-related quality of life.[3,4,18] • Improvement in dyspnea while spontaneous breathing during walking.[4] • Improvement in dyspnea and walking distance during NPPV-aided walking compared to unaided walking.[64] • Acceptable sleep quality.[17,63] • Superior to low-intensity NPPV using assisted ventilation with low IPAP regarding adherence to therapy.[4]
Important unknowns	• Improvement of long-term survival?

Abbreviations: EPAP, expiratory positive airway pressure; *I:E*, inspiratory-to-expiratory timing; *IPAP*, inspiratory positive airway pressure; *NPPV*, noninvasive positive–pressure ventilation; Pa_{CO_2}, arterial partial pressure of carbon dioxide.

used for HMV. Several physiological and clinical variables are reportedly improved by this approach (Table 28-6). This technique contrasts with the conventional approach of using assisted ventilation with low inspiratory positive pressures (typically 10 to 16 cm H_2O), defined as low-intensity NPPV,[5,21–23,65–68] which fails to effectively improve respiratory function. Direct comparisons following two randomized crossover trials clearly show the superiority of high- over low-intensity NPPV (Table 28-6).[4,63] Consequently, high-intensity NPPV is the first choice for HMV in patients with COPD.

QUALITY CONTROL OF VENTILATOR SETTINGS AT HOME

For HMV to be successful, it is essential that patients use the prescribed equipment as well as the ventilator modes and settings that were established in the hospital. Changing the system or the settings can reduce the quality of ventilation and result in either hypoventilation or hyperventilation. For this reason, a quality assessment of ventilator performance at home has been proposed.[51] A recent survey including 326 centers visited by more than 20,000 patients in sixteen European countries revealed significant deficits

in quality control; only 56% of centers assessed whether the patients and/or caregivers correctly cleaned or maintained the ventilator.[51] Considerable intercountry and intracountry differences were observed, and the size of the center was a major determinant of several quality-control aspects.[51] Considerable differences were found between several prescribed versus actually implemented ventilator variables, and important alarm functions, such as power off, disconnection, and obstruction, were sometimes defective.[48]

Different interfaces used for HMV have varying physical characteristics. This is particularly true for the resistance component, which is known to be flow-dependent, and applies to interfaces used for both noninvasive[69] and invasive mechanical ventilation.[70] Therefore, changing the interface in the home environment without control measures can produce alterations in the quality of HMV. Indeed, the type of interface has been shown to affect NPPV outcome even more than the ventilator mode.[71] Thus, changes to the ventilator system, the settings or interface should be done with adequate control in cooperation with the HMV-prescribing center.

Side Effects

Most side effects of HMV arise from the mismatch between the artificial airway and the natural human airway, although complications may also be caused by the ventilator itself. Side effects are highly dependent on whether invasive or noninvasive HMV is used (Table 28-7). Although side effects are common,[2,3,17] NPPV is safe. Nevertheless, side effects can impair HRQL and necessitate the discontinuation of ventilator treatment. Every effort should be made to minimize side effects. For example, humidification should be provided in cases of dry mouth or throat, and facial soreness or erythema or ulceration, resulting from mask pressure, can be ameliorated by minimizing strap tension or switching to an alternative interface. Despite frequently reported side effects, NPPV can improve symptoms and HRQL in many patients.[3]

The frequency and dimension of side effects depends on several factors including the ventilator modes, settings and interfaces. For example, volume-limited NPPV produces more gastrointestinal side effects because of higher and more variable peak inspiratory pressures as compared with pressure-limited NPPV.[17] Side effects of NPPV tend to diminish once patients become more familiar with HMV.[3]

TABLE 28-7: THE MOST RELEVANT SIDE EFFECTS OF HOME MECHANICAL VENTILATION

Noninvasive Home Mechanical Ventilation	Invasive Home Mechanical Ventilation
Mask-related:	*Canula-related:*
• Facial and/or nasal soreness • Facial and/or nasal erythema or rash • Facial and/or nasal ulceration • Gum pain	• Tracheal injury and/or bleeding/pain • Tracheal stenosis and/or tracheomalacia • Tracheal granulation tissue • Tracheal stenosis and/or fistula • Dislocation and/or obstruction • Difficulties in speaking and/or coughing • Infections
Airflow and air pressure or leakage related:	*Airflow and air pressure related:*
• Dry nose and/or throat and/or bronchial tree • Nasal congestion • Eye irritation • Ear and/or sinus pain • Epistaxis • Gastric insufflation and/or distension • Belching and/or flatulence • Abdominal pain • Nausea/vomiting	• Barotrauma • Volutrauma
Sleep problems:	*Sleep problems:*
• Not falling asleep • Sleep disruption	• Not falling asleep • Sleep disruption

OUTCOME

Long-Term Survival

There is overwhelming evidence that following the commencement of HMV, long-term survival is markedly improved in patients with restrictive thoracic diseases and neuromuscular disorders, particularly those that are slow-progressing,[19,72] although the effect of HMV on outcome in patients with COPD is still a matter of debate.[4,5,21–23] Evidence for improved survival in restrictive and neuromuscular patients is derived mostly from uncontrolled trials, but the data are sufficiently robust enough to support the conclusion that survival is increased in these patients. Randomized controlled trials in these patient groups presumably will never be conducted because of ethical concerns.[72]

Detailed information for six diseases typically treated by HMV follows.

EARLY KYPHOSCOLIOSIS

In landmark observational trials of the 1990s, 1-year survival rates reached 90% in patients with kyphoscoliosis following the commencement of NPPV treatment.[14,15] The 5-year survival rate was almost 80%,[9,15] and the 9-year survival rate reported by the Swedish registry reached 55%.[73] Survival was better in kyphoscoliosis patients receiving HMV compared to patients receiving long-term oxygen treatment, even though the HMV patients were deemed to be more ill.

POSTTUBERCULOSIS SEQUELAE

Five-year survival rates in patients with posttuberculosis sequelae were higher than 90% in one study,[15] although survival was considerably lower (50%) in two other trials.[9,74] This discrepancy is likely related to differences in baseline ages of patients: mean age was 61 years in the first trial, but 72 years[74] and 75 years[9] in the other two trials. The Swedish registry revealed that approximately 21% of patients had a 9-year survival rate when HMV was started at a baseline age of 72 years.[74] Uncontrolled data of the Swedish registry reveals that survival in posttuberculosis sequelae patients who received HMV was higher than in those who received oxygen treatment.[74]

DUCHENNE MUSCULAR DYSTROPHY

The mean age at death in patients with Duchenne muscular dystrophy is approximately 19 years if long-term mechanical ventilation is not instituted, and most die from ventilatory failure.[75] Although invasive mechanical ventilation,[75] mouthpiece ventilation,[76] and negative pressure ventilation[77] have shown beneficial effects on long-term outcome, NPPV is considered to be the treatment of choice.[78] Given that mean survival without HMV is less than 10 months once chronic hypercapnic respiratory failure has occurred,[79] the reported 5-year survival rate of 73% in patients with Duchenne muscular dystrophy who received long-term NPPV is phenomenal.[80] Thus, HMV must not be withheld in these patients. These positive results encouraged researchers to apply prophylactic long-term NPPV in nonhypercapnic patients. Unfortunately, NPPV did not ameliorate the respiratory handicap and even reduced survival.[38] Consequently, prophylactic HMV must be avoided. If NPPV is used, additional techniques for clearance of secretions are often required; if invasive ventilation is used, tracheal suction can easily be performed via a canula. The use of NPPV in addition to technically assisted coughing prolongs survival while significantly decreasing the pulmonary morbidity and hospitalization associated with conventional invasive technical ventilation.[81]

AMYOTROPHIC LATERAL SCLEROSIS

In contrast to Duchenne muscular dystrophy, amyotrophic lateral sclerosis tends to progress more rapidly. In addition, bulbar involvement may prevent the patient from receiving NPPV, although tolerance may be feasible in patients with mild-to-moderate bulbar involvement.[78,82] In severe and rapidly progressive neuromuscular disorders, as with amyotrophic lateral sclerosis, fears exist that use of HMV in advanced disease might simply protract death rather than prolong good quality of life.[19] Nevertheless, early, uncontrolled studies suggest that survival can be improved by the addition of NPPV,[82–85] and one randomized controlled trial demonstrated that NPPV improves survival and HRQL in patients with amyotrophic lateral sclerosis, although the survival benefit was restricted to patients without severe bulbar dysfunction.[86]

OBESITY-HYPOVENTILATION SYNDROME

Uncontrolled data suggest that prognosis of untreated obesity-hypoventilation syndrome is poor,[87–90] with a mortality rate of 23% after 18 months in one trial.[90] This contrasts with more recent long-term data on 126 patients showing 1-, 2-, and 5-year survival rates of 97%, 92%, and 70%, respectively, in patients treated with NPPV. A reduction in nocturnal Pa_{CO_2} by 23% or more was associated with improved survival rates in this trial.[91] Large randomized controlled, long-term trials do not exist, and several issues still need to be addressed, including the need to define clear treatment goals.[87] It is also unclear which type of ventilator support should be used in which patient. Recent data has convincingly shown that continuous positive airway pressure and bi-level ventilator support were equally effective in improving daytime hypercapnia in patients without severe nocturnal hypoxemia,[92] although differences in the effects on long-term survival still need to be established.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

In contrast to restrictive and neuromuscular patients, HMV has not been convincingly shown to improve survival in COPD. The approximate 5-year survival rate is 43%, which is much lower than in restrictive patients (excluding those with rapidly progressive diseases).[14] Two randomized controlled trials showed no survival benefit.[22,23] An Australian randomized controlled trial observed an improvement in survival, but this applied to the adjusted, but not to the unadjusted model; this minor effect occurred at the cost of worsening HRQL.[5] Low-intensity NPPV was used in most randomized controlled trials, and also failed to effectively improve respiratory function.[5,21–23] One could argue that improved survival cannot really be expected if the specific modality fails to improve physiology, that is, if NPPV is relatively ineffective. In contrast, high-intensity NPPV has indeed been shown to improve several physiological and clinical variables[3,4,18,25–27,63,64] and 5-year survival (58%) was higher than that previously reported.[18] This promising approach needs to be tested for survival benefits in randomized controlled trials.

Health-Related Quality of Life

HOW CAN HEALTH-RELATED QUALITY OF LIFE BE MEASURED IN PATIENTS WITH HOME MECHANICAL VENTILATION?

Evaluation of HRQL provides an important means of evaluating the human and financial costs and benefits of modern medical treatment modalities.[93–95] HRQL evaluation is particularly important for patients with chronic and noncurable disorders, and from a patient's point of view,

TABLE 28-8: THE MOST FREQUENTLY USED INSTRUMENTS FOR ASSESSMENT OF HEALTH-RELATED QUALITY OF LIFE IN PATIENTS RECEIVING HOME MECHANICAL VENTILATION

Instrument	First Author	Subscales (n)	Items (n)

Severe Respiratory Insufficiency questionnaire (**SRI**)[106,107]	Windisch W	7	49

the effect of HMV on HRQL may be more important than its effect on long-term survival.

Questionnaires are the most frequently used tool for HRQL assessment, and it is crucial that essential psychometric properties—the most important being objectivity, reliability, validity, sensitivity, and responsiveness—are established before they are used as an HRQL assessment tool in clinical trials.[93] Although generic questionnaires are not tailored to a particular disease and can thus be applied comparably in different diseases, they lack sufficient responsiveness and sensitivity to specific treatment interventions; thus these instruments only qualify for comparative, cross-sectional HRQL assessments. The opposite is true for disease- or condition-specific instruments, which are primarily designed to longitudinally assess changes in HRQL, but restricted to the particular condition for which they are developed.[93] Table 28-8 lists the instruments most frequently used in HMV cohorts.

The Severe Respiratory Insufficiency Questionnaire is a multidimensional health measure (Fig. 28-5), developed exclusively for patients receiving HMV.[106,107] It is valid for a broad variety of diseases, including restrictive thoracic and neuromuscular disorders, and obesity hypoventilation syndrome,[106] and additional research supports the questionnaire's validity for patients with COPD.[107] Intercultural

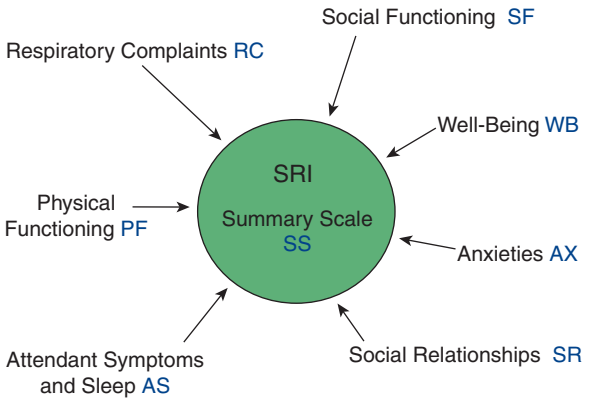

FIGURE 28-5 The multidimensional Severe Respiratory Insufficiency (SRI) Questionnaire with seven subscales.

adaption is currently in progress, with ten professional translations in the process of validation or consideration (Table 28-9.)

IMPACT OF THE UNDERLYING DISEASE ON HEALTH-RELATED QUALITY OF LIFE

The first study to systematically analyze HRQL in HMV patients readily established that the underlying disease is a main determinant of HRQL, with patients suffering from posttuberculosis sequelae experiencing worse HRQL than other restrictive patients, particularly those with kyphoscoliosis.[114] This study indicated that patients who are stable while receiving HMV have only minor impairments in psychosocial components of HRQL, similar to that of patients with other chronic diseases. The underlying disease has also been shown to be a determinant of HRQL in patients with chronic ventilatory failure who are not receiving HMV.[115] More recent research demonstrated that patients with COPD and posttuberculosis sequelae have more HRQL impairments than patients with other restrictive thoracic or neuromuscular disorders,[106,116,117] and that

mental health can be well preserved, despite severe physical handicaps, particularly in patients with Duchenne muscular dystrophy.[116] HRQL as assessed by the Severe Respiratory Insufficiency Questionnaire was an overall predictor of long-term survival in patients without COPD receiving HMV.[117]

IMPACT OF HOME MECHANICAL VENTILATION ON HEALTH-RELATED QUALITY OF LIFE

Numerous studies have investigated the influence of HMV on HRQL. Many of these trials used generic HRQL measures because specific instruments were not widely available at the time. Interpretation of these trials is limited because generic instruments do not cover the specific issues relevant to patients with chronic respiratory failure and are postulated to be less sensitive to any changes occurring.[93]

Compared to the effect on survival, there is little doubt that HMV substantially improves both HRQL (as assessed by the Severe Respiratory Insufficiency Questionnaire)[3,59] and sleep quality[16,17,59] in patients with restrictive diseases. In contrast, longitudinal studies, mostly using COPD-specific HRQL measures, have only recorded minor and inconsistent improvements in HRQL following HMV in patients with COPD.[118–120] One randomized controlled trial reported that application of the COPD-specific St. George's Respiratory Questionnaire revealed no differences in HRQL when HMV plus long-term oxygen therapy was compared to long-term oxygen therapy alone; in contrast, application of the more condition-specific Maugeri Foundation Respiratory Failure item set showed that HMV improved HRQL.[23] Thus, even COPD-specific instruments may fail to reliably show HRQL changes in patients with severe COPD. This observation is probably attributable to the fact that these instruments were developed for patients with milder COPD.[105] Nevertheless, the Severe Respiratory Insufficiency Questionnaire revealed substantially improvements in HRQL in patients with COPD following commencement of HMV.[3,4,18] These improvements were similar to those seen in restrictive patients. Therefore, robust data support the conclusion that HMV can improve HRQL in several different disease groups including patients with COPD.

IMPORTANT UNKNOWNS AND FUTURE CONSIDERATIONS

Despite HMV being fully accepted as a treatment option for patients with chronic respiratory failure, some important questions remain open.

First, new features and modes are being developed by the manufacturers of home ventilators. These are aimed at not only improving the tolerance and quality of ventilation, but also at facilitating the application of home ventilators. Scientific evidence, however, for these developments is lacking. A good example is target volume. Its rationale is clear and target volume has been implemented in various ventilators, although robust evidence to support its use is not available. New features with new names and abbreviations inevitably overwhelm the user. From a technical point of view, HMV has been extremely successful for decades and although technical refinements are warranted, the challenge for future research is to differentiate between the innovations that help patients and those that cause confusion without any benefit.

Second, a pressing issue to determine circumstances in which HMV can prolong life in patients with COPD. Here, the new approach of high-intensity NPPV is promising and needs testing with regards to its potential for improving survival. It is not just different ventilator strategies that need to be investigated; clearly specified criteria for starting HMV also need to be established. Recent research has demonstrated that institution of HMV following an acute exacerbation complicated by respiratory acidosis and the need for acute mechanical ventilation was capable of preventing recurrent clinical deterioration.[121,122] Whether further acute readmissions to hospital can be prevented by HMV application and whether this impacts survival is a question that needs to be elucidated in the future.

Third, HMV undoubtedly improves HRQL. Nevertheless, the clinical status of patients eventually deteriorates, ultimately leading to death, and there is no conclusive information about end-of-life issues and decision making in the terminal phase of seriously ill HMV patients. There is only one study, which indicates that many HMV patients during their last 3 months of life frequently had respiratory symptoms and received inadequate medication.[123] The family burden was high and more than 50% of patients were eventually hospitalized and many died in the hospital or even in the intensive care unit. Research should not only focus on physiologic, epidemiologic, technical, structural, financial, and outcome aspects, but also study how patients with HMV eventually die and how HRQL in the terminal phase can be improved so as to enhance the quality of dying.[124]

SUMMARY AND CONCLUSION

HMV has become a standard treatment for patients suffering from chronic ventilatory failure, with the most frequently treated diseases being COPD, restrictive thoracic disorders, neuromuscular disorders, and obesity-hypoventilation syndrome. NPPV using face masks has become the modality of choice, although some patients, particularly those with neuromuscular disorders and difficulties in clearing their secretions, still use invasive mechanical ventilation via tracheostoma, which enables tracheal suctioning.

HMV should be started when a disease or a particular circumstance is causing impairment of the respiratory pump, and there is evidence of chronic ventilatory failure together with symptoms related to chronic hypoventilation, especially dyspnea and sleep-disordered breathing,

headache, or edema. Ventilation should be commenced in specialized centers with suitable experience. Staff training and close collaboration between the ventilation center and the people caring for the patient in the home environment are essential for successful treatment. HMV has been shown to improve symptoms, quality of life, and long-term survival in most of these patients, but its full impact on long-term survival in patients with COPD still needs to be established. Finally, understanding how patients receiving HMV die and how the quality of dying can be improved needs to be elucidated in the future.

MECHANICAL VENTILATION IN THE ACUTE RESPIRATORY DISTRESS SYNDROME

John J. Marini

Few areas of critical care medicine have been the subject of as much investigative attention or clinical concern as the set of problems grouped under the label *acute respiratory distress syndrome* (ARDS). This syndrome, first formally described in 1967,[1] continues to be recognized clinically as a rapidly developing impairment of pulmonary oxygen exchange accompanied by diffuse infiltrates and altered respiratory system mechanics that cannot be attributed solely to hydrostatic forces. Fueled by better characterization of innate pathophysiology and of iatrogenic factors, considerable progress has been made in recent years toward reducing the adverse consequences of this condition. Yet, after more than four decades, active debate continues regarding key elements of the ventilatory prescription and appropriate therapeutic targets.

From the outset, mechanical ventilation with positive pressure has been essential in addressing the life-threatening gas exchange abnormalities and otherwise unsustainable workloads associated with ALI. Only in the relatively recent past, however, has there been clear documentation that the tidal pressures of mechanical ventilation can impact morbidity and survival.[2,3] This awareness has caused a conceptual shift away from attempting to restore normal blood gases at the costs of high pressure and toward adopting the avoidance of preventable iatrogenicity ("lung protection") as the first priority.

Many aspects of the debate concerning appropriate ventilator management of this group of conditions can be traced to the heterogeneity of the patient population, to our still imperfect comprehension of the mechanisms of

TABLE 29-1: CONCEPTUAL PRINCIPLES IN ACUTE RESPIRATORY DISTRESS SYNDROME VENTILATION

ARDS is a heterogeneous problem
Between patients
Over time
Between lung regions
Risk for ventilator-induced lung injury is proportional to *transalveolar* pressure
Lung recruitment is essential to avoid ventilator-induced lung injury
The chest wall influences regional lung volumes, tolerated pressures, and recruitability

ventilator-associated lung injury (VILI) and to the relative imprecision of the criteria upon which the label *ARDS and/or acute lung injury* (*ALI*) is assigned.[4] Despite an incomplete and still evolving understanding, a rich experimental and clinical database—much of it collected over the past two decades—allows for the development of a rational set of principles upon which to formulate an effective ventilation strategy.[5–7] Definitive answers for many important clinical questions related to this topic are not available; what is presented here reflects a pathophysiology-guided approach to accomplish essential clinical objectives while avoiding VILI (Table 29-1).

GENERAL OBJECTIVES FOR VENTILATOR SUPPORT

In the clinical setting, mechanical ventilation ensures adequate oxygenation of arterial blood, provides sufficient oxygen transport to vital organs and tissues, assists in eliminating carbon dioxide, relieves excessive burdens placed upon the respiratory muscles, helps maintain alveolar stability, and allows therapeutic measures that require controlled ventilation. Despite its undeniable value, however, mechanical ventilation also has the potential to inflict adverse clinical outcomes. The task of accomplishing ventilation safely in patients with injured lungs is made far more difficult by the mechanical heterogeneity of the respiratory system and the diversity of pathophysiology encountered among different patients who satisfy extant operational criteria for this condition.

DEFINING THE PROBLEM

The terms *ALI* and *ARDS* comprise a category of patients with varied pathoanatomy and mechanical characteristics. According to the widely used American-European consensus guideline,[4] the primary criteria relate to pulmonary oxygen exchange, the appearance of the plain chest radiograph, and to a clinical assessment of left ventricular function. Although such broadly inclusive criteria may be useful for some purposes, they prove problematic for others. In formal definitions, for example, no provision is made for the level of positive end-expiratory pressure (PEEP) at which the arterial sample is obtained or the chest radiograph is exposed. No stipulation requires that the defining criteria be met under standardized conditions and remain reproducible over time. Chest wall properties and body weight are left unaccounted for. Yet, pulmonary oxygen exchange is influenced not only by the properties of the lung, but also by end-expiratory lung volume, body position, mixed venous oxygen content, pulmonary blood flow, and the integrity and intensity of hypoxic pulmonary constriction. The chest radiograph is interpreted subjectively, and expert assessments often differ.[8] Moreover, it is clear that the lungs of different patients with ARDS vary with regard to radiographic appearance, inherent recruitability, and histopathology. Even within the same individual, assessed at the same moment, the pathoanatomy and mechanical environment varies from site to site within the injured lung. Such regional differences are partially explained by the properties of the surrounding chest wall, which profoundly influence the inflation characteristics of the integrated respiratory system as well as their regional distribution.[9,10]

Similar clinical presentations can mask radical differences in lung pathology, mechanical properties, and response to ventilator settings and maneuvers. Lungs of patients with ARDS resulting from pneumonic consolidation, for example, are less likely to inflate easily than are lungs made edematous by the circulating mediators of extrapulmonary sepsis.[11] Computed tomographic (CT) patterns may reflect these differences.[12] Moreover, inflexibility of the chest wall may substantially increase the pressures required to inflate the respiratory system (Fig. 29-1).[13] From these considerations, it is clear that inflexible guidelines for selecting PEEP and tidal volume that advise specific numerical values of these settings will be variably effective in accomplishing the goal of minimizing tissue stresses, depending on the type and severity of lung injury, the compliance of the chest wall, and the ranges for opening pressures and closing tendencies among the multiplicity of the lung units that comprise the injured lung.

PATHOPHYSIOLOGIC FEATURES RELEVANT TO VENTILATORY SUPPORT

A major conceptual advance of the past 25 years is the recognition that the lungs of patients with ARDS are mechanically heterogeneous and vary enormously in their patterns of infiltration, their inflation and collapse properties, and their regional expressions of pathology. CT scanning has revealed densities that may be localized or diffuse—with implications for response to ventilator interventions such as PEEP.[12] Variation in the underlying conditions that give rise to the clinical problem described as ARDS precludes categorical histologic descriptions that apply across the full range of

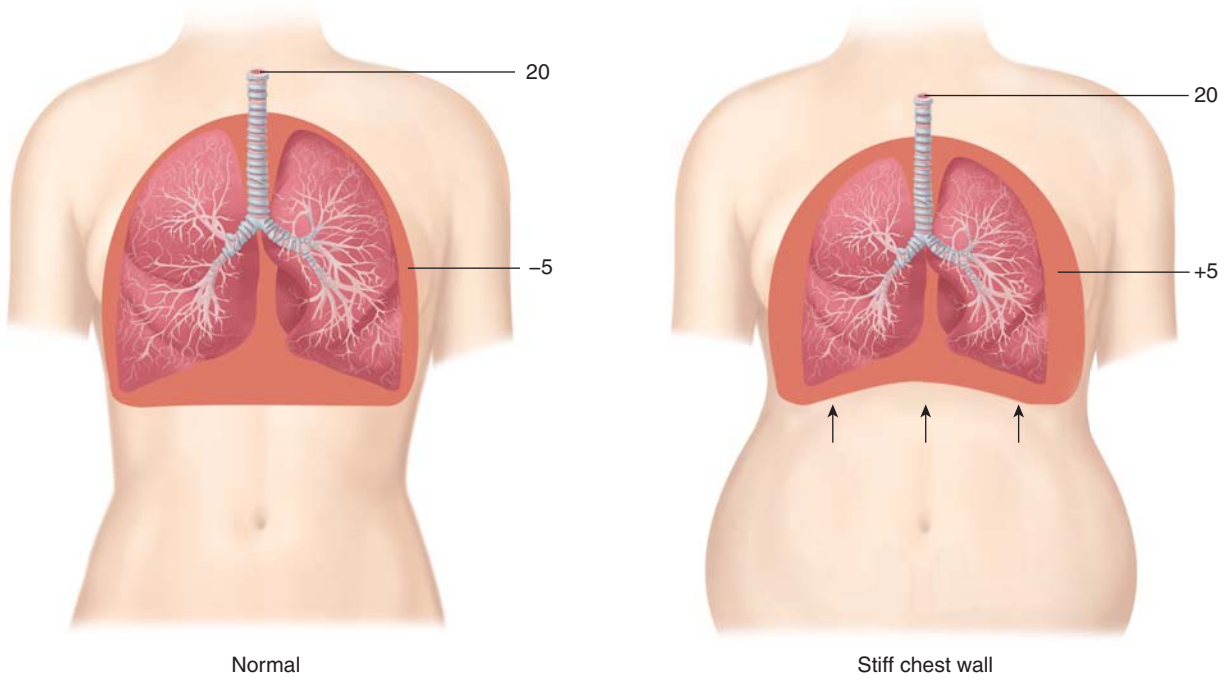

FIGURE 29-1 Influence of chest wall compliance on transpulmonary pressure and lung volume. Any specified airway pressure is associated with less transpulmonary pressure in the presence of chest wall stiffness or expiratory effort.

clinical experience. A few salient characteristics, however, are shared by most. In its earliest phase, noncardiogenic (high permeability) edema gives rise to a lung whose parenchymal airspace is partially occupied by proteinaceous edema and cellular infiltrate. A relatively large proportion of the lung—often exceeding 50%—is airless at end expiration, with the exact percentage depending jointly on severity, disease stage, etiology, and PEEP. Destruction of surfactant-producing type 2 alveolar cells leads to its diminished production, while exuded proteins and inflammatory products compromise the viability of the surfactant that remains.[14] Surfactant plays several important biologic and physiologic roles. From a purely mechanical standpoint, the loss of functional surfactant increases surface tension, thereby contributing to alveolar flooding, increased tissue elastance, small airway closure and atelectasis—particularly at low lung volumes.

The relative proportions of airless and aerated tissue also vary with disease type and stage. Although some controversy persists, CT scan estimates of gas and tissue volumes suggest that potentially "recruitable" tissue comprises only a minority of radiographic density at functional residual capacity in most cases.[15] Flooded and consolidated lung units comprise the remainder. Although clearly a minority viewpoint, a plausible argument has been advanced that "reopening" of lung units by alveolar pressure may occur primarily by redistributing alveolar liquid and shifting fluid volume from the alveolar to the interstitial compartments of the lung—not by atelectasis reversal ("recruitment").[16] The rapidity with which CT tissue density develops and resolves, however, as changes of alveolar pressure are imposed, as well as direct observations by intravital microscopy of alveoli at the lung's surface,[17] cast doubt on the primacy of the "fluid-shift hypothesis."

Mechanical Properties of the Injured Lung

Replacement of airspaces by inflammatory debris, cells, and fluid results in a lung whose aeratable capacity and compliance (measured in terms of volume accepted per unit of pressure) is severely reduced. The compliance of the respiratory system (lungs and chest wall) falls during ARDS for two reasons. First, airspace is lost to fluid and cellular infiltrates. Second, many functional lung units operate near their elastic limit because many fewer are available to accept the tidal volume. Under normal conditions, surfactant-modified surface forces allow the lung to inflate and deflate at similar pressures. In contrast, the injured lung is characterized by a right-shifted pressure volume loop, made so by its reduced aeratable capacity and by surfactant depletion.[13,18,19] For the same tidal volume, therefore, the mechanical work of breathing is dramatically increased.

Although clinicians characterize the mechanics of the injured lung by airway pressure and flow measurements made at the airway opening—the common entry and exit point for gas exchange with the environment—the mechanical properties of the lung's individual subunits are hardly uniform, even in health. In part, this heterogeneity relates to regional variations of pleural (and therefore transpulmonary) pressure that arise from interactions of the chest wall

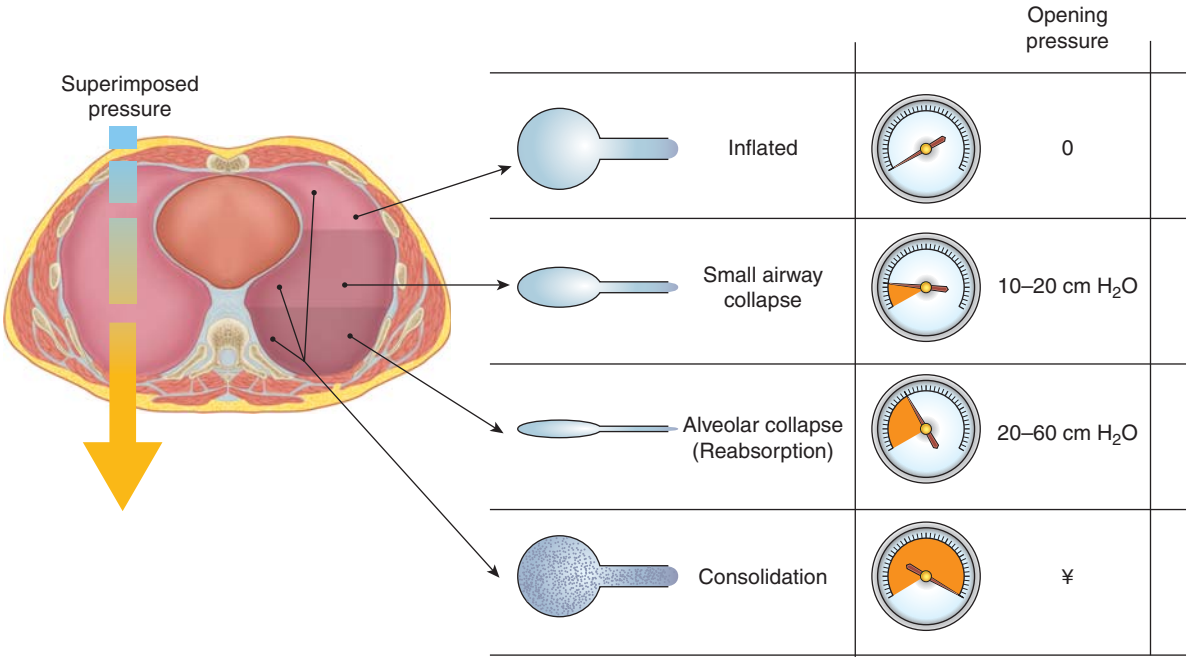

FIGURE 29-2 Spectrum of opening pressures associated with lung units within the injured lung. Lung units located in dependent areas are compressed by the weight of the overlying lung and mediastinum. Local transpulmonary pressures vary considerably, so that some lung units remain fully inflated throughout the tidal cycle, whereas others cannot be aerated. Less pressure is required to open small airways when the alveoli remain aerated than when all alveolar gas has been absorbed. (Image provided by Luciano Gattinoni and used with permission.)

with the injured lung and from the need for dependent tissues to support the weight of the mediastinal contents and the edematous lung (Fig. 29-2). This underlying mechanical heterogeneity is implied by quantitative CT imaging techniques that characterize the topographical anatomy in response to changing patterns of airway pressure, or more directly in real time by imaging of ventilation with radiotracer gases or electrical impedance tomography.[20,21]

For any specified airway pressure, some lung units are closed and others are open. Among the population of open units, there exists a range of states of lung unit expansion, depending on the local transpulmonary pressures that distend them. Even at airway pressures that are generally considered modest, some of the open lung units verge on overdistension, while others are on the compliant portion of their pressure volume relationship (Fig. 29-3). Alveolar distension that approaches the elastic limit stimulates surfactant production, but the repetitive application of nonphysiologic stretching forces, as during high tidal volume or high-pressure tidal ventilation, initiates molecular signaling of a local inflammatory response.[22,23]

Mechanical interdependence among the lung units of a heterogeneously affected lung amplifies the stresses of high pressure at the junctions of closed and open lung units in a nonlinear fashion (Fig. 29-4).[23,24] Such recurring forces at the points of stress focusing not only strain the lung's structural meshwork to initiate inflammation, but also assist in reopening potentially recruitable (atelectatic) lung units.[25] When atelectatic tissues are subjected to high pressures, amplified shearing forces within these zones at high risk for damage may be of sufficient magnitude to tear the delicate terminal airways or alveoli themselves, creating micro wounds that produce tissue hemorrhage and incite inflammation as a secondary phenomenon. Stress amplification at the margins of dissimilar tissues is at least partially a function of their relative volumes. (A flooded, gasless alveolus of volume similar to its air-filled neighbors may experience forces that are no

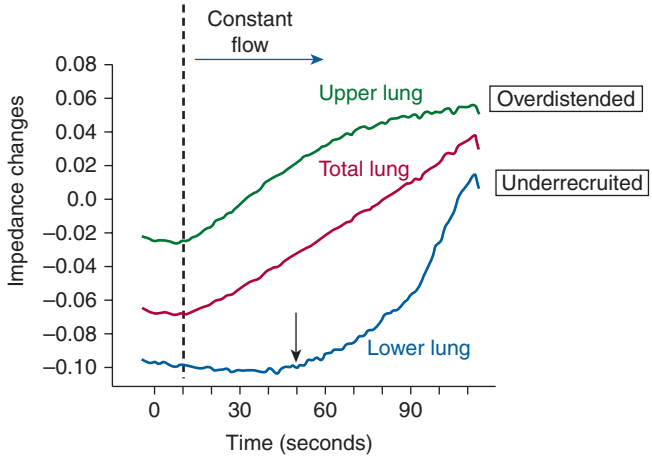

FIGURE 29-3 Mechanical characteristics of lung units in dependent (*lower*) and nondependent (*upper*) lung regions. As the lung is inflated by constant flow of gas, electrical impedance increases in proportion to aerated volume. Although the relationship of volume to impedance for the total lung appears roughly linear, upper lung regions are relatively overdistended whereas lower lung regions are relatively underrecruited until total lung capacity is achieved. (Image provided by Marcelo Amato and used with permission.)

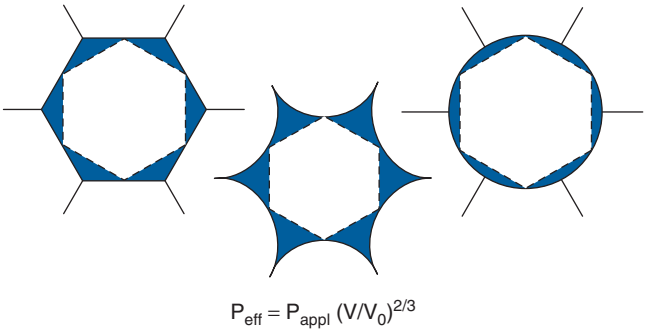

FIGURE 29-4 Amplification of tension at the boundaries of open end collapsing lung tissue. Normally distended (*left*), collapsing (*center*), and overdistended (*right*) states of inflation. Because of interdependence, the tensions applied to a collapsing alveolus are amplified. A simple mathematical model predicts that the tensions resulting from an alveolar pressure (P_{appl}) produce a tension comparable to an effective pressure (P_{eff}) described by the equation. At 30 cm H_2O applied pressure, the volume of an aerated alveolus (V) is approximately ten times that of a collapsed alveolus (V_0). Thus, the estimated pressure necessary to mimic the tensions at the interface is approximately 4.5 times as great as that applied, or 140 cm H_2O. (Used, with permission, from Mead et al.[23])

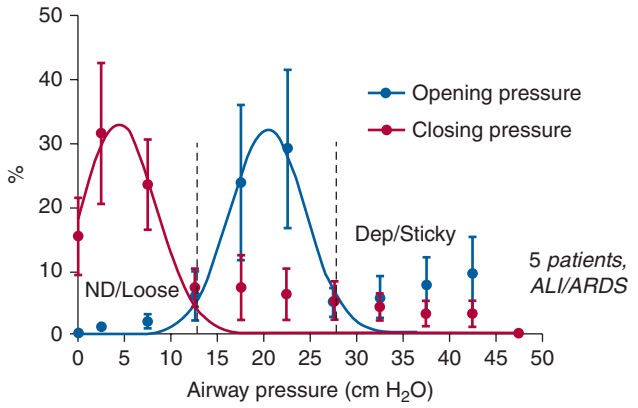

FIGURE 29-5 Histograms relating percentage of potentially recruitable lung units that are open to inflation and deflation airway pressures. Unstable airways open at relatively modest pressures, whereas alveoli that have undergone absorption collapse require much higher pressures to open. The spectrum of closing pressures is left shifted. Note that some lung units begin to collapse at relatively high airway pressures. (Reprinted with permission of the American Thoracic Society. Copyright © 2012 American Thoracic Society. more intense.) Because mechanical forces are amplified at the junctions of dissimilar tissues, it seems likely that injury abets the process of ventilator associated injury, so that damage propagates outward from injured into previously healthy zones. Whether injury results from the process of repetitive popping open of lung units under high pressure or simply is the cumulative result of high tension stretching at the interface remains to be resolved. It appears, therefore, that there are at least two critical elements that place the injured lung at risk for ventilation associated lung damage: high inflating pressures and the prevalence of collapsed lung units that interface with open ones.

Atelectasis

At the microscopic level, lung unit collapse may be thought of in two broad categories: "loose" atelectasis that arises primarily from compressive forces of the heavy lung acting to close small airways and responds to relatively low levels of transpulmonary pressure, and adhesive or "sticky" atelectasis that results from gas absorption and requires very elevated pressures to reverse.[26] High concentrations of inspired oxygen encourage the latter in poorly ventilated regions, as well as interfere with surfactant kinetics. These hard to recruit units may be among the first to close as high airway pressure is withdrawn. Loose and sticky types of atelectasis often coexist, perhaps accounting for the fact that lung units open throughout the entire range of total lung capacity (Fig. 29-5).[25–27] In the setting of severe ARDS, pressures that exceed 60 cm H_2O may be needed to complete the recruiting process. Although opening of lung units is primarily a function of transalveolar pressure, the duration with which pressure is applied also contributes; that is, a lower pressure may be sufficient if applied for an adequate period. Moreover, atelectatic lung units tend to "yield" (open) in a stuttering, discontinuous fashion, with high sustained pressure causing a serial snapping open of small blocks of units.[28] Discontinuous lung opening during the tidal cycle may give rise to audible crackles, usually best heard in dependent regions.

Pulmonary Edema

The increased microvascular permeability of ALI and/or ARDS renders it vulnerable to edema formation and impedes its relative rate of edema clearance. The weight of the normal lung does not begin to rise significantly until pulmonary venous pressure exceeds 20 mm Hg. Unlike the healthy lung, however, extravascular water in the injured lung bears a strong quasilinear dependence on hydrostatic microvascular pressure, a relationship that begins from capillary pressures that are considered low by most clinical standards.[29] The term *noncardiogenic pulmonary edema*, therefore, does not imply that gas exchange cannot improve by lowering the hydrostatic pressure gradient across the injured lung. Because extraalveolar microvessels as well as capillaries can leak,[30,31] numerous factors influence the vascular pressures relevant to edema formation. These include left ventricular filling pressure, cardiac output (which increases the pressure needed to drive blood flow through the lung with limited capillary recruiting reserve), the plasma oncotic pressure, the interstitial fluid pressure, and the integrity of the alveolar and lymphatic lung water clearance mechanisms. Clearance mechanisms are influenced by the degree of lung stretch. Translocation of blood from infradiaphragmatic vascular capacitance beds to the central vessels of the thorax can occur as intraabdominal pressure rises.[32]

MECHANISMS AND CONSEQUENCES OF VENTILATOR-INDUCED LUNG INJURY

For more than three decades, experimental studies have shown that *excessive mechanical stresses* developed during mechanical ventilation can inflict injury upon both normal and acutely injured lungs, and once injured, retard their healing.[33,34] Injury may result from overstretching of tissues that are already open, from shearing forces at the junctions of expandable and unyielding tissue, or from repeated percussion of closed terminal airways (Fig. 29-6). Repeated application of transalveolar pressures exceeding those corresponding to the inflation capacity of a healthy lung may disrupt the alveolar epithelial barrier, especially in the absence of sufficient end-expiratory pressure to reduce stress focusing by holding open mechanically unstable lung units.[33,35] From a theoretical standpoint, sustained recruitment reduces the potential for damaging forces to concentrate at the boundaries of inflating lung and unyielding or collapsed structures. Indeed, an overwhelming body of experimental work indicates the lung protective effect of sustained "recruitment" when high tidal inflation pressures are used.[36,37] Mechanosignaling at moderately high airway pressures may induce the formation and release of inflammatory mediators,[22,37–42] initiate programmed cell death (apoptosis), or produce necrosis.[38,41] Excessive strain may exceed cytoskeletal tolerances, causing physical tears and stress fractures of endothelium, epithelium, and intercellular matrix (Fig. 29-7).[38,39] Scientific data suggest that when the ratio between tidal volume and aerated functional residual capacity exceeds 2, the resulting transalveolar forces are sufficient to cause tissue damage.[40] Furthermore, the tendency for translocation of inflammatory mediators and bacteria into the bloodstream is influenced by the ventilator pattern.[42–44] Such observations suggest possible links between adverse patterns of ventilation and dysfunction in remote vital organs.

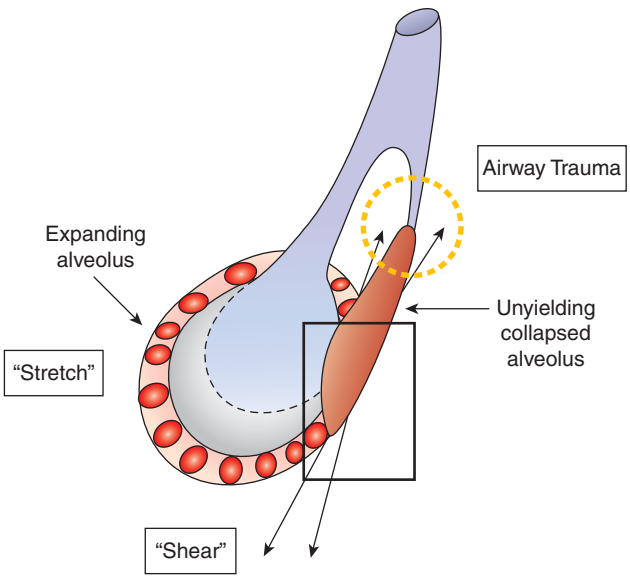

FIGURE 29-6 Forms of tissue stress that occur near the junctions of open and closed lung units.

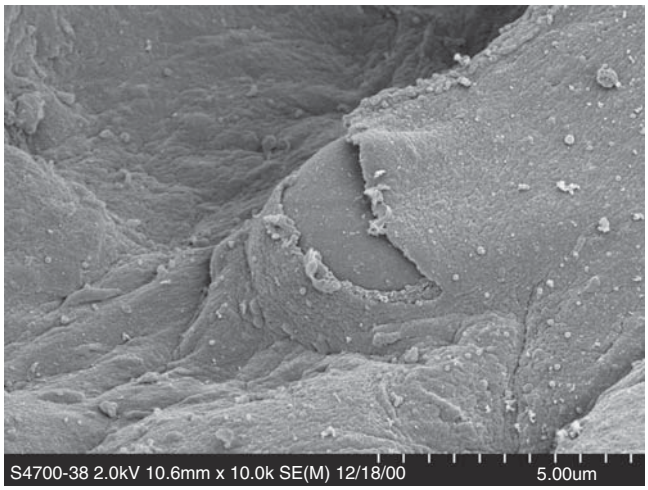

FIGURE 29-7 Stress fracture of the alveolar capillary membrane resulting from ventilator-induced lung injury in a previously normal rat lung. Similar tears have also been demonstrated to occur in human patients with ARDS.

Pathophysiology and Prevention of Ventilator-Induced Lung Injury

From available data, VILI appears to be a complex process initiated by the repetitive application of excessive, stress/strain to the lung's fibroskeleton, microvasculature, terminal airways, and delicate juxtaalveolar tissues. Defining the linkage between stress, strain, and diffuse alveolar damage is currently a subject of intense investigation.[22,37,38,42,43,45] It seems undeniable, however, that high levels of mechanical stress disrupt the normal functioning of cells that populate the pulmonary microenvironment and that sufficient dimensional strain triggers the release of inflammatory mediators and destructive enzymes (Fig. 29-8).[43,46,47] Under moderate degrees of strain, such mechanosignaling may be the primary pathway to injury. When the applied mechanical stress is very high, fibroelastic structural integrity may be directly breached, with the inflammatory process a consequence rather than initiator of the observed histopathology. These high tissue-rupturing forces are especially likely to be generated in dependent lung regions, where unstable alveoli are most prevalent (Fig. 29-9). Another important mechanism in the causation of lung tissue damage may occur at the level of the terminal airways as they remain closed as airway pressures build or open and reclose with each tidal cycle.[36] Damaging shear forces (those that run tangential to the structure) appear to rip the epithelium from its attachments. The rate at which these tissues expand, conditioned by the inspiratory flow profile, may also play an important role.[48] Although relatively few studies have focused on this aspect,

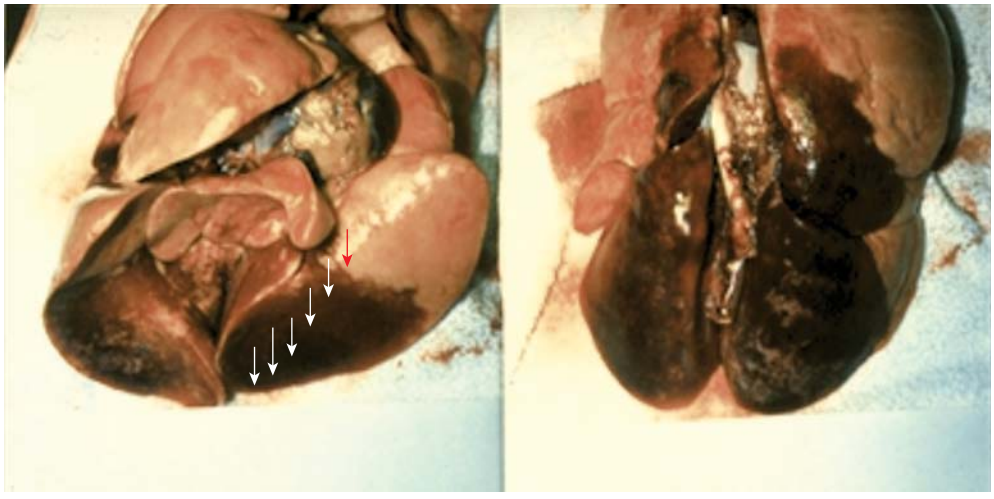

FIGURE 29-9 Excised heart–lung block from a previously normal animal subjected to high inflation pressure and low levels of positive end-expiratory pressure (PEEP). Specimen is shown inflated at 20 cm H_2O airway pressure in the supine (*left panel*) and prone (*right panel*) conditions. Note the sharp demarcation of hemorrhagic edema from relatively normal appearing lung. Damage may progress sequentially from dependent to nondependent regions, as indicated by the sequence of *arrows*.

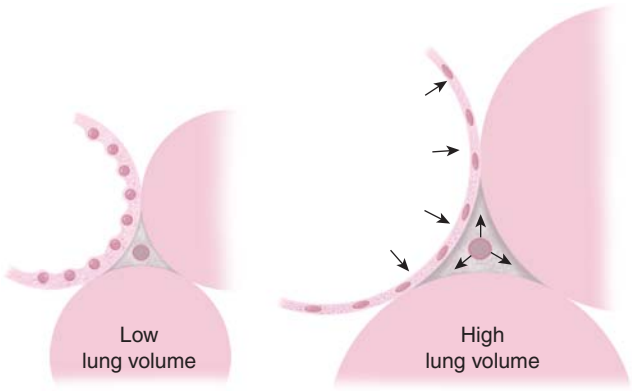

FIGURE 29-10 Mechanical behavior of capillaries embedded in the wall of inflatable alveoli and those microvessels within the interstitial spaces. Wall-embedded capillaries are compressed, whereas extraalveolar microvessels (and perhaps corner vessels) are dilated by lung expansion.

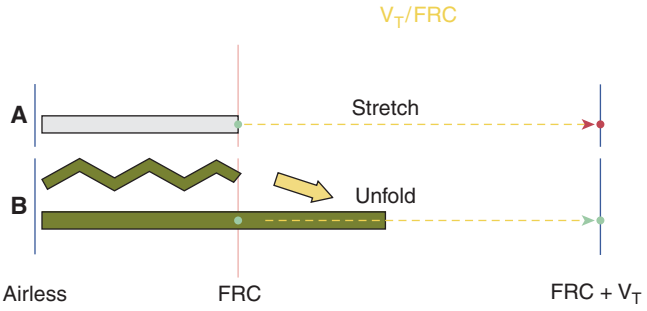

FIGURE 29-11 Concept of strain as relates to tidal volume (V_T) and functional residual capacity (*FRC*). Assuming that the lung has few recruitable units at rest (*A*), doubling of FRC by the applied V_T will result in excessive tissue strain (V_T/FRC ≥2). Peak transalveolar pressure would reflect that damaging stress. If tidal recruitment occurs during delivery of the V_T (*B*), the recruited tissue will relieve the stress even though the calculated ratio of V_T to FRC initially is the same. Peak transalveolar pressure would not rise as high as in situation *A*, but depending on driving pressure amplitude, tidal recruitment might have potential to injure secondary to stress amplification.

such a contribution seems likely, as the expansion velocity of the parenchyma is amplified by the reduced number of functioning airways that must accept what is typically an elevated total minute ventilation.

From an engineering perspective, mechanical *stress* is a function of transstructural tension; *strain* is the dimension-altering consequence of high transstructural pressure, conditioned by the elastance of the element in question. Although by no means the only determinant of tissue forces, the measurable analog of the stress across the entire lung is transpulmonary pressure—crudely estimated as the difference between static airway pressure (the "plateau" pressure) and average pleural pressure (often estimated by use of an esophageal balloon).[49] Regional transpulmonary pressures vary considerably, because of the influence of gravity, chest wall irregularities, intraabdominal pressure, mediastinal weight, and vascular-filling pressure (see Fig. 29-2).[50,51] Available laboratory data illustrate that pleural pressure, however measured, does not accurately reflect interstitial pressure when the lung is edematous and inflamed.[51,52] Even directional changes of pleural and interstitial pressures may not track together in a nonuniform environment (Fig. 29-10). Although not directly measurable, strain correlates with aerated volume as a fraction of aeratable capacity. As already noted, excessive strain may be experienced when VT exceeds the aerated functional residual capacity of a well-recruited lung by a factor of 2.0[40] (Fig. 29-11).

HOW DOES TIDAL VOLUME RELATE TO TISSUE STRESS?

Once this latter concept is understood, it becomes clear that tissue stress is not a predictable function of tidal volume but rather is strongly influenced by tidal volume in relation to the size (and compliance) of the compartment forced to accept it. Logically, the developed transpulmonary pressure would seem a variable that integrates these relationships. Even this, however, is not the full story—stress amplification and flow-influenced shearing forces at the boundaries of tissues with differing capacities to expand must be considered. Peak tidal transalveolar pressure interacts with end-expiratory transalveolar pressure to determine measurable stress, which varies markedly from site to site across the damaged lung. The alveolar pressures resulting from tidal volume and PEEP are both interactive elements in the injury process, but even when considered together cannot precisely estimate tissue stresses, as interstitial pressure is an unmeasured variable that differs throughout.

Moreover, the damaging *strain* that results from a given stress depends on tissue fragility. In the setting of ARDS, tissue integrity is likely to be at least normally delicate or even compromised, especially in its earliest phase. The low compliance typically associated with ALI results primarily from the reduced number of aeratable lung units—not from increased stiffness of the individual lung units themselves.[26,52] The tidal volumes pulled during exercise by a healthy athlete may exceed 25 to 30 mL/kg of lean body weight, whereas much smaller breaths eventually cause damage or lung rupture in the setting of ALI. Although increasing the tidal volume delivered to the same individual will invariably cause tissue stresses to rise in some lung units, a raised tidal volume may actually cause the stresses in other units to *fall*. This apparent paradox owes to the recruiting effect of the higher pressures and perhaps improved ventilation of marginally ventilated units predisposed to absorption collapse.[53] At any clinically selected tidal volume, tissue stresses may be reduced or accentuated by the application of PEEP, depending on whether PEEP effectively recruits vulnerable tissue or simply raises plateau pressure. Quests for a universally applicable predetermined tidal volume or PEEP value applicable to all patients would seem destined to be a fruitless exercise.

Modifying the characteristics of the chest wall (e.g., by prone positioning[54,55]) is an effective mechanism for altering the regional distribution and amplitude of transpulmonary

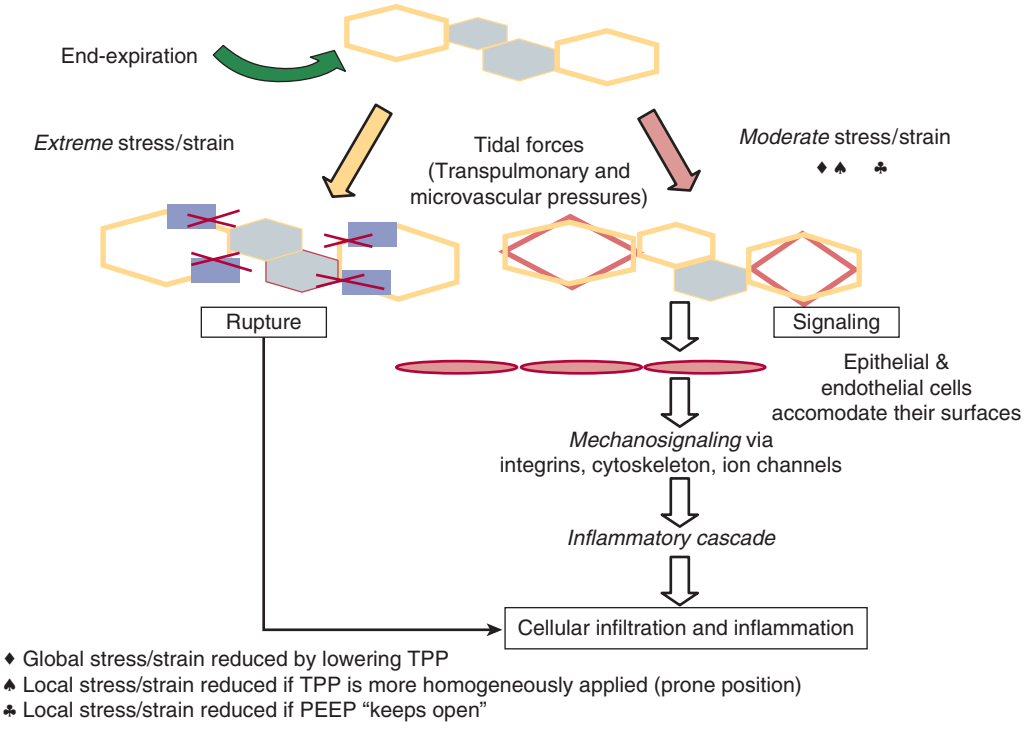

FIGURE 29-12 Hypothetical relationship between tissue damage and the severity of mechanical stress or strain during the tidal cycle. Moderate forces applied repeatedly to junctional tissues may result in mechanosignaling of inflammation. Extreme stress or strain causes micro wounds to develop, with inflammation occurring as an epiphenomenon. *PEEP*, positive end-expiratory pressure; *TPP*, trans-pulmonary pressure. pressure. Even within the same small region, inflationary stresses can vary markedly in magnitude and even in direction between structures situated within microns of one another. Shearing forces, one of the varied forms of mechanical stress resulting from lung inflation, intensify at the junctions of tissues with different compliance values and anchoring attachments.[23] Minimizing or eliminating these irregularities reduces the potential for adverse "stress focusing" and tissue strain. In such a microenvironment, limiting end-tidal alveolar pressure assumes major importance for two primary reasons: (a) A high plateau pressure may overstretch open alveoli, and (b) perhaps more importantly, because junctional tension rises in nonlinear proportion to airway pressure,[23] the plateau pressure acts as a potent lever arm at stress focus points.

By reducing the number of junctional interfaces and by preventing the repetitive opening of terminal lung units at high pressure, recruitment of lung tissue—defined as the sustained reversal of atelectasis on whatever scale it occurs—may be lung protective. When nearly all potentially recruitable tissue is aerated, the lung is said to be "open."[56] A given transpulmonary pressure applied to a fully open lung should be associated with less stress than the same pressure applied to a lung with closed units juxtaposed to open ones (Fig. 29-12). Some authors argue that the injured lung should be fully "opened" so as to reduce the potential for repetitive opening and reclosure.[56] Presently, however, it is not clear that this should always be given highest priority; to what extent repetitive opening and closure of small airways produces injury and whether the prevention of such behavior is the key to lung protection remain debatable, especially when peak tidal pressures are restrained; modest airway pressures may not inflict shearing injury when opening occurs at low pressure. In addition, because the difference between opening and closing pressures is often quite narrow in units that do open at higher pressure, some degree of tidal recruitment may be unavoidable. Therefore, how much of the lung should be "opened" and what pressure cost is acceptable remain key unresolved questions.

PATHOGENETIC COFACTORS OF VENTILATOR-INDUCED LUNG INJURY

Experimentally, a variety of cofactors apart from end-inspiratory, end-expiratory, and driving tidal transpulmonary pressures are important in the generation or prevention of VILI (Table 29-2). Prone positioning confers a protective advantage in both normal and preinjured animals.[57,58] A potential role for high inspired oxygen fraction as a contributor to iatrogenic injury has been intimated for many years but never convincingly documented in the clinical setting.[1,37] As other examples, higher precapillary[59] and lower postcapillary[60] vascular pressures intensify the injury caused by a fixed ventilatory pattern. As the lung expands, alveolar and extra-alveolar microvessels are compressed and dilated,

Note the quasilinear relationship of mortality rate to plateau pressure. (Used, with permission, from Brower et al.[70])

respectively (see Fig. 29-10). At some intermediate point on the luminal pathway that links them, the pushes and pulls are oppositely directed, giving rise to forces that stress the microvascular endothelium. Energy dissipation across the waterfall created by intermittent zone 2 conditions, vascular interdependence, and opening and closure of the microvascular endothelium could potentially explain the damaging influence of reduced postalveolar vascular pressure.

For identical tidal inflation and end-expiratory pressures, reducing respiratory frequency and minute ventilation attenuates or delays damage, provided that the tidal ventilatory stresses are sufficiently high.[61] Large tidal breaths and sighs occur infrequently as part of an inherent pattern of normal breathing. Sighs, for example, are inherent to the natural breathing pattern and are not injurious.[62] Multiple high-tension tidal cycles are required to signal inflammation. Experimental evidence also demonstrates that effective repair of minor defects within the cell membrane may occur within seconds of reducing stress,[63,64] and reducing respiratory frequency may allow these repair processes sufficient time to run to completion. Alternatively, less cumulative damage to the lung may occur per unit time as injurious forces unzip structural elements of the lung's fibroskeleton.

What level of transpulmonary pressure is likely to be damaging, therefore, depends on variables other than the tidal "plateau" pressure. Moreover, when the lung is comprised of large numbers of recruitable units, PEEP attenuates the tendency for high plateau pressures or tidal volumes to cause injury.[65–67] Consequently, it is difficult to specify an exact level of transpulmonary pressure that serves as an appropriate threshold criterion for safety. From a theoretical standpoint, repeated tidal application of a transpulmonary pressure of 15 to 20 cm H_2O (corresponding in a patient with a normal chest wall to a plateau pressure that may be in the range of 25 to 35 cm H_2O) gives cause for concern, as some higher compliance regions of the injured lung may approach their elastic limits at this pressure. It is worth noting that a transpulmonary pressure of only 15 cm H_2O subjects the normal lung to about two-thirds of its total capacity and is associated with a tidal volume exceeding 2500 mL.[13]

Experimental data suggest that lung tissues can be injured by mechanical stretching forces more easily in the setting of other noxious influences. In other words, it takes a higher stretching force to cause injury in a previously healthy lung than in one that has been exposed previously or concurrently to another inflammatory stimulus, such as endotoxin, hyperoxia, or cytotoxic drugs.[68,69] Such observations have given rise to the "two-hit hypothesis" for VILI, and underscore the potential vulnerability of the preinjured lung to imprudent ventilatory prescriptions. At the same time, such vulnerability can be viewed as an opportunity to modulate the severity of VILI by altering both nonventilatory and ventilatory factors.

A post hoc analysis of the ARDS Network tidal volume trial (ARMA) indicates that observed mortality paralleled plateau pressure to very low values—considerably lower than 20 cm H_2O (Fig. 29-13).[70] This correlation, which is difficult to explain entirely by indices of disease severity, suggests the possibility that for the injured lung there is no obvious safety threshold below which ventilator-associated lung damage does not occur. Other data suggest danger at relatively low plateau pressures,[71] but detailed analysis of human clinical trials argue that plateau pressures less than 30 cm H_2O have little impact on mortality once PEEP and disease severity are accounted for.[72] (Tidal volume must correlate with plateau pressure in any given individual; prestudy tidal volume and plateau pressure data from the ARMA trial, however, showed remarkably poor correlation because compliance [the inverse of elastance] is the missing parameter [Fig. 29-14].)

ACTIONS OF POSITIVE END-EXPIRATORY PRESSURE

Elevating the pressure baseline from which breaths are taken or delivered raises mean and end-expiratory lung volumes. Doing so nearly always improves oxygenation to some extent—primarily a function of keeping the lung open. When the breaths are drawn spontaneously or with pressure support, it is customary to call the end-expiratory pressure *continuous positive airway pressure* (*CPAP*); during breaths of predetermined length, the term is *PEEP*. Both are instrumental in the supportive care of patients with ARDS.

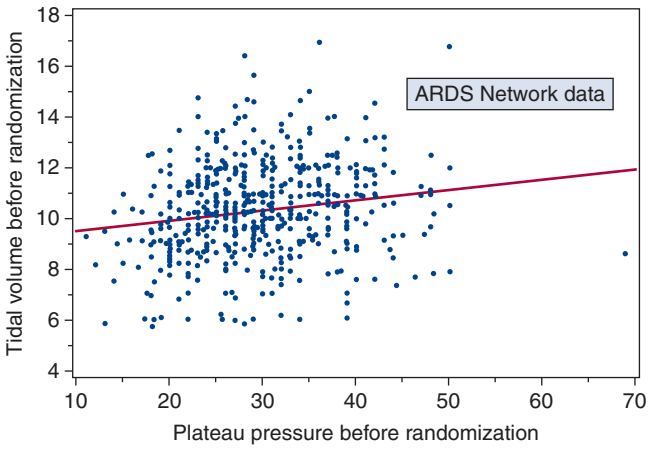

FIGURE 29-14 Scatterplot of tidal volume versus plateau pressure before randomization to the limbs of the National Institutes of Health-ARDS Network ARMA trial. (Used, with permission, from Brower et al.[70])

Gas Exchange. The potential clinical utility of PEEP in improving oxygenation was mentioned in the paper that first brought ARDS to widespread clinical attention.[1] Subsequent work demonstrated its potential to increase ventilation dead space and impair cardiac output by impeded venous return and increased right ventricular afterload.[73] In patients in whom PEEP stabilizes lung units that are susceptible to collapse, the response to increasing PEEP is generally to improve pulmonary oxygen exchange efficiency. Many patients show limited or negligible response, however, presumably because the recruitable population of lung units under baseline conditions is small. Infrequently, increasing PEEP can actually cause the partial pressure of arterial oxygen (Pa_{O_2}) to fall, presumably by redirecting pulmonary blood flow, by causing pulmonary arterial pressure to rise high enough to shunt venous blood through a patent foramen ovale, or by causing sufficient reduction in oxygen delivery to force an increase in systemic O_2 extraction and desaturate venous blood (see Chapter 37).

The benefit of PEEP on oxygenation depends on improving functional residual capacity. When patients labor to breathe, as during hyperpnea, expiratory efforts made against PEEP may force the lung's volume to fall below its equilibrium value, effectively storing elastic energy to aid inspiration but interfering with improvement in O_2 exchange. Under these circumstances, eliminating forceful expiratory muscle action (as by sedation) tends to improve O_2 exchange efficiency.[74]

Alteration of Tissue Stress. Because PEEP has the potential to maintain recruitment of unstable lung units (thereby reducing "stress amplification"), there has been intense interest in its role as a core element of a lung protective ventilating strategy. When plateau pressure is held constant, raising PEEP not only reduces the number of closed lung units, but also shortens the lever arm ("driving pressure") applied to the unstable lung units at risk to open forcefully (Fig. 29-15). Yet, when tidal

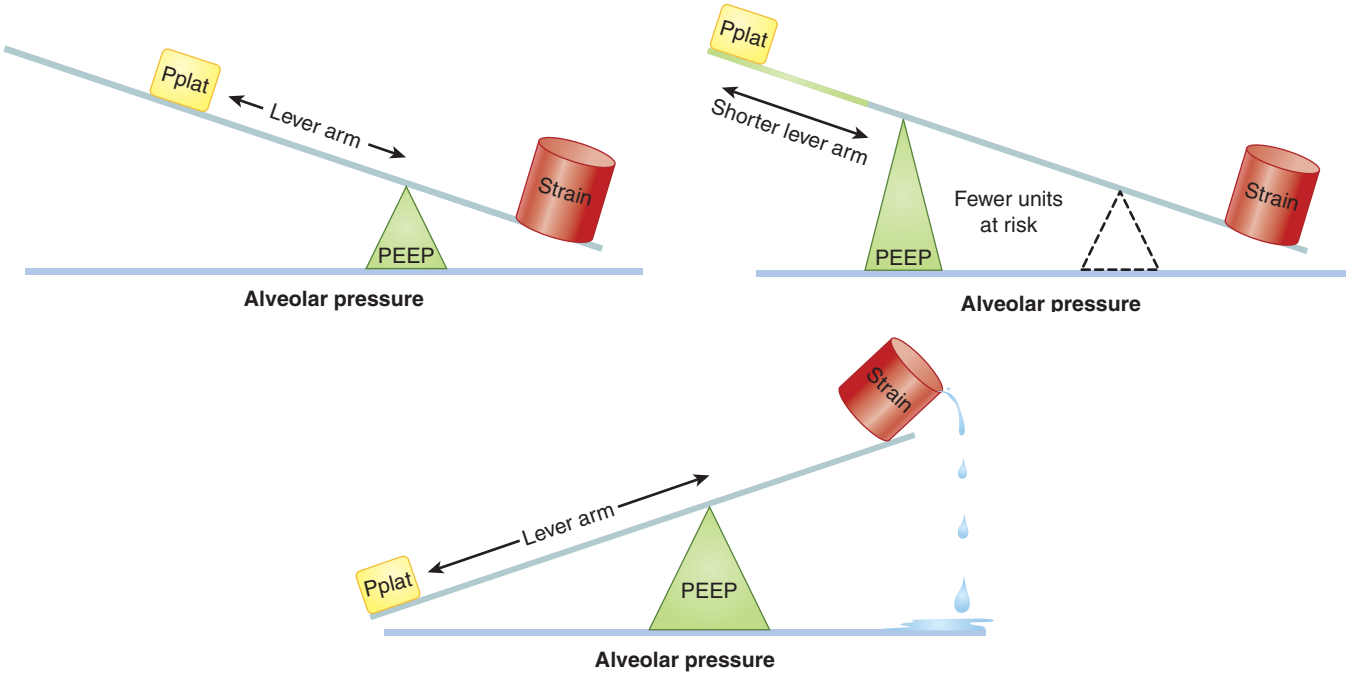

FIGURE 29-15 Hypothetical relationship among plateau pressure PEEP and tissue strain. In the generation tissue strain, the driving pressure for tidal volume (the difference between plateau pressure and PEEP) acts as a force lever arm, whereas PEEP is the fulcrum. *Upper Left.* Levels of plateau pressure (*Pplat*) and PEEP produce strain within acceptable limits. *Bottom Center.* Increasing Pplat while keeping PEEP at a level insufficient to hold open unstable units lengthens the lever arm and produces excessive tissue strain. *Upper Right.* When PEEP is increased, the same high Pplat that caused damage previously is better tolerated in that fewer lung units are placed at risk after recruitment and the lever arm of driving pressure is shortened.

driving pressure is preserved, PEEP raises both mean and peak tidal pressures, distends lung units that are already open, redirects blood flow, and alters cardiac loading conditions. Moreover, those lung units at the interface of closed and open units that remain unopened or continue to undergo repeated cycles of tidal recruitment despite an increase of PEEP are subjected to any PEEP-related elevation of end-inspiratory pressure, increasing the tendency for damage to those specific units. Thus, PEEP has the clear potential for benefit or harm depending on the balance among its multiple effects. Prone positioning tends to even the distribution of ventilation and reduce the gradient of transpulmonary pressure across the lung that exists in the supine position.[55,75] Airway and lymphatic drainage also tend to improve. This improved uniformity facilitates the selection of a single combination of PEEP and tidal volume that achieves a protective strategy for the entire organ.

RECRUITING MANEUVERS

A major clinical challenge is to apply sufficient pressure to keep the lung fully recruited without either increasing the stress applied to tissue that remains closed or overdistending alveoli that remain patent. Certain steps can be taken to minimize the number of unstable units by reversing those conditions that predispose to compressive and absorptive atelectasis (Table 29-3). PEEP cannot keep open lung units that were never open, and the recruiting process is not completed until pressures are reached that considerably exceed the total capacity of the healthy lung (Fig. 29-16). Although most lung units open at pressures less than 25 cm H_2O, some refractory units of the acutely injured lung may require much higher pressures to establish patency. To reach the "yield" (opening) pressures of refractory lung units requires the initial application of pressures that would be hazardous during tidal ventilation.[15,27,76] Newly opened lung units tend to close at lower pressures, allowing ventilation with the same tidal volume and PEEP to occur in the context of a more open lung with fewer lung units at risk for opening and closure (Fig. 29-17).

Because of viscoelastance and other time-dependent force-distributing phenomena, the tendency of a previously collapsed airway to open (or "yield") is a jointly hyperbolic function of both transmural pressure and time.[76] Of these, pressure is the most important variable. A variety of techniques, known as recruiting maneuvers, are designed to "open" the lung so that safe and effective combinations of PEEP and tidal volume can be utilized. Each recognizes that recruitment depends not only on the magnitude of transpulmonary pressure, but also on the duration of its

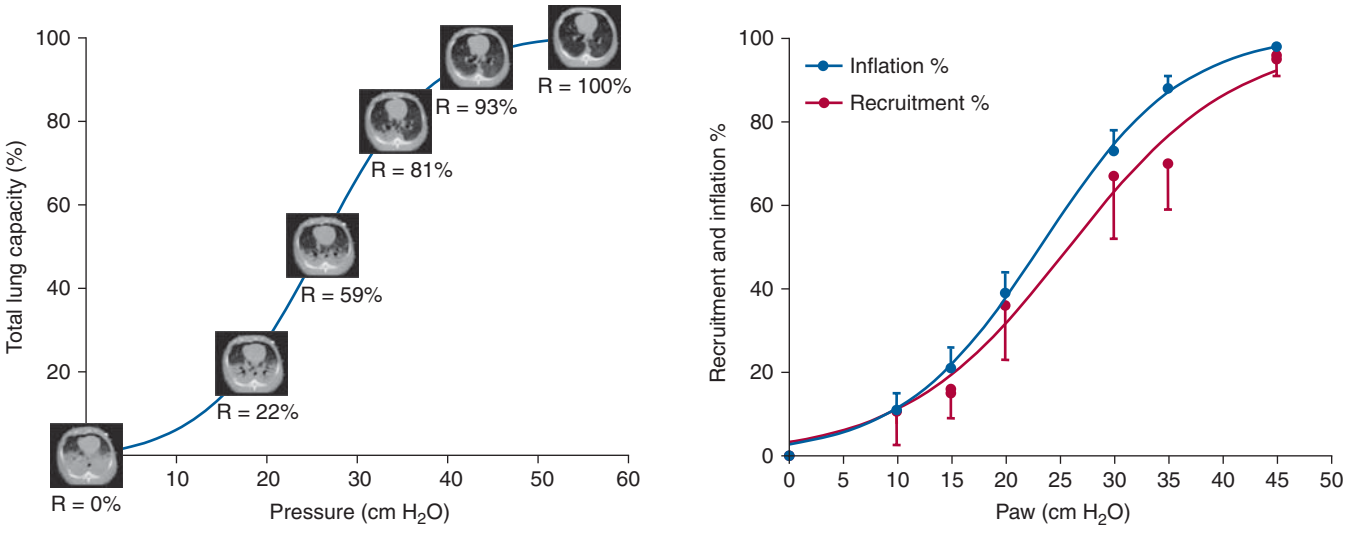

FIGURE 29-16 *Left.* CT scan slices obtained after oleic acid injury of the lung superimposed on the pressure-volume relationship of the respiratory system. Consolidation and radiographic density are greatest in the dependent lung regions and high pressures must be applied, even in this "highly recruitable" lung model, to fully reverse the radiographic evidence for collapse. Percentages denote aerated recruitable tissue. *Right.* Recruitment and inflation percentages as functions of static airway pressure. In these five patients with ARDS, the pressure–recruitment curve parallels the pressure–inflation curve when both are expressed as percentages of their maximum ranges. (Used, with permission, from Pelosi et al[27] and Crotti et al.[15])

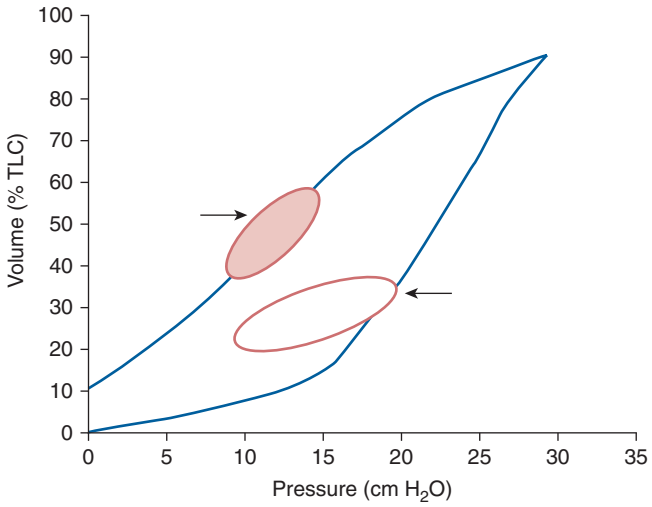

FIGURE 29-17 Effect on the tidal pressure volume relationship (*small loops*) before and after a sustained inflation recruiting maneuver. Hypothetically, first opening the lung by increasing pressure to high values allows tidal ventilation to occur at similar or lower pressures with more lung units open at end-expiration. Note that any volume gained is quickly lost after recruitment if original PEEP and position remain the same.

application (Fig. 29-18). To consolidate benefit after a successful "recruiting maneuver," end-expiratory pressure must remain high enough to hold open these newly recruited units once safe tidal plateau pressures are resumed. With few exceptions, this "stabilizing" value of PEEP is higher than

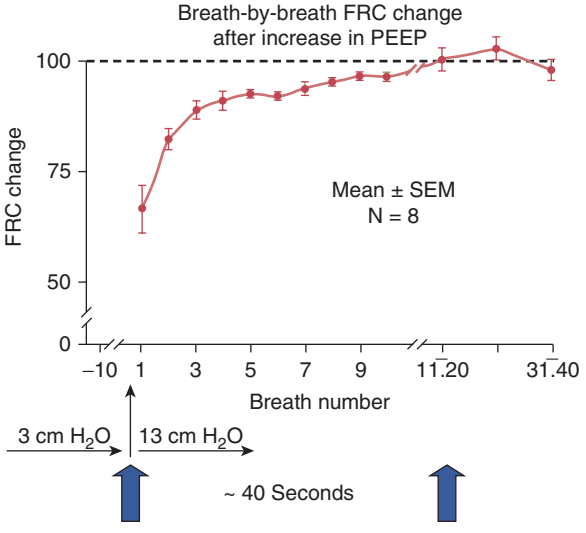

FIGURE 29-18 Time course of functional residual capacity (*FRC*) changes in respiratory failure following a step increase of PEEP from 3 to 13 cm H_2O. Multiple tidal cycles are required to fully achieve the ultimate increase in an expiratory lung volume. Although tidal volume would affect the time needed to equilibrate, in this instance, approximately 40 seconds were required. (Used, with permission, from Katz JA, Ozanne GM, Zinn SE, Fairley HB. Time course and mechanisms of lung-volume increase with PEEP in acute pulmonary failure. *Anesthesiology*. 1981;54(1):9–16.)

the initial one before recruitment.[77–80] Any benefit from a recruiting maneuver is extremely short lived if PEEP returns to its original value.[80]

Although most unstable lung units can be kept open with end-expiratory alveolar pressures (total PEEP) of approximately 10 cm H_2O (assuming a normally compliant chest wall), some units close at pressures considerably higher than those that are safe to apply with each tidal breath (see Fig. 29-5).[15,27] It is a fallacy to consider all injured tissue as potentially recruitable. Unlike most experimental models of ALI,[27,80] only a small fraction of the lungs of pneumonia-caused ("primary") ARDS, for example, can be "opened."[80–82]

Although a variety of recruiting maneuvers have been described, their efficacy depends on numerous factors (Table 29-4). Moreover, even when indicated, the best technique with which to perform a recruitment maneuver is currently unknown and may well vary with specific circumstances and repeated recruiting maneuvers may be required for maximum benefit. The two most commonly used are the sustained-inflation and the incremental-PEEP and/or fixed driving-pressure methods (Fig. 29-19).[81] The latter is often applied by PCV. When sustained pressure is applied without relief, mean and peak airway pressures are equivalent. This imposes extraordinary backpressure to venous return and poses a high afterload to the right ventricle for the period of its application. Both in experimental models and the clinical setting, ARDS caused by pneumonia (a "primary" form of alveolar damage) appears to be the condition with greatest risk for hypotension and least responsiveness to the sustained-inflation recruiting maneuver.[83]

Sustaining high pressure is believed to be an important component of the recruiting process, whereas the length of time required for its effect remains unsettled. Moreover, it is possible that for the same maximum pressure, briefer applications more frequently may be as effective as fewer cycles applied for a longer time. Recruitment tends to maximize early, while hemodynamic compromise continues to

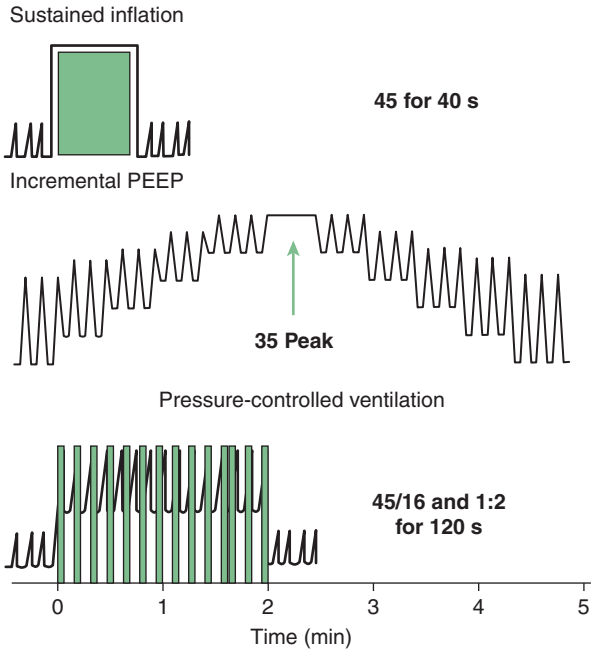

FIGURE 29-19 Three types of recruiting maneuver that combine high pressures with extended application time. Recruitment that employs tidal ventilation with pressure control (pressure-controlled ventilation [PCV]) achieves the same peak pressure for the same cumulative time as sustained inflation but at considerably lower mean airway pressure. PCV also provides multiple recruiting cycles and ventilates during the maneuver. (Used, with permission, from Lim S-C et al.[81])

worsen as the high airway pressure is sustained. Mean airway pressure can be considerably reduced while maintaining the same peak airway pressure value—the actual recruiting pressure—using a limited period of tidal ventilation with a constant driving pressure (e.g., <1 minute of pressure control with driving pressure 30 cm H_2O and high PEEP [e.g., 25 cm H_2O]). Thus, the pressure control recruiting maneuver may hold an advantage if pressures beyond those tolerated during the sustained high-pressure method are needed to complete lung opening.[81,83]

SPONTANEOUS VENTILATORY EFFORTS

Preservation of spontaneous breathing efforts during assisted ventilation may help to improve ventilation–perfusion matching by preferentially ventilating the peridiaphragmatic regions that receive disproportionate blood flow.[84–86] For the same minute ventilation, varying the amplitude of tidal breaths may also be helpful, either because of better recruitment or improved distribution of blood flow during biologically variable ventilation or "noisy" pressure support.[86] Whether this redistribution of ventilation and/or perfusion aids *sustained* recruitment, and thus whether it reduces or augments the tendency for VILI, currently remains unknown. The answer may well vary with the intensity of the breathing efforts and the vigor of expiratory muscle activity. It is seldom prudent to preserve spontaneous breathing at the expense of high exertion.

VENTILATING OBJECTIVES AND DECISIONS IN ACUTE RESPIRATORY DISTRESS SYNDROME

The foregoing discussion suggests that a rational lung-protective ventilator strategy should include the following elements: (a) avoidance of high tidal end-inspiratory alveolar pressures; (b) provision of adequate end expiratory pressure to avoid extensive end-expiratory tidal collapse and damaging driving pressures; (c) reduction of regional nonuniformity of mechanical properties; and (d) to the extent possible, avoidance of cofactors that abet the development of VILI, such as high inspired concentrations of oxygen and increased metabolic demands for ventilation and cardiac output. Choice of the appropriate therapeutic targets is fundamentally linked to lowering the risk for iatrogenic lung injury.

Therapeutic Targets

There is little evolutionary precedent for surviving ARDS that requires advanced levels of life support. Yet, the limits of tolerance to abnormalities of gas exchange in this setting and the capacity for the patient to adapt to abnormal blood gases have not been extensively explored and remain largely unknown. Trade-offs must be made when intervening to sustain life, as the supports applied to maintain oxygenation and ventilation—inspired oxygen and positive pressure—are both potentially injurious to the lung.[68,69,87] The discipline of intensive care evolved as an extension of postoperative care. Therefore, it was natural to employ ventilatory parameters that serve well in that setting, where the general aim is to hold arterial blood gases reasonably close to their preoperative values and large tidal volumes are needed to forestall atelectasis and to avert dyspnea. Three decades ago, awareness of oxygen toxicity was well entrenched, and the acutely injured lung was viewed on the basis of the plain frontal chest radiographs as mechanically uniform—diffusely stiff and therefore tolerant of the high ventilating pressures needed to maintain normal blood gases.

These assumptions were eventually challenged. Premature infants ventilated for infantile respiratory distress syndrome were clearly vulnerable to the application of high ventilating pressure. In adults, the high mortality rate of survivable diseases, such as asthma,[88] the high incidence of radiographically evident barotrauma,[89] and newfound awareness of dynamic hyperinflation[90,91] brought the wisdom of traditional practices and therapeutic targets into question. Reducing ventilatory requirements by allowing partial pressure of arterial carbon dioxide (Pa_{CO_2}) to rise was first successfully implemented in the care of patients with

status asthmaticus.[92] Five years later, the same strategy was reported to have been successfully implemented in patients with ARDS.[93] Subsequent research has emphasized that acute hypercapnic acidosis occurring in this setting is a complex phenomenon with diverse physiologic effects that include those with potential benefit (e.g., inhibiting inflammation) as well as those with potentially undesirable consequences (e.g., stimulation of ventilatory drive and cerebral vasodilation) (see Chapter 14).[94] Although guidelines for selecting the most appropriate values for pH and Pa_{CO_2} are elusive and should undoubtedly vary with the individual in question, it is clear from accumulated experience that mild to moderate deviations from the normal ranges of both parameters are generally well tolerated. At present, the dangers of VILI are perceived to outweigh those attributable to either inspired oxygen or hypercapnia.

Implementing Ventilator Support

Important principles gathered from laboratory experiments, shared clinical experience, observational studies, and randomized clinical trials have emerged regarding the application of ventilatory support to lung-injured patients (see Table 29-1). Noninvasive ventilation has been reported to be successful in patients with mild to moderate severity of injury,[95–97] and when feasible to employ, benefit is likely to accrue from the need for less sedation and the lower incidence of infection associated with this approach.[96,97] Although the interface between ventilator and patient continues to improve, only limited pressure can be tolerated, many patients cannot protect the upper airway, and the lung must be kept well recruited to avoid hypoxemia, precluding intermittent removal. For these reasons, airway intubation is virtually always required in cases of severe lung injury. That said, efficient and less-invasive extrapulmonary gas exchangers may complement noninvasive ventilation to make avoidance of invasive ventilation a genuine possibility for the alert and cooperative patient.[98,99]

Patterns of lung expansion differ for passive and actively assisted breathing. Preservation of muscular effort conceptually holds an advantage regarding the matching of ventilation to perfusion—at least in the healthy lung. The same advantage may hold for the acutely injured lung as well, provided that breathing remains comfortable and unlabored. Vigorous efforts, however, are undesirable for several reasons: increased ventilatory workload, oxygen consumption and CO_2 production, increased cardiac output and pulmonary blood flow (which may accelerate edema formation and possibly VILI), and expiratory muscle contraction that counters the effects of PEEP.[100] Whether gentle or vigorous, it has yet to be convincingly shown that patients who expend effort in breathing experience a lower risk of mortality. In fact, a recently published study demonstrated a potential survival advantage for patients receiving paralytic agents in the early phase of ARDS.[101]

Modes of Ventilation for Acute Respiratory Distress Syndrome

An extensive array of ventilatory options is available to the clinician for treating patients with ARDS. Each of these methods is described in detail elsewhere in this volume. As a general statement, it is accurate to state that the choice of ventilating mode is of much less importance than how the selected mode is implemented. When guided by the principles of attaining efficient gas exchange, targeting appropriate therapeutic objectives, and protecting the lung against iatrogenic damage, many different selections can be justified. What is presented here is a brief outline of some of the more important characteristics applicable to ALI.

For the past two decades, four modes have served to ventilate patients with ARDS at conventional frequencies: (a) flow-controlled, time-cycled, or volume-cycled ventilation (*volume control*); (b) pressure-targeted, time-cycled ventilation (*pressure control*); (c) pressure-targeted, flow-cycled ventilation (*pressure support*); and (d) combination modes in which a specified number of stereotyped time-limited machine cycles (pressure or volume controlled), which are specified by the clinician and synchronized to be triggered by patient effort, are delivered intermittently at evenly spaced intervals among additional breaths of variable size and depth taken by the patient (synchronized intermittent mandatory ventilation). As described in detail elsewhere in this book, flow and pressure cannot be controlled simultaneously, as the energetics of ventilation require one or the other to become a dependent variable in order to satisfy the equation of motion for ventilating the respiratory system.[102]

Flow control ensures that the desired tidal volume will be delivered reliably but obligates the patient to a specified inspiratory flow contour, independent of flow demand. Therefore, alveolar pressure, a function of delivered volume and compliance during passive ventilation, has the potential to ascend to dangerous levels. The flow profile delivered may be unchanging ("square") or decelerating. Pressure control offers the flexibility to satisfy flow demand and under passive conditions ensures that alveolar pressure rises no higher than a known peak airway pressure. (During active breathing [assisted cycles], the maximum transpulmonary pressure is not regulated by pressure control.) Flow is inherently decelerating, which may moderately improve distribution of ventilation among heterogeneous lung units, as compared with constant flow. The potentially adverse trade-off with using pressure control is that the delivered volume is a function of the impedance to breathing and any backpressure opposing inspiratory flow, so that tidal volume may change abruptly with muscular activity, airway resistance, lung and chest wall compliance, or auto-PEEP. It is worth noting that with airway pressure capped and the patient passive, the "strain ratio" of tidal volume to functional residual capacity tends to decline as disease worsens, conferring a lung-protective effect not seen with volume-controlled ventilation[103]

In recent years, the imperative to maintain consistent ventilation and nearly normal levels of Pa_{CO_2} has declined in its relative importance. Awareness of the potential for high ventilating pressures to inflict iatrogenic lung injury, coupled with a growing clinical experience that suggests the safety of higher than normal Pa_{CO_2} values (permissive hypercapnia) have caused many clinicians to adopt pressure control as the default mode. In the absence of effort and provided that both tidal volume and end-inspiratory pause pressure are closely monitored, the choice of pressure or volume control makes little practical difference to physiology or outcome.

Inverse-ratio ventilation, a mode that extends inspiratory time with the intent of raising mean airway pressure and capping applied airway pressure while maintaining adequate ventilation, is typically applied with pressure control.[104,105] Preventing airway closure at end expiration, however, may require generation of auto-PEEP that narrows the inspiratory pressure difference and limits tidal volume (Fig. 29-20). Although there may be rare exceptions, inverse-ratio ventilation appears not to offer any notable advantage over conventional-ratio ventilation that is applied with adequate PEEP.

During vigorous breathing, as during the first days of severe ARDS, it may be difficult to avoid patient–ventilator dyssynchrony with either assist-control or pressure-control ventilation because both require preset inspiratory times. Pressure limitation and failure to deliver full tidal volumes may then occur. In these instances, high-level pressure support, a flow-cycled mode, offers response flexibility. When the chest is very stiff, however, pressure rise time should be slowed and flow offswitch trigger minimized so as to avoid overly abrupt and ineffective tidal cycling. When used alone or in combination with intermittent time-limited mandatory machine cycles (synchronized intermittent mandatory ventilation), pressure-support ventilation may minimize the timing collisions that otherwise occur between the cycling phases of patient and machine. In any form of pressure-targeted or flow-regulated breathing, the ventilator's alarms should be carefully set so as to avoid over application of pressure or underventilation.

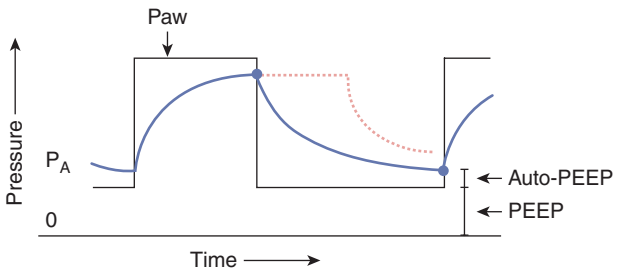

FIGURE 29-20 Concept of inverse-ratio ventilation using pressure control. As airway pressure is applied and released, alveolar pressure rises and falls exponentially (*heavy line*). Extending the inspiratory time fraction increases mean airway pressure and levels of auto-PEEP, without changing peak alveolar pressure. PA, alveolar pressure; Paw, airway pressure.

NEWER MODES OF VENTILATION

For patients capable of sustaining ventilatory effort, it is an option to elevate the airway pressure baseline, allowing the patient to draw breaths from that higher volume level. When airway pressure is maintained relatively constant throughout both phases of the breathing cycle, the condition is termed CPAP.[106] If the baseline shifts periodically with the patient able to draw breaths unimpeded through a valveless system at each level, ventilator assistance is given to an extent governed by the difference between pressure baselines and the frequency with which these baseline shifts occur. This mode is known as *biphasic airway pressure* (BIPAP).[107] When a high CPAP baseline is released only for a very brief period and then quickly restored to its original level, BIPAP contracts into *airway pressure release ventilation* (APRV).[108,109] The putative advantage of each of these modes for the care of patients with ARDS is that they encourage maintenance of an open lung with their high pressure baselines and ensure that the spontaneous breathing pattern is preserved. Neurally adjusted ventilator assist and proportional-assist ventilation regulate airway pressures in direct accordance with spontaneous respiratory motor output and have been used effectively in some patients with ALI, but their safety and effectiveness for this condition remain to be shown (see Chapters 12 and 13).[110,111] As with so many mode options, however, no definitive evidence exists to confirm their relative advantage over a well-adjusted traditional approach with similar mean airway pressure.

High-Frequency Ventilation. Awareness of the tissue-damaging potential of applying high end-inspiratory plateau pressures with insufficient end-expiratory pressure to keep unstable alveoli open ignited interest in using methods that apply very small tidal volumes so rapidly that alveolar collapse has no time to occur. Over the past three decades, various techniques for providing high-frequency ventilation have been explored with enthusiasm, tried tentatively in the clinical setting, and then reluctantly set aside.[112,113] These have included positive-pressure ventilation with valved-circuit closure to separate the phases of the ventilatory cycle (as traditionally done) but applied at nonconventional frequencies and tidal volumes. The technical demands of such high-frequency valving have limited its operating frequency range, efficiency, and safety. Another form of high-frequency ventilation, jet ventilation, uses a lung-directed injector pulsating at rapid frequencies into an open circuit. Problems with gas trapping, drying of airway secretions, and limited efficacy have dampened enthusiasm for its use in critically ill patients. At present, a third form, high-frequency oscillation, is in most widespread clinical use for patients with ARDS.[114–116] This "open circuit" technique uses a rapidly reciprocating piston-like action to rapidly vibrate the air column, building and releasing small alveolar pressure excursions in the process. A fresh-gas source allows effective gas exchange via mechanisms that complement the bulk flow

responsible at lower frequencies (see Chapter 19). Deep sedation is usually required, and mean alveolar pressure is maintained at a high level. Although experimental and clinical data amply document the feasibility of high-frequency oscillation for the setting of ALI in adults, the prevailing opinion is that this unfamiliar and seemingly exotic technique seems to offer little advantage over ventilation performed conventionally with equivalent attention to the principles of lung protection.[117]

The combination of conventional ventilation with superimposed oscillation of the airway-pressure baseline (vibropercussive ventilation) has been used with the objective of improving secretion elimination and reopening plugged or collapsed airways.[118] Here again, the mode has its advocates and adherents, but convincing evidence to substantiate its advantage has not yet appeared.

Adjuncts to Mechanical Ventilation

Attention to limiting tissue strain mandates that the pressure driving each tidal cycle (the difference between end-inspiratory and end-expiratory pressures), as well as the number of high-pressure cycles applied per unit time be kept within acceptable bounds. These requirements limit tidal volume and minute ventilation and stimulate interest in methods that reduce the demands for ventilation and oxygenation, reduce local tissue stresses, and improve the efficiency of pulmonary gas exchange, all without the need for additional ventilating pressures or higher ventilating frequency (Table 29-5). The majority of these "adjunctive" techniques are discussed in detail elsewhere in this book. Here it should be emphasized that perhaps the most effective and universally applicable means for avoiding the need for high ventilator pressures is to reduce the demand for them by the patient or to readjust the clinician's therapeutic targets for ventilator support. Thus, avoidance of high fever, pain, agitation, and metabolic acidosis reduces oxygen and ventilation demands, as well as the need for cardiac output—an important potential cofactor for VILI in the experimental setting. Optimizing oxygen delivery by improving cardiac performance and providing adequate hemoglobin concentration also minimizes the ventilatory requirements. At present, improved and simplified technology has spurred enthusiasm for using extracorporeal CO_2 removal to reduce ventilator demand and for extracorporeal membrane oxygenation when oxygenation cannot be assured by conventional means. Both were used extensively and effectively during recent epidemics of H1N1 influenza-induced ARDS.[119]

Using the prone position evens the distribution of transpulmonary pressure, reducing local tissue strains and effectively recruiting well-perfused dorsal parenchyma, thereby improving oxygenation in most patients.[55] Methods for improving gas-exchange efficiency include those directed at oxygenation (inhaled nitric oxide[120–122] or inhaled prostacyclin[123]), and those that lessen wasted ventilation (tracheal gas insufflation[124–126] or reduction of apparatus dead space[126]). Although often considered to be a ventilatory adjunct of limited value, recruiting maneuvers are incorporated by many practitioners, including this author, as an entrenched part of clinical practice.[127] In difficult cases, the recruiting maneuver affords a logical means of reopening the atelectatic lung so that the appropriate values of PEEP and tidal volume may be selected (see the section General Guidelines for Ventilatory Management).

SETTING THE VENTILATOR: RECOMMENDATIONS FOR PRACTICE

Given the joint potential for the ventilator to offer life support or to extend the severity and duration of the illness, the prescribed settings for the ventilatory cycle are of unquestioned importance. How best to achieve the appropriate trade-off, however, remains a topic of active debate. The available clinical database, albeit difficult to reconcile, appears broadly consistent with the highly consistent scientific body of information that addresses ventilator usage in the setting of ALI.

Insights from Clinical Trials of Lung Protection

With the rise of "evidence-based practice," physicians have sought guidance from clinical trials that have addressed the relative merits of different ventilation strategies.[2,3,128–130] Generally speaking, these well-intentioned efforts have been compromised by overly broad disease definitions and loose co-intervention controls. Yet some valuable insights have been generated. Studies in which the highest tidal volumes and pressures were applied in the "control arm" have shown benefit from low-tidal-volume ventilation.[2,3] Results were particularly impressive when higher PEEP was used in conjunction with small tidal volumes in a setting where emphasis was placed on establishing stable recruitment, avoidance of high ventilating pressures, and managing clinical cointerventions consistently.[2,131]

Only one of the several studies that randomized selectively on tidal volume—by far the largest yet published—successfully demonstrated mortality benefit for a smaller-tidal-volume approach.[3] The physiologic impact of tidal volume—mediated through transalveolar pressure—depends on compliance. The ratio of tidal volume to functional residual capacity may crudely approximate tissue strain,[40] as do the magnitudes of transalveolar pressure and its tidal excursion. In the clinical setting, the former can be readily measured by some ventilators, while the latter is computed by the difference between static airway and esophageal pressures.[49] Provocative examinations of the data collected in the ARDS Network ARMA study and a meta-analysis of all published trials addressing the selection of tidal volume have suggested that "lower is not necessarily better," especially when compliance is less severely impaired and periodic sighs or recruiting maneuvers are not employed.[132,133] Knowing that tidal volume is only indirectly linked to tissue strain, inflammation, and rupture (consider the noninjurious effects of high tidal volumes during exercise), it is interesting to speculate that the recruiting effects of higher tidal volumes might actually have a salutary effect on inflammatory signaling if peak transpulmonary pressure were kept below the "overstretch" signaling threshold and an appropriate level of PEEP were used. Whatever the validity of that controversial argument, the collective results of these clinical studies have focused attention on transalveolar stresses rather than on tidal volume per se. They have also demonstrated that the levels and effects of hypercapnia experienced during low-tidal-volume ventilation, although complex,[94,134–136] generally are modest and well tolerated.

The National Institutes of Health-sponsored trial of high versus moderate PEEP failed to demonstrate a significant survival advantage for patients allocated to the high PEEP group when both were ventilated using small to moderate tidal volumes.[137] Important considerations, however, were (a) neither group was exposed to plateau pressures that were clearly in a dangerous range; (b) recruitment potential was not stratified, so that patients who were not likely to benefit were assigned to both groups; and (c) no recruiting maneuver preceded PEEP application, nor was PEEP regulated as in conventional clinical practice. Unfortunately, there was also a failure of the randomization process, so that a disproportionate number of older patients were assigned to the high-PEEP limb. Two subsequent trials of high PEEP and small-to-moderate tidal volumes demonstrated some benefit of a higher PEEP strategy, but no overall mortality benefit.[138,139] The importance of PEEP is likely to depend on the severity of illness and the recruitability of lung units, which tend to track together, as well as the plateau pressure achieved.[140,141] A Spanish multicenter trial of modest size appears to confirm that PEEP is an integral part of a lung-protective approach,[131] an implication supported by an analysis of "real-world" ventilator practice and outcomes.[72] A meta-analysis of high PEEP strategy trials indicated that high PEEP exerts a mortality benefit for those with greatest disease severity.[142,143]

TABLE 29-6: COMMON EFFECTS OF PRONE POSITIONING IN EARLY ACUTE RESPIRATORY DISTRESS SYNDROME

More homogeneous transpulmonary pressure

Reduced tidal tissue strain [V_T/FRC (and VILI?)]

Abbreviations: FRC, Functional residual capacity; $\dot{V}/\dot{Q}$, ventilation–perfusion ratio; V_T, tidal volume; *VILI*, ventilator-induced lung injury.

Recruitment maneuvers have also been examined in a clinical trials format as a substudy of the high-PEEP National Institutes of Health investigation.[144] The recruiting maneuvers were applied only in the high-PEEP limb, and the peak pressure achieved was limited to 35 cm H_2O. The small separation between plateau pressure and PEEP, the underlying disease characteristics of the study population, the relatively high level of PEEP at baseline, and the failure to augment PEEP after the recruiting maneuver undoubtedly biased the result against showing a significant benefit. Indeed, a meta-analysis of studies that employed recruiting maneuvers concluded that they have no routine place in ARDS management.[145] Again, however, it must be understood that most studies have used them as a supplement to the ventilator strategy, which remained unmodified, and not as a means for setting PEEP by decremental titration.

Finally, notwithstanding considerable theoretical appeal (Table 29-6), oxygenation benefit,[146] and suggestive experimental evidence,[57,58,147] four relatively large randomized trials[148–151] failed to demonstrate a statistically significant mortality benefit for prone positioning in broad samples of patients of varying severity with ARDS. A French study reported a lower incidence of ventilator-associated pneumonia in the prone cohort,[150] but this did not translate into a survival advantage for that trial limb. A large Italian trial utilized prone positioning for less than one-third of each day, and showed no overall mortality benefit.[149] Notably, however, patients who responded by improving CO_2 exchange and those with most severe physiologic disturbances fared better than nonprone patients.[152] Moreover, a prematurely truncated Spanish trial,[151] in which prone positioning was maintained for three-quarters of the day, showed an impressive separation (25% relative risk of death) between the supine and prone treatment arms. Unfortunately, neither study entered its targeted number of patients. The large follow-up Italian trial that entered only patients with moderate and severe illness strongly suggested that the most seriously affected patients, those exposed to higher ventilating pressures, and those who demonstrate improved ventilation efficiency are most likely to benefit (Fig. 29-21).[153,154] As with PEEP, a meta-analysis of prone studies that focused on the

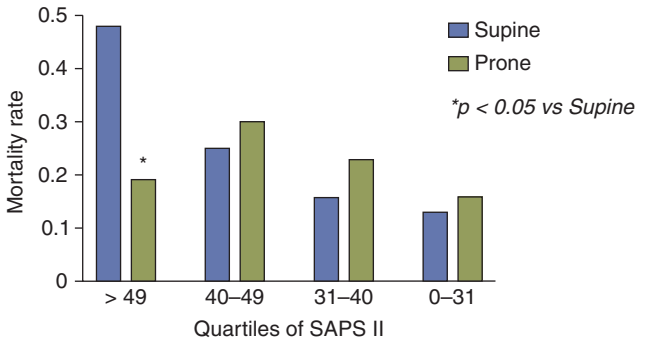

FIGURE 29-21 Effect of prone positioning on mortality as a function of illness severity. The cohort of most severely ill patients with acute lung injury by Simplified Acute Physiology Score (SAPS) II scoring benefit from proning. Less severely affected patients did not. (Data from first Italian multicenter clinical trial of prone vs. supine positioning in ARDS.[149])

most severely ill cohorts convincingly shows the benefit of the prone position in that specific patient category.[155]

Disappointingly, clinical trials of various other adjuncts to ventilation have also not demonstrated major outcome advantages.[156–160] From a physiologic perspective, this is hardly surprising. Precise numerical guidelines for selecting PEEP, tidal volume, and body position that are applicable to any given individual patient should not be expected from the results of studies conducted in a diverse sample population whose inclusion criteria are broadly inclusive and management details are unconstrained. In the end, the best that can be hoped for is a proof of principle—not a prescription for care. However internally valid such trials may be, they do not correspond to the "real-world" environment wherein comorbidities impinge and management of potentially influential variables (such as PEEP, Pa_{CO_2}, fluid management) is not protocolized. What follows is an approach to the care of the individual patient with ARDS based on an understanding of the physiologic principles that must be brought to bear in the complex clinical environment.

General Guidelines for Ventilatory Management

Key guiding principles include the following. First, adjust ventilator parameters empirically, rather than by formula-driven rules; prioritize patient comfort and safety. Second, assign the prevention of mechanical trauma precedence over maintenance of normocapnia and avoidance of oxygen toxicity. Although no exact upper limits for acceptable plateau pressure or fractional inspired oxygen concentration (FI_{O_2}) can be specified, very high FI_{O_2} pose a risk for absorption atelectasis as well as oxygen toxicity. Therefore, FI_{O_2} should be held to less than 0.7 whenever possible. Third, consider the impact of chest wall stiffness (including abdominal contents) on transpulmonary pressure and gas-exchange efficiency. In questionable situations, determine abdominal (bladder) and/or esophageal pressures to help estimate the transalveolar pressure.[49] Fourth, monitor hemodynamics as well as mechanics and gas exchange when regulating ventilatory therapy. Assess cardiac function by echocardiography and use reliable, noninvasive methods for tracking cardiac output if available. Although certainly not required for all, the much maligned pulmonary artery catheter is still quite useful in patients with complex cardiopulmonary problems.[161,162] Wide respiratory variation in the arterial pulse pressure, as well as other more precise echocardiographic indicators of vascular dimensions and heart preloading, suggest the need for additional intravascular volume.[163] A surrogate for measuring hemodynamics directly may be to monitor the central venous oxygen saturation. A value greater than 0% and a difference of 25% or less between arterial and mixed venous saturations strongly suggest an adequate cardiac index (>2.5 L/m^2/min).[164] Fifth, in severe cases, attempt to minimize ventilatory demands and thereby reduce needs for high airway pressures, high rates of gas flow, and increased cardiac output. Sixth, incorporate the "challenge" principle in making therapeutic decisions, regarding both the intensification and the withdrawal of therapeutic measures. Examples of such challenges include recruiting maneuvers to assess lung-unit instability and closely monitored (and preferably quickly reversible) challenges of fluid administration or removal (e.g., leg raising). Seventh, whereas aggressive fluid resuscitation is mandatory in the first phase of support, attempts should be made to avoid gross volume excess. Diuretic drips, repair of serious albumin deficits, and continuous hemofiltration hold important therapeutic potential once the resuscitation phase has been completed. Eighth, unless otherwise contraindicated, use prone positioning when high values for ventilatory pressure, PEEP, and FI_{O_2} are needed to maintain adequate supine arterial oxygen tension. Ninth, employ pressure limited forms of ventilation (e.g., pressure control, pressure support, or BIPAP/APRV) for evaluation of thoracic mechanics and ongoing management.

As a general rule, the desired goal is to use the least PEEP and tidal volume needed to achieve acceptable gas exchange while avoiding extensive tidal collapse and reopening of unstable lung units. Knowing that moderate hypercapnia generally is well tolerated, therapeutic targeting priorities are directed toward lung protection and maintenance of appropriate hemodynamics and oxygen delivery. Recruiting maneuvers help to characterize PEEP responsiveness, to determine the relative status of intravascular filling and response to altered cardiac loading conditions, and to set the PEEP–tidal volume combination (Fig. 29-22). Prone positioning is strongly considered in severe cases. On rare occasions, noninvasive mechanical ventilation using a comfortable full face mask (or a helmet, if available) may overcome short-lived deficits of oxygen exchange without the need for intubation. In practice, however, the needs to control the airway, to reduce ventilatory requirements, to apply high levels of PEEP, and to sustain support for extended periods usually preclude the use of noninvasive ventilation.

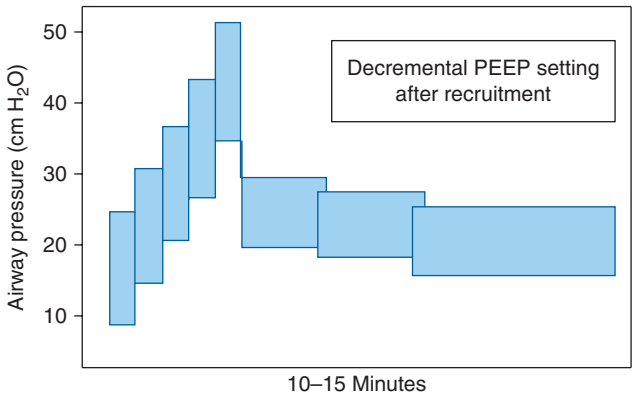

FIGURE 29-22 Procedure for setting decremental PEEP. Final PEEP is set after brief recruitment procedure, using progressive steps of PEEP with a fixed driving pressure. Note that PEEP is released abruptly from its highest level to a high tidal value, which is gradually reduced until deterioration of the monitored parameter (compliance or oxygenation) becomes apparent. After re-recruitment, tidal PEEP would then be set to the next higher step.

In the first phase of ventilatory support, patient comfort must be assured and ventilatory effort kept to a minimum. Existing data strongly suggest that muscle relaxing drugs are effective and well tolerated initially by many. Controlling ventilation for longer than 48 to 72 hours, however, is likely to contribute to muscle wasting and ventilator-induced diaphragmatic dysfunction.[165] Modes such as APRV, BIPAP, and high-frequency oscillation have persuasive advocates and considerable theoretical appeal.[109,166,167] The existing database and shared personal experience, however, have not provided convincing evidence that they offer a great deal beyond that which can be accomplished with carefully adjusted PCV in a well-sedated patient.

All patients should be assessed for severity of disease and for recruitment potential. After deficits of intravascular volume have been addressed and hemodynamics have been optimized, recruitment potential is gauged by applying high-level PCV: PEEP of 15 to 25 cm H_2O, driving pressure of 30 cm H_2O, and plateau pressure 50 to 60 cm H_2O for a maximum of 1 to 2 minutes, as tolerated. Even higher pressures may be appropriate for some severely affected patients and for patients with very stiff chest walls—for example, burn victims with chest wall edema or eschar. Although sustained inflation with high pressure has been traditionally used, widely employed, and selected for most reported research,[168] it is no more effective and tends to be less-well-tolerated hemodynamically than a recruiting method based on PCV that achieves lower average pressure but similar peak pressure during its inspiratory phase.[81,83] If oxygenation and lung mechanics do not improve substantially with high-level PCV as a recruiting technique, the patient is considered to have low recruiting potential *in that position and at that specific time*. Management goals in the "recruitable" group emphasize the maintenance of high-level PEEP, whereas in poorly recruitable patients, PEEP is maintained as low as feasible—generally in the range of 7 to 10 cm H_2O. In both groups end-inspiratory plateau pressure is kept less than 30 cm H_2O, except when chest wall compliance is very low. Periodic sighs may be advisable when very low tidal volumes (<5 to 6 mL/kg of predicted weight) are in use.[169,170]

ADJUSTING POSITIVE END-EXPIRATORY PRESSURE

Setting PEEP is an individualized empirical process that involves some degree of compromise (Table 29-7). Patients with an extensive "recruitable" population of lung units should respond to increased PEEP and recruiting maneuvers by demonstrating improved alveolar mechanics and improved gas exchange, reflected both by increased Pa_{O_2} and a reduction in the ration of minute ventilation to Pa_{CO_2}. These salutary changes are accompanied by only marginal effects on hemodynamics, as judged by systemic blood pressure and central venous oxygen saturation.[168] Assuming an unchanged rate of CO_2 production, the latter index—like a dead-space calculation—reflects the efficiency of CO_2 elimination, which is expected to improve with recruitment and deteriorate with overdistension. Inspiratory crackles (rales) audible over the dependent zones of the chest suggest that recruitment and derecruitment are occurring with each breath and indicate that recruitment maneuvers and higher levels of PEEP may be indicated to silence them.[171] Crackles occurring late in inspiration are of particular concern because they may originate in units opening under relatively high pressures. In gauging response to PEEP, it is important to consider CO_2 exchange as well as oxygenation response. With rare exception (e.g., when PEEP-impaired cardiac output causes mixed-venous O_2 content to fall), Pa_{O_2} tends to increase when PEEP is applied. This oxygenation improvement, however, may be accounted for either by recruitment of lung units or by reduced or redirected blood flow within the injured lung. In the latter circumstance, Pa_{CO_2} may also rise. When recruitment is the explanation for O_2 improvement, however, CO_2 exchange is not compromised and may even improve, reflecting increased alveolar ventilation. Similar principles apply during prone positioning.

The prone position should be considered in patients with severe gas-exchange impairment regardless of their

TABLE 29-7: HOW SHOULD POSITIVE END-EXPIRATORY PRESSURE BE ADJUSTED? A PRACTICAL COMPROMISE

Ensure adequate preload.
Use small to moderate tidal volume or driving pressure.
Recruit by increasing PEEP and/or pressure-controlled ventilation to plateau of approximately 50 to 60 cm H_2O for approximately 1 to 2 minutes.
Reduce driving pressure to 15 to 20 cm H_2O.
Reduce PEEP until arterial O_2 or compliance falls significantly.
Re-recruit and select next higher PEEP if hemodynamics are acceptable.
Ensure that plateau pressure remains below acceptable maximum (e.g., <30 cm H_2O).

"recruiting test" result in the supine position. Patients requiring more than 10 to 15 cm H_2O PEEP at FI_{O_2} equal to or greater than 0.7 to maintain oxygen saturation at 90% or greater should be considered for prone positioning unless there is a clear contraindication or the patient is improving rapidly. The prone position should be considered independently of supine recruiting potential because as prone positioning will help lymphatic drainage and secretion removal and release the lower lobes of the lungs from the need to support the weight of the heart. Although provocative experimental data have challenged the concept,[172] the preferred angle for head elevation in supine patients is 30 degrees to horizontal (Fowler) with frequent (at least every 2 to 4 hours) lateral turning. Similar rules apply in the prone position; reverse Trendelenburg at 15 to 30 degrees is preferred to flat (0 degrees) horizontal. Tidal volume is adjusted to the same value used in the supine position. An increase of plateau pressure strongly suggests that chest wall compliance has been altered by proning. In those instances, a proportional increase of PEEP may also be justified. (For example, if plateau pressure rises by 10%, PEEP would be increased by 10%.)

PREVENTION OF INJURY PROPAGATION

Patients in the first stage of localized lung inflammation, such as lobar pneumonia, may have mobile secretions and edema that are both initially contained regionally rich in inflammatory mediators and surfactant-inhibiting protein. These injurious biofluids temporarily have the potential to spread via the airways to other healthy regions, propagating tissue damage (Fig. 29-23). Measures to contain them include use of moderately high PEEP, small tidal volumes and modest gravitational inclination, as well as the avoidance of forceful expiratory efforts. Although currently unproven, it seems prudent to take such "lung protective" measures during the earliest phase of ventilation so as to avoid the blossoming of focal inflammation into ARDS.[173]

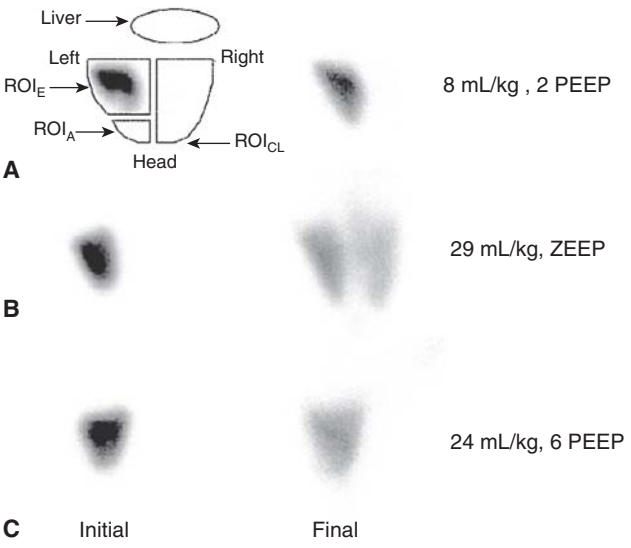

FIGURE 29-23 Propagation and limitation of intraalveolar biofluid via the airway network. In this experimental small-animal model, radiolabeled albumin can be spread from its initial lobar position throughout the lungs by high tidal volumes and low levels of PEEP. Conversely, moderate PEEP contains the fluid to the lung in which it was instilled. *ZEEP*, zero end-expiratory pressure. (Adapted, with permission, from de Prost N, Roux D, Dreyfuss D, Ricard JD, Le Guludec D, Saumon G Alveolar edema dispersion and alveolar protein permeability during high volume ventilation: effect of positive end-expiratory pressure. *Intensive Care Med.* 2007;33(4):711–717.)

Suggested Sequence of Management Decisions

Figure 29-24 is a suggested algorithm for decision making in ARDS ventilation.

INITIAL PHASE OF STABILIZATION AND SUPPORT

1. Determine whether the patient with oxygenation impairment has ALI, and if so, determine whether it is complicated by such reversible comorbidities as volume overload, pleural effusion, abdominal distension, or pneumothorax.
2. Initiate ventilation with face mask or intubate as severity warrants.
3. Decide on controlled versus spontaneous ventilation. Use controlled or nearly controlled ventilation to subdue respiratory efforts for the most severely involved patients during the early stage of support.[174]
4. Initial ventilator settings: FI_{O_2} 0.8, PEEP 5 to 8 cm H_2O (depending on concern regarding hemodynamic tolerance); tidal volume 6 to 10 mL/kg predicted body weight (depending on inspiratory plateau pressure and minute ventilation requirement).
5. Estimate volemic status initially from arterial blood pressure, respiratory variations of pulmonary and systemic arterial pulse pressure, central venous pressure, urinary output, and urinary electrolytes.
6. Confirm adequacy of intravascular volume using echocardiography, results from a volume challenge, and central venous and pulmonary artery catheter data (cardiac index, mixed venous O_2 saturation, and occlusion pressure), if available.
7. Replete any volume deficits and support the circulation with vasopressors and inotropes to the extent necessary to perform the ventilatory manipulations safely.
8. Determine the recruitment potential of the patient by using a recruiting maneuver and/or decremental PEEP trial.
9. Selected tidal volume should be inversely proportional to individual thoracic compliance and may range from 5 to 9 mL/kg of ideal body weight. During the PEEP trial, consider together the oxygenation change, the Pa_{CO_2} change, the alterations of mechanics, and the hemodynamic response. Adjust the PEEP and tidal volume combination to the lowest tolerated values that sustain the recruitment benefit.

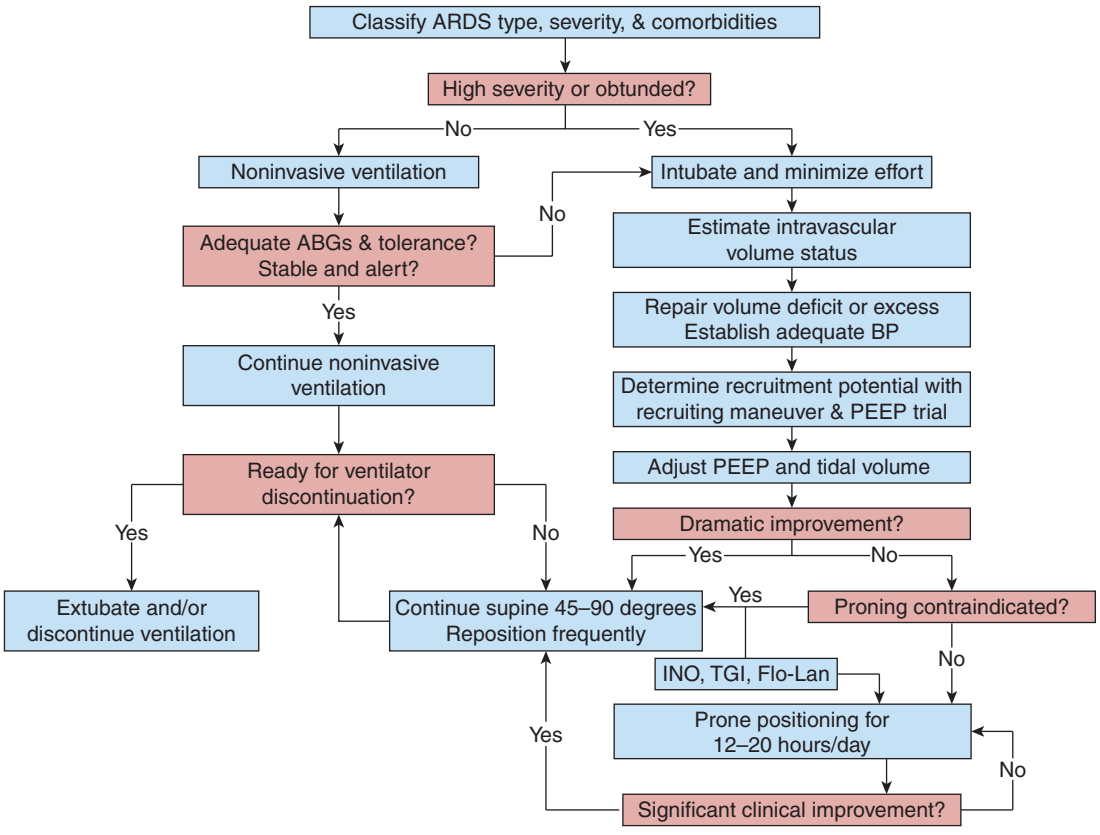

FIGURE 29-24 A suggested decision sequence for ventilation decisions in ARDS. *ABGs*, arterial blood gases; *BP*, blood pressure; *Flo-Lan*, proprietary name for prostacyclin; *INO*, inhaled nitric oxide; *PEEP*, positive end-expiratory pressure; *TGI*, tracheal gas insufflation. (Used, with permission, from Marini and Gattinoni.[5])

10. Proning is advisable in those with no contraindication and severe disease regardless of recruiting test, unless they are already improving rapidly. If the patient does not respond to the prone position, another recruiting maneuver is attempted while the patient is prone. The PEEP and tidal volume combination is readjusted as before.
11. When proning is used, scheduled reversion to the supine position is conducted at least once a day for cleanup, dressing changes, edema clearance, diagnostic procedures, transport to imaging, and so on, unless supine position is not physiologically tolerated. Many patients require almost continuous proning to maintain adequate gas exchange during the first several days of illness. Proning can be discontinued when it no longer makes an impressive contribution to oxygenation and plateau pressure can be kept in a "safe" range when the patient is supine.

SUBSEQUENT CARE

Recovery onset is recognized by improving Pa_{O_2}/FI_{O_2} and minute ventilation-to-Pa_{CO_2} ratios, clearing radiographic opacity, and rising compliance of the total respiratory system. Appropriate adjustments are then made to sedation and ventilating pressures and spontaneous breathing encouraged by conversion to pressure-support ventilation or to PCV with lower driving pressures as tolerated. Proning is discontinued when the alterations in Pa_{O_2} observed during position changes are less than 10%, status is clearly improved, or no obvious benefit has been achieved after a lengthy trial (>48 hours). Reductions in FI_{O_2} to an acceptable range are undertaken before cutbacks of PEEP.

PEEP weaning is initiated when FI_{O_2} is 40% or less and Pa_{O_2} is 80 mm Hg or greater.

FUTURE DIRECTIONS AND RESEARCH

Numerous questions related to the practical application of mechanical ventilation remain incompletely answered. These include the following.

Pathogenesis and Detection of Ventilator-Induced Lung Injury

Experimental data suggest that numerous intersecting variables can influence the severity of VILI. For a given combination of PEEP and tidal volume, vascular pressure, breathing frequency, and body temperature appear to be important

contributing variables in the expression of VILI. Although both mechanical and inflammatory disruption of the air–blood interface are likely to be in some part responsible, how mechanical forces causing structural alterations and signaling inflammation are not well elucidated. Markers for damaging patterns of ventilation are badly needed.

Long-Term Damage to Airways and Parenchyma

The determinants of alveolar and small-airway damage occurring in patients ventilated for ARDS are not clear—peak pressure, end-expiratory pressure, or both. Future outcome studies should target the incidence of obstructive, restrictive, and disordered gas exchange following recovery from ARDS.

Relationship of Ventilator-Induced Lung Injury to Multisystem Organ Dysfunction

Although laboratory studies have shown the release into the systemic circulation of gas, bacteria, and inflammatory mediators from injured lungs ventilated at high pressures with insufficient PEEP, the causative role of VILI in multiorgan failure must be investigated further for the clinical setting.

Ventilator-Associated Pneumonia

The incidence of ventilator-associated pneumonia is high in intubated patients, especially among those with ALI. Whether and how ventilator-related injury predisposes to ventilator-associated pneumonia needs to be clarified, and the measures necessary to reduce its incidence identified.

Environmental Modifications

Multiple factors have been shown in the laboratory to be important in the expression of VILI, including elevations of precapillary pressure, reduced left-atrial pressure, and elevated body temperature. Whether such factors play a role in the clinical setting is not clear. Do such cofactors as edema, FI_{O_2}, vasoactive and antiinflammatory drugs, and plasma protein concentrations determine the severity of expression of VILI? Are there additive or synergistic interactions among these variables?

Appropriate Patterns for Positive End-Expiratory Pressure, Tidal Volume, and Inspiratory Flow

How to select the most lung-protective combination of PEEP and tidal volume remains an area of active controversy. Although considerable progress has been made, the debate needs to be settled regarding the relative importance of limiting peak inflation pressure, optimizing PEEP, reducing driving pressure, or limiting tidal volume. Should arterial oxygenation, thoracic mechanics, or bedside imaging (as by electrical impedance tomography or acoustic mapping) be used to guide these selections? What are the added values of using strain ratio (tidal volume-to-functional residual capacity) and transpulmonary pressure calculations using the esophageal balloon to adjust ventilator parameters? The advisability of reducing inspiratory flow rate and minute ventilation to minimize VILI deserves to be studied carefully.

Recruitment Maneuvers

Sustained inflation with high airway pressure is an effective means of opening collapsed tissue and may be integral to selecting PEEP. The value of repeated recruiting maneuvers and the best means of doing so, however, have not been studied carefully. The effectiveness of recruitment maneuvers may well vary with the type or stage of ALI. Moreover, the incidence of lung rupture, hemodynamic compromise, and other complications requires documentation. How should such maneuvers be performed? In which patients? How often, and at what FI_{O_2}? Whether sighs help maintain recruitment in patients with low tidal volumes and unstable airways should be clarified.

Prone Positioning

The duration of proning (how long each day, when to cease proning in each patient) remains unsettled. Most investigators favor proning for most of each day, at least until there are clear improvements in mechanics and gas exchange, allowing adequate arterial oxygenation with FI_{O_2} less than 0.50 to 0.60 at tolerated levels of PEEP in the supine position. Whether proning confers an advantage on key outcomes other than oxygenation, at what stage of illness, and in which categories of patient, are other questions that merit further investigation. The advisability and appropriate intervals for body repositioning need further definition.

Noninvasive Ventilation

Noninvasive ventilation has been successfully applied to problems of acute respiratory failure, including some patients with ALI and ARDS.[95–97] Although vastly better than before, interfaces must be improved to ensure reliability and patient comfort. More information is needed to guide clinicians regarding optimal selection of patients, timing, equipment, and monitoring.

Therapeutic Value of Hypercapnia and Tolerance of Hypoxemia

Laboratory data suggest that hypercapnic intracellular acidosis protects against some forms of oxidant injury.[134–136]

Its therapeutic value for the clinical setting requires further investigation. Adaptation to hypoxemia occurs gradually in healthy individuals exposed to altitude and in many patients with chronically impaired oxygen exchange. Can patients who are acutely ill adapt to gradual imposition of hypoxemia? If so, how fast do they do so?

SPONTANEOUS VERSUS CONTROLLED VENTILATION

Strong arguments can be made for reducing ventilatory requirements and controlling ventilation in the first stages of ARDS management. The publication of a trial on use of paralytic agents[101] has energized debate as to the advisability of ceding control of the ventilatory pattern to the severely affected patient. The circumstances under which this is advisable or contraindicated as well as the most desirable ventilator mode need careful study.

Newer Modes of Ventilation

The physiologic rationale for high-frequency ventilation in ARDS is strong. It is not yet clear, however, that it confers benefits in beyond those achieved with conventional ventilator-based lung protective strategies. Definitive comparisons of high-frequency ventilation versus lung-protective strategies using a conventional ventilator are needed to identify possible benefits and hazards, as well as to learn the best approach to using this technology in the clinical setting. Certain less commonly introduced modes for ventilating ARDS, such as neurally adjusted ventilator assist,[110] proportional assist ventilation,[111] "noisy pressure support,"[86] APRV,[109] and high-frequency percussive ventilation,[118] are of strong interest, but their eventual place in ARDS ventilator management has not yet been settled.

Value of Adjunctive and Pharmacologic Measures

Tested as isolated interventions, nitric oxide, partial liquid ventilation, aerosolized surfactant, corticosteroids, almitrine, and prone positioning have not been demonstrated in multicenter trials to influence mortality except in highly selected patient cohorts.[156] The physiologic rationale for these measures, however, is strong for certain types of patients and for certain clinical conditions. Moreover, few of these adjuncts have been tested in combination. (Prone positioning, for example, adds to the oxygenation benefit of inhaled nitric oxide, but the impact of oxygenation of inhaled nitric oxide on survival has not been addressed.) The utility of such adjunctive measures—used alone and in combination—requires further study in populations most likely to benefit.

SUMMARY AND CONCLUSION

Injury to the alveolar–capillary membrane originates from diverse causes that may initially disrupt either the epithelial or endothelial surfaces. Managing the spectrum of conditions grouped together under the all-encompassing label of ARDS is a challenging assignment that must take into account the severity and stage of illness, as well as the interactions among the ventilatory and nonventilatory variables that influence the progress of this condition. Prevention of excessive tissue strain during the tidal cycle entails the avoidance of intolerable peak transalveolar and driving pressures, repetitive opening and closing of unstable lung units, as well as attention to pathogenetic cofactors that may initiate or exacerbate lung injury or retard healing. Because of the diversity of mechanical problems presented by different patients as well as the heterogeneity of mechanical properties among the lung units within the same individual, a logical approach requires mastery of key physiologic principles, awareness of the guidelines provided by well-conducted clinical trials, and integrated clinical judgment at the patient's bedside.

MECHANICAL VENTILATION FOR SEVERE ASTHMA

James W. Leatherman

It is estimated that 6000 to 10,000 patients require mechanical ventilation for acute asthma in the United States each year.[1] Asthma exacerbations that lead to mechanical ventilation typically progress over 1 or more days, with viral infections being the most common etiology (Table 30-1).[2] Airways typically show extensive mucous plugging and eosinophilic infiltration with edema, explaining the often limited immediate response to bronchodilators.[3] Approximately 20% of patients experience a more explosive onset, with attacks occurring over minutes to hours.[2–4] The precise cause of "sudden asphyxial" asthma is not always apparent, but recognized triggers include aeroallergens, nonsteroidal antiinflammatory agents, airway irritants, and emotional distress.[2,4] Rapid-onset attacks are characterized by profound bronchospasm with minimal mucous plugging, explaining both their sudden onset and rapid resolution.[3]

Regardless of the mode of onset, life-threatening asthma is associated with a markedly increased airway resistance, pulmonary hyperinflation, and high physiologic dead space, which together lead to hypercapnia and risk of respiratory arrest.[5] Hypercapnia per se is not an indication for intubation, as most asthma exacerbations with hypercapnia do respond to bronchodilator therapy and others may be successfully managed with noninvasive ventilation (Fig. 30-1).[6–11] Inhalation of a helium–oxygen gas mixture (heliox) may also reduce work of breathing and might decrease the likelihood of intubation.[11,12]

Indications for intubation include respiratory arrest, depressed level of consciousness, or progressive fatigue and exhaustion. Rapid-sequence intubation has been advocated by some experts,[13] but a high degree of confidence in being able to intubate is a prerequisite before use of a paralytic because it may be difficult to achieve effective bag-mask ventilation in patients with markedly increased airway resistance. Regardless of the technique used, intubation should be performed by the most skilled operator present. Prolonged airway manipulation and repeated failed intubations in the setting of fulminant asthma may prove catastrophic.

Various drugs have been used to facilitate intubation. Ketamine does not cause respiratory depression or hypotension, but may increase laryngeal reflexes and predispose to laryngospasm with excessive upper airway manipulation.[14] Propofol decreases airways resistance after intubation as compared with etomidate or thiopental.[15] Etomidate, however, causes less hypotension than propofol and may be a better alternative in hemodynamically unstable patients.[14] Indeed, many of the drugs used to facilitate intubation reduce vascular tone, which, together with a sudden decrease in venous return secondary to pulmonary hyperinflation, may result in postintubation hypotension.[16] The latter should be anticipated and managed by rapid fluid administration and manual ventilation via an Ambu bag at a slow rate to limit the severity of hyperinflation.[17] Postintubation hypotension that is profound and refractory to these first-line interventions may be managed with a bolus dose of a rapidly acting vasopressor, such as phenylephrine, vasopressin, or epinephrine.

VENTILATOR MANAGEMENT

Controlled hypoventilation with permissive hypercapnia was first proposed as a ventilator strategy for severe asthma almost 30 years ago.[18] In brief, the rationale for this approach is that hypercapnia poses less risk than does markedly

TABLE 30-1: PATTERNS OF NEAR-FATAL ASTHMA

	Slow-Onset	Rapid-Onset
Time course (onset)	One or more days	Minutes to hours
Triggers	Virus, unknown	Aeroallergen, nonsteroid antiinflammatory drug, airway irritant, emotional stress, unknown
Frequency	~80%	~20%
Mechanisms of airflow obstruction	Mucous plugging and airway edema > bronchospasm	Bronchospasm ("dry airways")
Airway inflammation	Eosinophils	Neutrophils
Response to treatment	Slow: minimal response to initial bronchodilators	Rapid: good response to initial bronchodilators
Prevention	Steroids early in exacerbation	Avoid triggers
Duration intubation	Often several days	Often <24 hours

increased lung volume.[19,20] Although randomized studies of controlled hypoventilation in asthma are lacking, a retrospective analysis suggested that it is associated with better outcomes than a conventional ventilator strategy.[19] To apply controlled hypoventilation rationally, it is essential to understand methods for monitoring pulmonary hyperinflation and how the latter is influenced by the choice of ventilator settings.[21–25] Subsequent discussion of ventilator strategy and monitoring will be limited to use of volume-cycled ventilation, the preferred method for managing patients with severe airflow obstruction.[23]

Pulmonary Hyperinflation: Mechanism and Assessment

Patients with acute severe asthma breathe near their total lung capacity; with mechanical ventilation, lung volumes may increase further (Fig. 30-2).[23] During mechanical ventilation, dynamic hyperinflation is initiated when there is insufficient time during expiration for complete exhalation of delivered tidal volume, resulting in an increase in end-expiratory lung volume and auto–positive end-expiratory alveolar pressure (auto-PEEP). With subsequent breaths, a progressive increase in lung volume leads to improved expiratory gas flow because of higher elastic recoil pressure and an increase in airways diameter, permitting the entire tidal volume to be exhaled (Fig. 30-3). Although dynamic hyperinflation may be an adaptive process that enhances expiratory flow, it can result in severe hypotension and barotrauma, life-threatening complications that are a consequence of extreme alveolar overdistension.

The severity of hyperinflation in severe asthma varies among patients and within individual patients over time. Serial monitoring of dynamic hyperinflation is important for identifying an increased risk of hypotension and barotrauma and to assess changes in the severity of airflow obstruction in response to therapy.

Two methods of monitoring the severity of airflow obstruction in status asthmaticus have been used: measurement of total exhaled volume during a prolonged apnea beginning at end inspiration and assessment of airway pressure. Tuxen et al[21–24] used a prolonged apnea to assess dynamic hyperinflation in patients with severe asthma, with the total amount of gas exhaled during the apnea defined as the volume (above functional residual capacity) at end inspiration (V_{EI}). The volume at end expiration (V_{EE}) represents the increase in lung volume

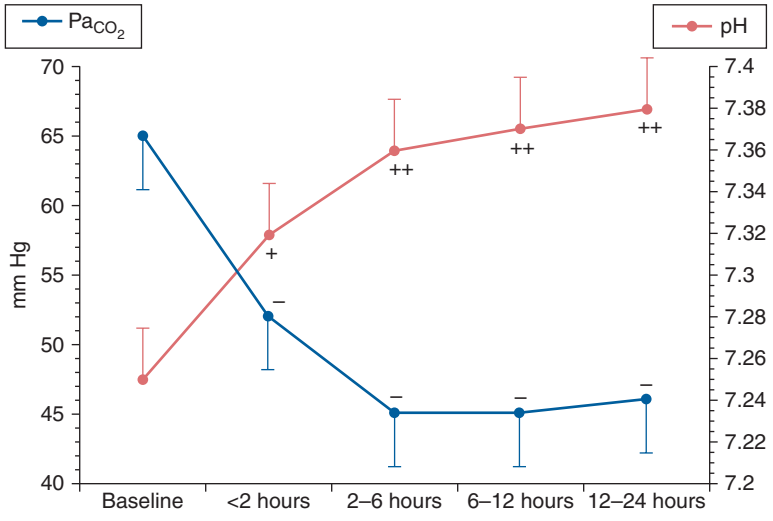

FIGURE 30-1 Change in partial pressure of arterial carbon dioxide (Pa_{CO_2}) and pH associated with the use of noninvasive positive-pressure ventilation by face mask in patients with severe asthma. (Used, with permission, from Meduri GU, Cook TR, Turner RE, et al. Noninvasive positive pressure ventilation in status asthmaticus. *Chest.* 1996;110:767–774.)

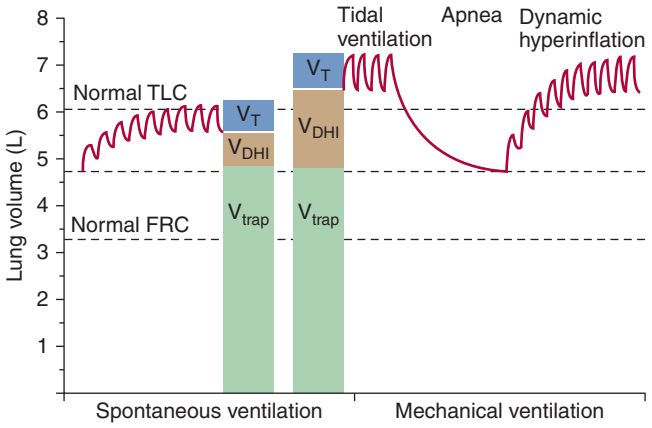

FIGURE 30-2 Lung volumes in severe asthma during spontaneous ventilation and with mechanical ventilation. Tidal breathing occurs near total lung capacity (*TLC*) during spontaneous ventilation and above TLC during mechanical ventilation. After delivery of tidal volume (V_T) during mechanical ventilation, a prolonged apnea permits exhalation of volume produced by dynamic hyperinflation (V_{DHI}); lung volume at the end of apnea, however, remains well above normal functional residual capacity (*FRC*) because of gas trapped behind occluded airways (*Vtrap*). (Adapted, with permission, from Tuxen et al.[23])

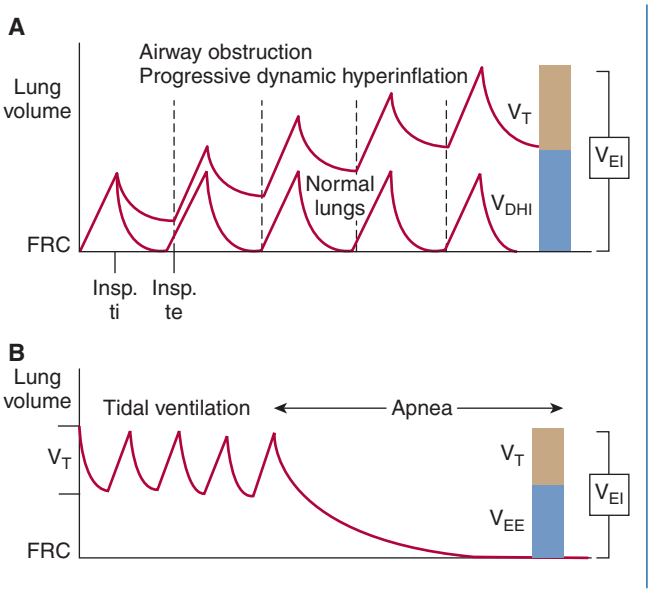

FIGURE 30-3 **A.** Dynamic hyperinflation. *FRC,* functional residual capacity; V_{DHI}, volume (above FRC) caused by dynamic hyperinflation; V_{EI}, volume (above FRC) at end inspiration; V_T, tidal volume. V_{EE} (volume at end expiration) and V_{DHI} (volume produced by dynamic hyperinflation) are equivalent. (Used, with permission, from Tuxen DV, Lane S. The effects of ventilatory pattern on hyperinflation, airway pressures, and circulation in mechanical ventilation of patients with severe air-flow obstruction. *Am Rev Respir Dis.* 1987;136:872–879.)

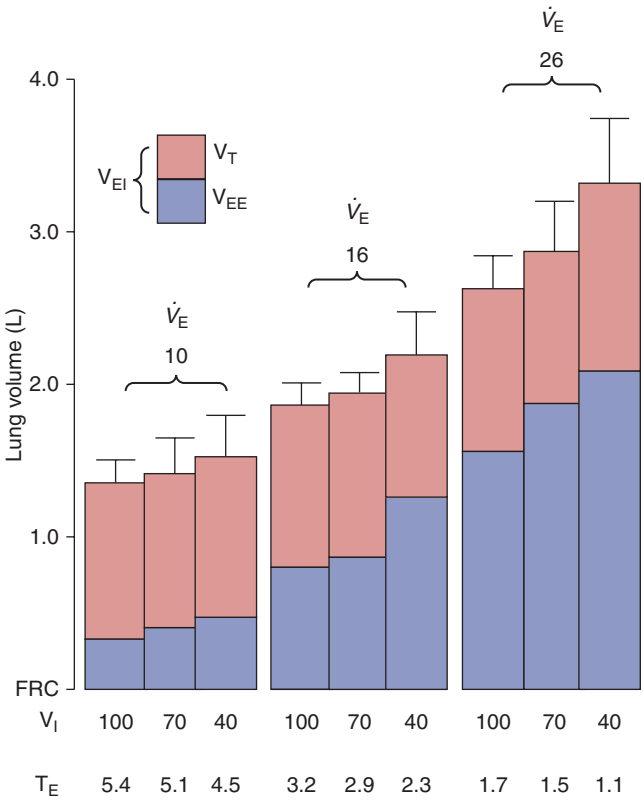

FIGURE 30-4 Effect of minute ventilation ($\dot{V}_E$) and inspiratory flow rate (V_I) on dynamic hyperinflation during mechanical ventilation for severe asthma. V_{EE}, volume at end expiration; V_{EI}, volume at end inspiration; V_T, tidal volume. (Used, with permission, from Tuxen DV, Lane S. The effects of ventilatory pattern on hyperinflation, airway pressures, and circulation in mechanical ventilation of patients with severe airflow obstruction. *Am Rev Respir Dis.* 1987;136:872–879.)

caused by dynamic hyperinflation and is calculated by subtracting tidal volume from V_{EI} (see Figs. 30-3 and 30-4). In one study, hypotension and barotrauma were more reliably predicted by V_{EI} than by airway pressures.[24] Nonetheless, measurement of V_{EI} and V_{EE} has not gained widespread clinical acceptance, in part because of the need for paralysis.[23]

A more commonly used monitoring method is assessment of airway pressures (Fig. 30-5). As described initially,[18] controlled hypoventilation in status asthmaticus targeted a peak airway pressure (P_{PEAK}) below 50 cm H_2O, a strategy used by others subsequently.[26] P_{PEAK}, however, is highly dependent on inspiratory flow-resistive properties and may not accurately reflect the degree of hyperinflation.[23,27] Patients with asthma often have a P_{PEAK} above 50 cm H_2O when managed with high inspiratory flow rate (see below), but their risk of barotrauma may be negligible.[27] Furthermore, P_{PEAK} may not consistently reflect the reduction in dynamic hyperinflation after expiratory time is prolonged, presumably because of an increase in airways resistance as lung volume decreases (Fig. 30-6).[25]

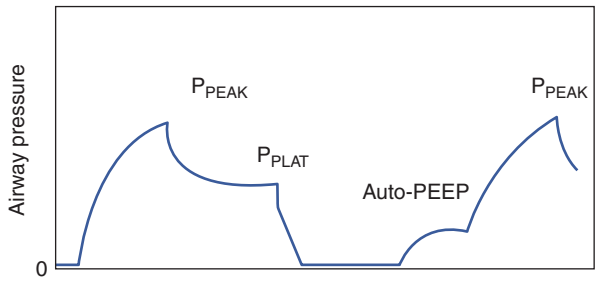

FIGURE 30-5 Proximal airway pressure during an end-inspiratory and end-expiratory airway occlusion. End-inspiratory occlusion is followed by an initial rapid fall in airway pressure, secondary to intrinsic airways resistance and then a more gradual fall in pressure secondary to gas redistribution and tissue resistance. P_{PEAK}, peak airway pressure; P_{PLAT}, plateau airway pressure; auto-PEEP, auto–positive end-expiratory pressure.

Plateau airway pressure (P_{PLAT}) may be a better parameter for monitoring lung hyperinflation in status asthmaticus (see Fig. 30-5).[23,27–31] Patients with severe airflow obstruction typically have near-normal respiratory system compliance and an increase in P_{PLAT} results from dynamic hyperinflation. At constant tidal volume, changes in the degree of dynamic hyperinflation in response to bronchodilators or manipulation of expiratory time can be inferred from changes in P_{PLAT}.[25] Because P_{PLAT} provides an estimate of maximal alveolar pressure, it might (in theory) help to predict risk of alveolar rupture. It should be noted, however, that P_{PLAT} represents the *average* end-inspiratory alveolar pressure and the maximal alveolar pressure in some units will be higher (Fig. 30-7).[31] The safe threshold for P_{PLAT} is not well defined in status asthmaticus, but an acceptable upper limit of 25 to 30 cm H_2O has been suggested most often (Table 30-2).[23,27,30,31]

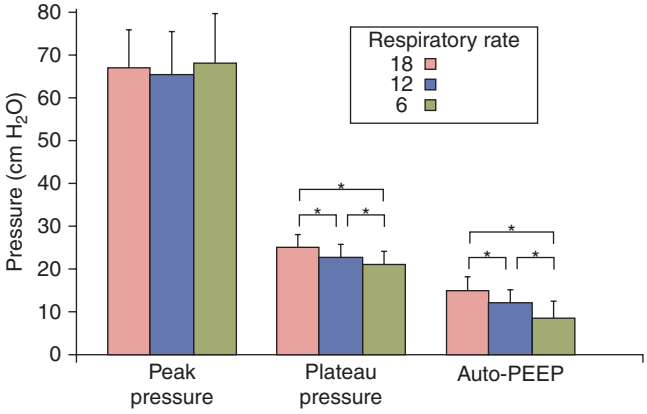

FIGURE 30-6 Peak airway pressure, plateau pressure, and auto-PEEP at respiratory rates of 18, 12, and 6 breaths/min during mechanical ventilation for severe asthma (n = 12). (Used, with permission, from Leatherman JW, McArthur C, Shapiro RS. Effect of prolongation of expiratory time on dynamic hyperinflation in mechanically ventilated patients with severe asthma. *Crit Care Med.* 2004;32:1542–1545.)

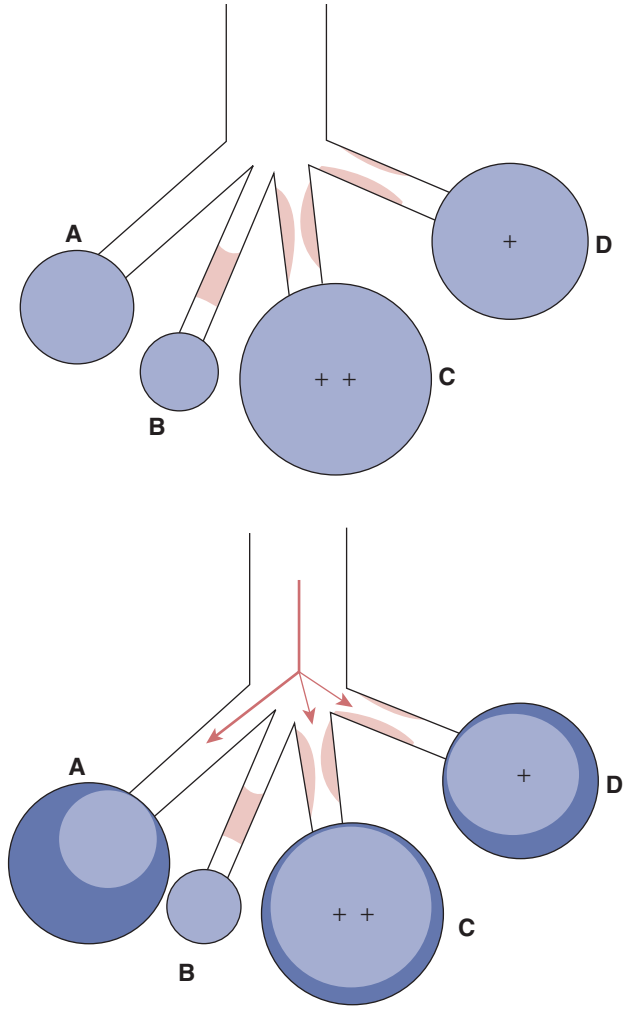

FIGURE 30-7 *Top.* Effect of varying degrees of airway obstruction on end-expiratory alveolar volumes and pressures. *Bottom.* Expected distribution of the tidal volume on application of pressure during mechanical ventilation in the setting of inhomogeneous obstruction (With kind permission from Springer Science and Business Media: Oddo et al. Management of mechanical ventilation in acute severe asthma: practical aspects. *Intensive Care Med.* 2006;27:1–10.)

When measured by end-expiratory airway occlusion, auto-PEEP provides an estimate of average end-expiratory alveolar pressure. The expected levels of auto-PEEP in status asthmaticus have been infrequently reported, but two studies found average values of 15 and 10 cm H_2O, respectively.[25,32] In general, changes in auto-PEEP track closely with changes in P_{PLAT}, and either (or both) may be helpful for following the degree of dynamic hyperinflation. On occasion, patients with status asthmaticus who have radiographic evidence of hyperinflation and elevated P_{PLAT} may have unexpectedly low values of measured auto-PEEP when ventilated at very low respiratory rates that encourage airway closure, preventing accurate assessment of end-expiratory alveolar pressure.[33] Auto-PEEP should always be measured during passive expiration, because forceful exhalation often leads to gross

TABLE 30-2: MECHANICAL VENTILATION FOR SEVERE ASTHMA: ONE APPROACH

Ventilator settings (initial)	
Mode	Assist-control
V_T	7 to 9 mL/kg
Rate	10 to 14 breaths/min
V_I	60 to 70 L/min
Waveform	Decelerating or square
PEEP	≤5 cm H_2O
FI_{O_2}	SaO_2 > 90%
Sedation/paralysis	
Propofol	2 to 5 mg/kg/h infusion
Fentanyl	50 to 200 µg/h infusion
Vecuronium	0.1 mg/kg bolus PRN
Therapy of airflow obstruction	
Albuterol-ipratropium MDI	6 puffs qh × 4, then q1-2h
Methylprednisolone	2 mg/kg/day
Ventilator adjustments	

Goals: P_{PLAT} < 30 cm H_2O (≤25 ideal) and pH ≥ 7.2
- P_{PLAT} > 30 cm H_2O → decrease $\dot{V}_E$ (rate)
- pH < 7.2 and P_{PLAT} < 25 → increase $\dot{V}_E$ (rate)
- pH < 7.2 and P_{PLAT} 25 to 30 → no change (consider buffer if adverse effects of acidosis suspected clinically)

Abbreviations: MDI, metered-dose inhaler; P_{PLAT}, plateau airway pressure; $\dot{V}_E$ minute ventilation; V_I, inspiratory flow rate; V_T, tidal volume.

overestimation of auto-PEEP and the severity of dynamic hyperinflation, potentially leading to unnecessary restriction of minute ventilation.[34]

Ventilator Settings

In severe asthma, three key factors determine the degree to which V_{EE} increases during mechanical ventilation: expiratory resistance, tidal volume, and expiratory time. The ventilator settings that most influence the severity of hyperinflation are tidal volume, respiratory rate, and inspiratory flow rate.

MINUTE VENTILATION: TIDAL VOLUME AND RESPIRATORY RATE

Tuxen and Lane[21] examined various ventilator settings in severe asthma and found that minute ventilation was the most important determinant of dynamic hyperinflation (see Fig. 30-4). For a given minute ventilation, the extent of dynamic hyperinflation was similar regardless of the specific combination of respiratory rate and tidal volume.[21] The degree of hyperinflation became quite marked when minute ventilation was increased from 10 to 16 and 26 L/min; at the highest minute ventilation, both hypotension and barotrauma were noted.[21]

Although these very high levels of minute ventilation clearly pose a risk in the ventilated patient with asthma, the benefit of extreme limitation of minute ventilation, as advocated by some authors,[35] is less certain. One study examined the effect of prolongation of expiratory time on dynamic hyperinflation—as assessed by P_{PLAT} and auto-PEEP—when the baseline minute ventilation approximated 10 L/min.[25] As expected, P_{PLAT} and auto-PEEP decreased when expiratory time was prolonged, but the magnitude of the reduction was not profound (see Fig. 30-6). For example, when respiratory rate was reduced from 12 to 6 breaths/min (adding 5 seconds to expiratory time), P_{PLAT} and auto-PEEP fell by only 2 to 3 cm H_2O.[25] The relatively modest effect on dynamic hyperinflation is understandable given the low expiratory flow rates after a few seconds of expiration (Fig. 30-8). Because flow decreases progressively throughout expiration, the reduction in hyperinflation that results from a given prolongation of expiratory time will depend on the baseline respiratory rate (i.e., less benefit at lower respiratory rates) (Fig. 30-8).

Another factor that may limit the degree to which prolongation of expiratory time lessens lung hyperinflation is the presence of gas trapped behind occluded airways. Total pulmonary hyperinflation has two components: a dynamic component that is amenable to ventilator manipulation and a second component caused by gas trapped behind occluded airways, with the latter being

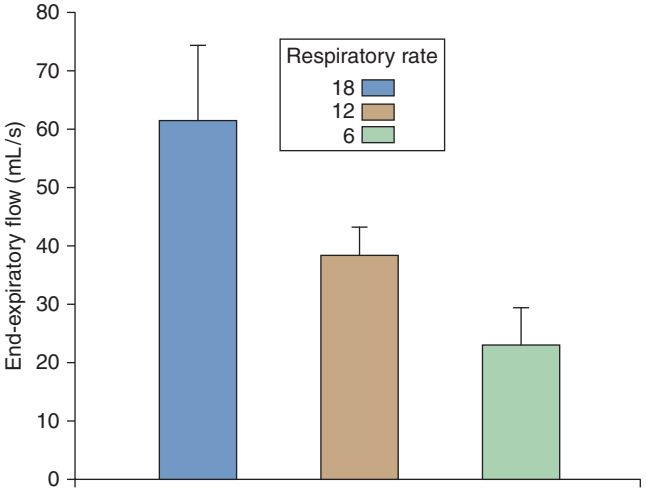

FIGURE 30-8 End-expiratory flow rates at respiratory rates of 18, 12, and 6 breaths/min during mechanical ventilation for severe asthma (n = 7). (Used, with permission, from Leatherman JW, McArthur C, Shapiro RS. Effect of prolongation of expiratory time on dynamic hyperinflation in mechanically ventilated patients with severe asthma. *Crit Care Med.* 2004;32:1542–1545.)

unaffected by expiratory time (see Fig. 30-2). One study suggested that trapped gas accounted for a greater percentage of total pulmonary hyperinflation than did dynamic hyperinflation.[22]

In essence, there is often little to be gained by reducing the respiratory rate below 10 to 14 breaths/min when a tidal volume of 7 to 9 mL/kg is used (see Table 30-2). An exception might be when hyperinflation is marked (e.g., P_{PLAT} >30 cm H_2O) or has resulted in complications, because even a small reduction in hyperinflation might have a meaningful clinical impact. Unfortunately, dramatic reductions in hyperinflation may not be easily achieved by ventilator manipulation alone and must await improvement in airflow obstruction.

INSPIRATORY FLOW RATE

It has been suggested that an inspiratory flow rate of 100 L/min and a square waveform be used in patients with status asthmaticus to shorten inspiratory time and lengthen time for expiration.[23,27,28] This strategy may yield a favorable inspiratory-to-expiratory timing (I:E) ratio, but the impact on dynamic hyperinflation will be modest (Table 30-3). Conventional flow rates (60 to 70 L/min) and a decelerating waveform are appropriate for patients whose minute ventilation has been limited (see Table 30-2).

TABLE 30-3: EFFECT OF INSPIRATORY FLOW RATE IN SEVERE ASTHMA

V_I and Waveform	T_I(s)	T_E(s)	I:E Ratio	Δ DHI (ml)	Δ auto-PEEP (cm H_2O)
60 L/min, decelerating	1.1	3.2	1:3	—	—
120 L/min, square	0.3	4.0	1:13	~−50	~−1

Note: Assume V_T 600 mL, respiratory rate 14 breaths/min, respiratory compliance 60 mL/cm H_2O, and end-expiratory flow rate approximately 60 mL/s.

Abbreviations: DHI, dynamic hyperinflation; I:E ratio, inspiratory-to-expiratory timing ratio; T_E, expiratory time; T_I, inspiratory time; V_I, inspiratory flow rate.

APPLIED POSITIVE END-EXPIRATORY PRESSURE

External PEEP has been used during mechanical ventilation of patients with chronic obstructive pulmonary disease (COPD) to decrease the effort required to trigger the ventilator without increasing lung volume.[36–38] There is less of a rationale for the use of external PEEP when a patient is undergoing controlled mechanical ventilation. In addition, the impact of applied PEEP on lung volume may be different in asthma and COPD (see Fig. 30-9).[36,38,39] One study found that external PEEP of 10 to 15 cm H_2O increased the lung

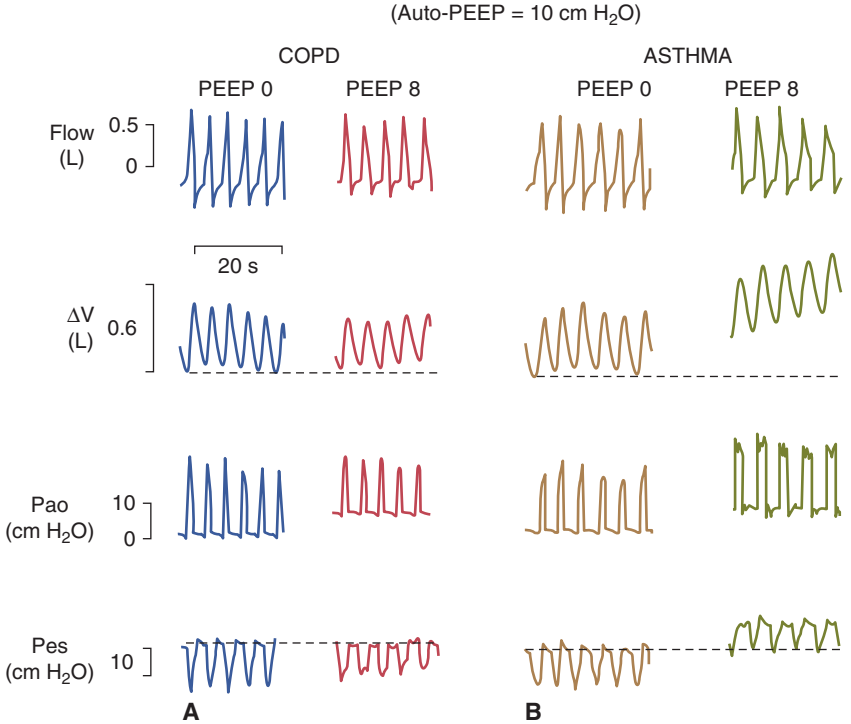

FIGURE 30-9 Response to 8 cm H_2O of PEEP in COPD and asthma during proportional-assist ventilation. Esophageal pressure (*Pes*) indicates a similar reduction in inspiratory effort in both patients. External PEEP did not affect lung volume (*V*) or airway opening pressure (*Pao*) in COPD, but both were increased by PEEP in asthma. (Adapted, with permission, from Ranieri VM, Grasso S, Fiore T, Giuliani R. Auto-positive end-expiratory pressure and dynamic hyperinflation. *Clin Chest Med.* 1996;17(3):379–394.)

volumes of ventilated patients with severe asthma, suggesting that minimal PEEP (≤5 cm H_2O) levels should be used in this setting[39] (see Table 30-2). A recent study claimed that the response to PEEP in patients with airflow obstruction is variable, with the effect being an increase, decrease, or no change in lung volume.[40] The likelihood of a beneficial effect of external PEEP in asthma would seem to be minimal, and if a trial of PEEP is attempted, it should be abandoned immediately if P_{PLAT} increases.

Gas Exchange: Hypercapnia

Hypercapnia is common during mechanical ventilation of patients with severe asthma, with an average partial pressure of arterial carbon dioxide (Pa_{CO_2}) of 68 mm Hg and pH of 7.18 in one study.[25] On occasion, the Pa_{CO_2} may exceed 100 mm Hg. Hypercapnia despite normal minute ventilation is a result of markedly increased physiologic dead space from alveolar overdistension. The impact of an increase in minute ventilation to lower Pa_{CO_2} is mitigated by further increase in dead space related to progressive hyperinflation. As such, hypercapnia in fulminant asthma may not be truly "permissive," because it may be impossible to normalize Pa_{CO_2} through ventilator manipulation.

Given the potential risks of excessive hyperinflation, a reasonable strategy may be to select ventilator settings that typically provide a safe level of dynamic hyperinflation (tidal volume of 7 to 9 mL/kg, respiratory rate of 10 to 14 breaths/min) and accept the resulting Pa_{CO_2} (see Table 30-2). Fortunately, hypercapnia in status asthmaticus is usually well tolerated, with serious adverse consequences being uncommon.[18,19] The most serious consequence of hypercapnia is an increased intracranial pressure in patients with acute neurologic pathology. Although rare, cerebral edema and subarachnoid hemorrhage attributed to hypercapnia has been reported in status asthmaticus.[41–43] Hypercapnia is of greatest concern when there has been cerebral anoxia secondary to respiratory arrest before intubation. Unfortunately, it may be difficult to achieve normocapnia in fulminant asthma without extracorporeal CO_2 removal unless the patient has rapidly reversible bronchospasm.

One approach to managing acute respiratory acidosis in status asthmaticus is to accept the elevated Pa_{CO_2} and administer buffering agents. Unfortunately, standard buffer therapy is relatively inefficient in acute respiratory acidosis. Even partial correction of severe respiratory acidosis will typically require a minimum of several hundred milliequivalents of sodium bicarbonate in an adult.[18] An animal study did find that administration of sufficient sodium bicarbonate (14 mEq/kg) to preserve a normal pH during induction of acute hypercapnia (Pa_{CO_2} = 80 mm Hg) prevented an increase in cerebral blood flow and intracranial pressure.[44] The effect on intracranial pressure is less certain if a smaller amount of bicarbonate is given slowly to raise the pH to 7.15 to 7.20, as has been recommended.[18,44] One problem with giving large amounts of bicarbonate is that once airflow obstruction and hypercapnia resolve, the patient will be left with a therapy-induced metabolic alkalosis.

As a general rule, unless there is some compelling reason to correct underlying respiratory acidosis (e.g., arrhythmia, hyperkalemia, or otherwise unexplained hemodynamic instability), it is probably reasonable to forego attempts to correct serum pH and wait for the Pa_{CO_2} to decrease as airflow obstruction improves. Fortunately, many patients experience substantial improvement in their hypercapnia during the first 12 hours of intubation.[45] If bicarbonate therapy is given, ideally it should be administered by slow infusion rather than by rapid bolus administration because the latter may lead to an acute increase in CO_2 production and a transient fall in intracellular pH as a consequence of rapid diffusion of CO_2 into cells. An alternative to sodium bicarbonate is tromethamine (THAM), a buffer that does not generate CO_2 during the buffering process.[18] Even though THAM may offer some theoretical advantages over sodium bicarbonate for buffering respiratory acidosis, its use may lead to the same problem of a posthypercapnic metabolic alkalosis.

NONVENTILATOR MANAGEMENT

All ventilated patients with severe asthma require inhaled bronchodilators, corticosteroids, and sedation. In rare instances, one or more unconventional approaches also may be considered.

Standard Therapy

BRONCHODILATORS AND GLUCOCORTICOIDS

The optimal dose of inhaled bronchodilators during mechanical ventilation of patients with severe asthma has not been defined. Based on studies of patients with COPD, the optimal dose of albuterol given by metered-dose inhaler is likely to be 4 to 6 puffs.[46–48] Hourly dosing is appropriate initially. Assessment of lung mechanics during incremental dosing of inhaled β_2 agonists may be useful to determine both the optimal number of puffs and dosing interval for individual patients, using an "n = 1" trial. Ipratropium might also be considered, given its benefit when added to albuterol therapy in nonintubated asthmatics with severe airflow obstruction.[49]

Glucocorticoids are an essential component of the treatment of severe asthma, with an effect being evident within 12 hours of administration.[50] An initial dose of 2 mg/kg/day of methylprednisolone or equivalent seems appropriate.[51]

SEDATION AND PARALYSIS

As with other causes of respiratory failure, minimal goals of sedation in status asthmaticus include provision of anxiolysis, analgesia, and prevention of patient–ventilator dyssynchrony. Patients with status asthmaticus present an additional challenge because of the need to enforce controlled hypoventilation despite acute respiratory acidosis that increases

respiratory drive.[8] A combination of propofol or a benzodiazepine (midazolam or lorazepam) with a narcotic (fentanyl or morphine) often proves optimal, and very large doses may be required (see Table 30-2).[8] Because airflow obstruction often improves within 24 to 48 hours,[27,45] residual sedation that delays extubation is undesirable. A major advantage of propofol over benzodiazepines is that propofol allows deep sedation that reverses promptly on its discontinuation. The maximal propofol dose should not exceed 5 mg/kg/hour, because prolonged infusion of very high doses of propofol can lead to life-threatening complications.[52]

Large doses of sedatives and narcotics in combination with marked lung hyperinflation may result in hypotension. When additional muscle relaxation is needed in the face of hemodynamic instability, it may be safer to administer a nondepolarizing neuromuscular blocking agent than increase the dose of sedatives and narcotics. Even when hypotension is not present, intermittent administration of one or more boluses of a neuromuscular blocking agent may help to provide a period of temporary muscle relaxation, during which time sedative doses can be escalated gradually to achieve target levels. Prolonged use of a neuromuscular blocking agent may increase the likelihood of myopathy in status asthmaticus (see the section Death and Complications), but short-term use likely does not carry significant risk.[53,54] The specific neuromuscular blocking agent selected is likely unimportant, although vecuronium, perhaps, should be avoided in patients with renal failure.[55] Intermittent bolusing is preferred to a continuous infusion because this permits ongoing assessment of the adequacy of sedation and lessens the likelihood that the patient will undergo unnecessarily prolonged neuromuscular paralysis. When sedatives and narcotics are used liberally, supplemented by short-term intermittent boluses of a neuromuscular blocking agent if needed, very few patients with status asthmaticus will require prolonged, continuous neuromuscular paralysis.

Alternative Therapies

Occasionally, one of several nontraditional approaches may be considered in patients with fulminant asthma. Strategies that have been reported anecdotally to be beneficial include the use of heliox, inhalational anesthetics, or ketamine, nitric oxide, mucolytic agents, bronchoscopy, and extracorporeal support.

HELIOX

The lower gas density of heliox reduces frictional resistance where gas flow is turbulent and, by lowering the Reynolds number, also encourages laminar flow.[11] One study reported that heliox produced a rapid fall in peak airway pressure and Pa_{CO_2} of ventilated patients with asthma.[56] The effects on P_{PLAT} and auto-PEEP, however, were not reported, and it is unclear whether changes in Pa_{CO_2} were at constant minute ventilation.[56] A second study of heliox in severe asthma found little change in Pa_{CO_2} when tidal volume and respiratory rate were held constant.[57] Two prospective studies found that a 70:30 mixture of heliox reduced auto-PEEP during mechanical ventilation of patients with COPD.[58,59] This suggests that heliox may have a measurable benefit in selected patients and might be considered for use when conventional management results in an unacceptable degree of dynamic hyperinflation in patients with status asthmaticus.[23] Continuous use of heliox is very expensive and can only be justified if it significantly improves indices of hyperinflation (P_{PLAT}, auto-PEEP) or hypercapnia.[60]

Before using heliox, it is crucial to fully understand how its use will affect performance of the ventilator.[61] Use of a density-independent spirometer in the expiratory limb of the ventilator circuit is advisable to ensure accurate setting of tidal volume.[11]

GENERAL ANESTHETICS

Inhalational anesthetics have potent bronchodilating properties, and several anecdotal reports have described their use in status asthmaticus.[62,63] In the only study to carefully assess lung mechanics, isoflurane resulted in a decrease in airways resistance and auto-PEEP in three patients with asthma, although only one had a marked response (Fig. 30-10).[64]

Isoflurane and sevoflurane are less arrhythmogenic than halothane and have equal or greater bronchodilator properties.[63] All these agents may cause hypotension secondary to their peripheral vascular effects, and an increase in venous capacitance may be particularly detrimental when marked dynamic hyperinflation already has compromised venous return. The adverse hemodynamic effects generally can be mitigated through liberal administration of fluid and with vasoactive support if necessary. It is mandatory, of course, that personnel highly skilled in the use of anesthetic agents be responsible for their administration. Some intensive care unit ventilators have a port to which the anesthesia vaporizer can be attached, and with appropriate scavenging

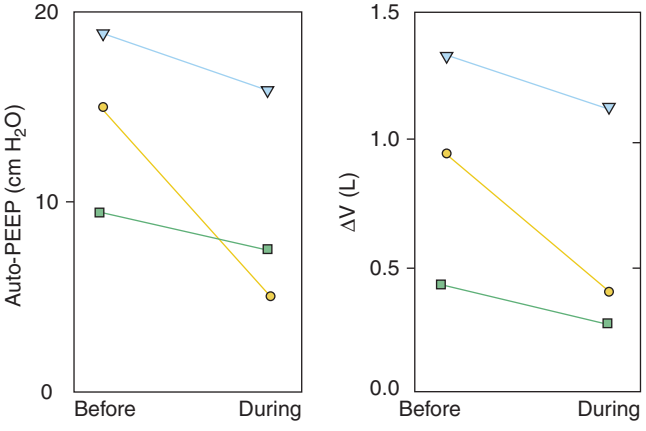

FIGURE 30-10 The effect of isoflurane on auto-PEEP and change in lung volume (ΔV) in three patients with severe asthma. (Adapted, with permission, from Maltais F, Sovilj M, Goldberg P, Gottfried SB. Respiratory mechanics in status asthmaticus. Effects of inhalational anesthesia. *Chest*. 1994;105:1401–1406.)

of anesthetic gases, the general anesthetic can be administered in the intensive care unit.[62]

Ketamine, an intravenous dissociative anesthetic, also has been advocated for use in severe asthma. This drug, however, can lead to significant increases in blood pressure, heart rate, and intracranial pressure. There seems little justification for the use of ketamine in ventilated patients with status asthmaticus.

MUCOLYTICS

The potential benefit of *N*-acetylcysteine as a mucolytic is unknown; in an anecdotal report, it seemed to enhance bronchoscopic extraction of mucous plugs.[65] Benefit from rhDNAse also has been reported.[66]

BRONCHOSCOPY

Patients with fatal asthma often have extensive mucoid impaction.[67] Removal of impacted mucus by bronchoscopy has been reported to lower airway pressures and improve gas exchange in ventilated patients with severe asthma.[65] However, there is a potential for worsening bronchospasm and several large series have reported good outcomes without use of bronchoscopy.[18,24,26,32,45] Patients who fail to improve after several days of mechanical ventilation might be considered for diagnostic bronchoscopy to inspect the airways for mucous plugs that might be extracted, the goal being to reduce the duration of ventilator support.

EXTRACORPOREAL LIFE SUPPORT

Both pump-driven and pump-less extracorporeal life support has been used in severe asthma.[68–70] Because severe asthma is fully reversible, this approach clearly would be justified if there were an imminently lethal impairment in gas exchange. Refractory hypoxemia, however, is unusual in asthma and hypercapnia generally is well tolerated (see the section Gas Exchange:Hypercapnia, above). Extracorporeal life support might be considered if there is profound hypercapnia and extreme hyperinflation, especially if accompanied by barotrauma or hemodynamic instability.[69,70] Besides correcting hypercapnia and avoiding complications related to hyperinflation, extracorporeal life support could also permit safe use of bronchoscopy to treat mucoid impaction.

DEATH AND COMPLICATIONS

Mortality

Published mortality rates for patients undergoing mechanical ventilation for severe asthma have varied greatly, ranging from 0% to 38%.[32,45,71–74] A literature review of more than 1220 patients reported an average mortality of 12.4%.[23] Although the outcome seems to have improved over the last two decades, perhaps because of more widespread use of controlled hypoventilation, mortality rates as high as 15% to 20% have been reported in series published during the last decade.[72,73] Most fatalities result from cerebral anoxia secondary to cardiorespiratory arrest before intubation. Indeed, in a recent analysis of 1223 patients who underwent mechanical ventilation for severe asthma, 80% of in-hospital deaths were preceded by cardiorespiratory arrest before admission to the intensive care unit.[73]

Complications

Patients with severe asthma are at risk for many of the same complications affecting other ventilated patients, including atelectasis, nosocomial pneumonia, sinusitis, pulmonary embolism, and gastrointestinal bleeding. Additional complications may result directly from the asthma exacerbation or from medications used to treat airflow obstruction and provide muscle relaxation; these include ventilator-associated hypotension, barotrauma, myocardial injury, rhabdomyolysis, lactic acidosis, neurologic injury, and acute myopathy (Table 30-4).

HYPOTENSION

Hypotension during mechanical ventilation for status asthmaticus is most often a result of the combined effects of sedatives and the excessive pulmonary hyperinflation that impedes venous return. In one series, mild-to-moderate hypotension was documented at some point during the course of mechanical ventilation in 35% of patients, with risk being greatest in patients whose V_{EI} exceeded approximately 20 mL/kg (Fig. 30-11).[24] Extreme hyperinflation can lead

TABLE 30-4: COMPLICATIONS OF MECHANICAL VENTILATION FOR SEVERE ASTHMA

Complications	Likely Mechanism
Hypotension	Primary: excessive hyperinflation, sedatives Secondary: pneumothorax, myocardial depression
Barotrauma	Excessive hyperinflation
Myocardial dysfunction	Primary: stress cardiomyopathy secondary to massive catecholamine release Secondary: severe myocardial hypoxia and/or acidosis
Rhabdomyolysis	Primary: extreme muscle exertion with or without hypoxia Secondary: high-dose propofol
Lactic acidosis	Primary: excessive β_2 agonists Secondary: extreme muscle exertion and/or hypoxia
CNS injury	Primary: cerebral anoxia secondary to respiratory arrest Secondary: hypercapnia-related cerebral edema, subarachnoid hemorrhage
Acute myopathy	Glucocorticoids plus prolonged paralysis or deep sedation

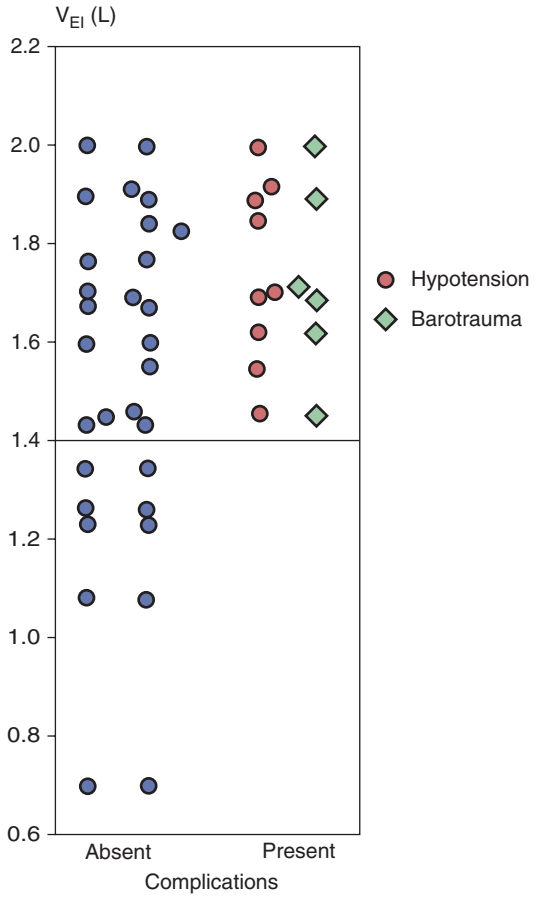

FIGURE 30-11 Relationship between hypotension, barotrauma, and lung volume at end inspiration (V_{EI}). (Used, with permission, from Williams TJ, Tuxen DV, Scheinkestel CD, et al. Risk factors for morbidity in mechanically ventilated patients with acute severe asthma. *Am Rev Respir Dis.* 1992;146:607–615.)

to cardiac arrest with pulseless electrical activity.[17] When a ventilated patient with severe asthma develops significant hypotension, a 1-minute apnea trial is recommended.[23] If the apnea trial and a rapid infusion of fluid do not restore blood pressure, then less-common causes of hypotension (e.g., pneumothorax, myocardial depression) must be considered.

BAROTRAUMA

Pneumothorax also occurs most often in patients with the highest end-inspiratory lung volume (see Fig. 30-11).[24] The incidence of pneumothorax was as high as 30% in some early series,[71] but is relatively infrequent (<10%) when a strategy of controlled hypoventilation is used.[8,26,27,32,45,74] In an analysis of barotrauma in various types of respiratory failure, pneumothorax was documented in only 6% of patient with status asthmaticus.[75] A pneumothorax may be particularly dangerous in patients with severe asthma because the hyperinflated lungs resist collapse and allow even a small pneumothorax to be under tension, resulting in rapid deterioration and sometimes death.[23] For this reason, clinical (and radiographic) diagnosis of tension pneumothorax may be challenging.[23] Chest tubes always should be placed by blunt dissection rather than by the blind trocar method to avoid injuring the hyperinflated lungs.[23]

CARDIAC COMPLICATIONS

A reported cardiac complication of status asthmaticus is stress cardiomyopathy, typically manifested as decreased myocardial contractility with reversible segmental myocardial wall-motion abnormalities and deep T-wave inversions in the electrocardiogram, simulating myocardial ischemia (Fig. 30-12).[76,77] Stress cardiomyopathy in status

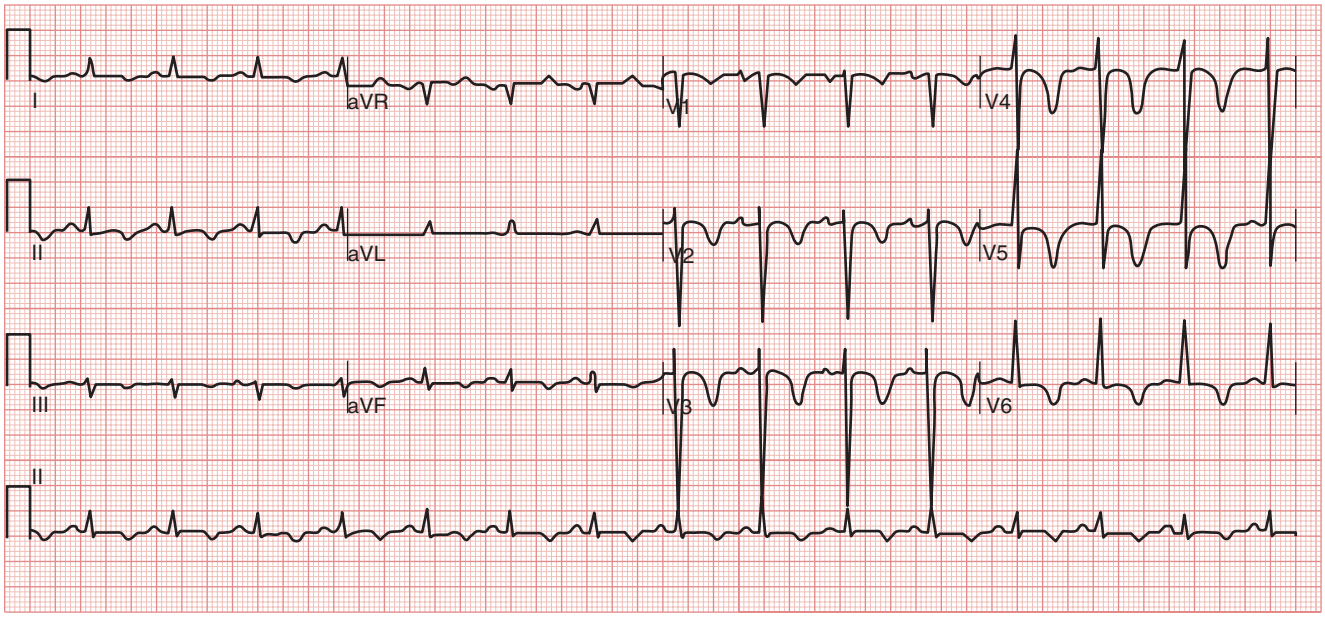

FIGURE 30-12 Electrocardiogram of a patient with acute reversible left-ventricular dysfunction caused by status asthmaticus. Deep inverted T-waves in anterior precordial leads are seen commonly in this condition.

asthmaticus is similar to that seen after subarachnoid hemorrhage, severe psychological stress, and other conditions associated with massive endogenous sympathetic activation. It often follows a benign course with no long-term cardiac sequelae, but may be associated with significant hypotension.[77]

RHABDOMYOLYSIS

Rhabdomyolysis has been reported in patients with status asthmaticus, presumably as a result of extreme muscular exertion coupled with hypoxia.[78] Rhabdomyolysis also has been noted in patients who had received prolonged infusions of propofol in very high doses.[52]

LACTIC ACIDOSIS

Mild lactic acidosis is relatively common in status asthmaticus and has been attributed to lactate production by respiratory muscles.[79–81] Lactic acidosis can also occur as a result of excessive use of β_2 agonists. Although more common when the latter are given intravenously, lactic acidosis also can follow high-dose inhalational therapy with albuterol.[82] Even a moderate degree of lactic acidosis may be problematic in patients with significant hypercapnia.

CENTRAL NERVOUS SYSTEM INJURY

As noted earlier, cerebral anoxia is the most common cause of death in patients with status asthmaticus.[73] Rarely, cerebral edema or subarachnoid hemorrhage in status asthmaticus can occur in the absence of prior cerebral anoxia and have been attributed to hypercapnia.[41–43]

MYOPATHY

Acute myopathy probably is the most common cause of morbidity affecting patients with asthma who undergo mechanical ventilation. The pathogenesis of myopathy is incompletely understood, but has been attributed to the combined effects of glucocorticoids and prolonged neuromuscular paralysis (Fig. 30-13).[53,54] Myopathy also occurs in patients with asthma who have undergone prolonged (>5 to 7 days) mechanical ventilation under deep sedation without paralysis.[83,84] It is possible that prolonged near-total muscle inactivity, whether induced by neuromuscular paralysis or by deep sedation, may increase the risk of this complication.[84] Recent studies show that daily physical therapy during scheduled awakening significantly reduces the incidence of intensive care unit-acquired weakness.[85] When patients with asthma are unable to be extubated within a few days of intubation, daily scheduled awakening for physical therapy should be strongly considered, provided airflow obstruction is not so severe that withdrawal of sedation is deemed unsafe.

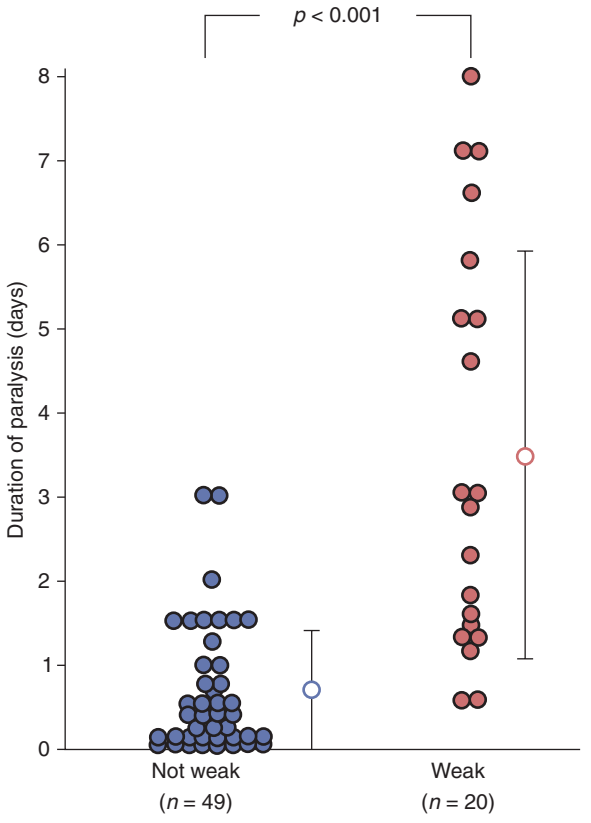

FIGURE 30-13 Duration of paralysis in patients with and without weakness (defined clinically) after undergoing mechanical ventilation for severe asthma. POSTHOSPITALIZATION PROGNOSIS

Although in-hospital mortality of patients who receive mechanical ventilation for severe asthma is relatively low, one study reported that seventeen of 121 (14%) patients died of a recurrent asthma attack during a follow-up period of 6 years, with most deaths occurring in the first year after hospital discharge.[86] Another study identified prior intubation as the strongest risk factor for death from asthma.[1] These data emphasize the crucial importance of outpatient management—including regular use of inhaled glucocorticoids, avoidance of smoking and other factors known to increase airway responsiveness, close supervision, and intensive education—following hospital discharge of patients with asthma who undergo mechanical ventilation.

MECHANICAL VENTILATION IN CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Franco Laghi

Acute exacerbation of chronic obstructive pulmonary disease (COPD) is defined as an increase in dyspnea, cough, or sputum production that requires therapy. The annual rate of exacerbations is 0.5 to 3.5 per patient.[1] Hospitalization rates range from 0.1 to 2.4 per patient per year.[1] Most exacerbations are caused by viral infections, such as *Rhinovirus* or influenza species or bacterial infections, such as *Haemophilus influenzae*, *Streptococcus pneumoniae*, *Moraxella catarrhalis*, or *Pseudomonas* species.[2] Occasionally, exacerbations are caused by air pollution and other environmental factors.[2] When evaluating a patient suspected of having an exacerbation, concurrent conditions such as pulmonary emboli, pneumothorax, and congestive heart failure should be clinically excluded.[2] In about one-third of cases, no underlying etiology is identified.[3]

The clinical presentation of exacerbations of COPD is highly variable. Most patients require only an increase of maintenance medications, while others develop frank respiratory failure and require ventilator assistance.[4,5] The goals of ventilator assistance are to decrease respiratory distress and dynamic hyperinflation, to improve gas exchange, and to buy time for resolution of the processes that triggered the episode of acute respiratory failure.

This chapter focuses on the aspects of ventilator management that are unique for patients with COPD. General principles of ventilator management are covered in other chapters—such as ventilator modes, bronchodilator therapy, weaning, and so on—and only the aspects specific to COPD are discussed in the present chapter. More than is the case with any other group of patients, clinical decision making and ventilator management in COPD is predicated on a detailed knowledge of the underlying pathophysiology.

PATHOPHYSIOLOGIC FEATURES RELEVANT TO VENTILATOR SUPPORT

The basic physiologic abnormalities of patients who experience acute respiratory failure in COPD include deteriorations in respiratory mechanics, respiratory muscle function, and gas exchange.

Deterioration of Respiratory Mechanics

INCREASED INSPIRATORY AIRWAY RESISTANCE

In stable patients with COPD, inspiratory flow resistance is approximately 6 cm H_2O/L/s above normal.[6] During an episode of acute respiratory failure, resistance can increase by

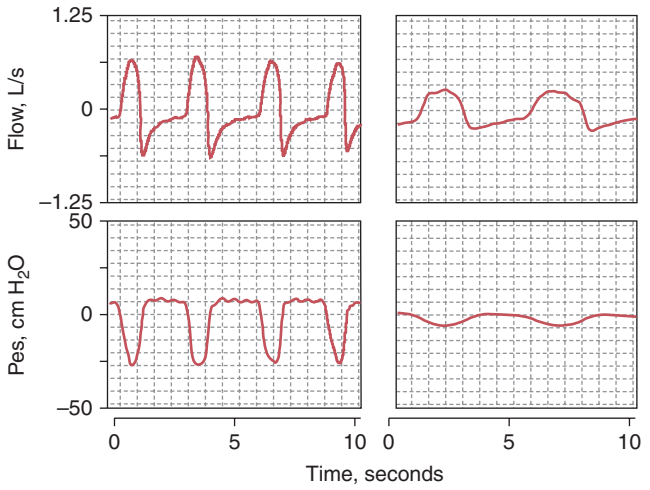

FIGURE 31-1 Respiratory effort during spontaneous respiration. Recordings of flow (*inspiration upward*) and esophageal pressure (*Pes*) in a patient with chronic obstructive pulmonary disease (COPD) in respiratory failure (*left panel*) and in a stable patient with COPD (*right panel*). The patient in respiratory failure exhibits a steeper fall and greater excursion in esophageal pressure than does the stable patient, signifying greater respiratory motor output. Despite the fivefold larger excursion in Pes in the patient in respiratory failure, peak inspiratory flow is only two times more than in the stable patient, signifying more abnormal mechanics in the former than in the latter patient. The patient in respiratory failure exhibits tachypnea, reflected by the shorter respiratory cycle, and exhibits a supramaximal flow transient at the beginning of exhalation, which is typical of expiratory flow limitation.

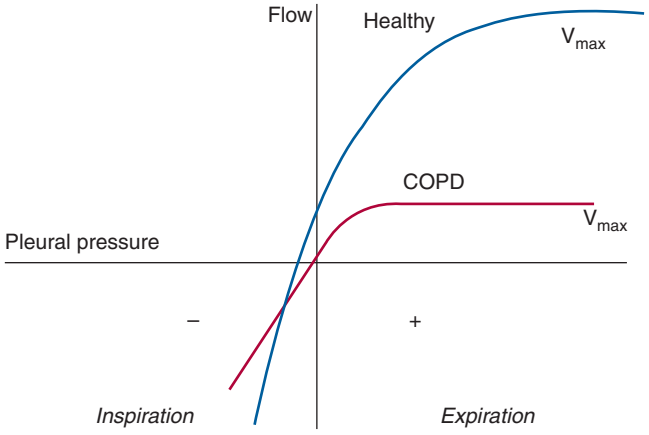

FIGURE 31-2 Schematic of the isovolume pressure–flow relationship. Patients with chronic obstructive pulmonary disease (COPD) exhibit an initial diagonal segment, where increases in pressure produce increases in airflow (the effort-dependent region on the *left*), followed by a flat portion, where increases in pressure do not produce increases in flow (the effort-independent region on the *right*). Compared with a healthy subject, the slope of the initial diagonal segment is decreased, indicating an increase in airway resistance, and maximum flow is much reduced in the remaining portion secondary to expiratory flow limitation. (Used, with permission, from Tobin et al.[16])

an additional 6 cm H_2O/L/s or more.[7,8] Mechanisms responsible for the increase include bronchospasm, airway inflammation, and mucus production.[9]

Increases in inspiratory resistance and respiratory motor output lead to increased inspiratory effort (Fig. 31-1).[7] In patients with severe COPD, the pressure output of the inspiratory muscles during resting breathing is three times higher than in healthy subjects: average pressure-time products of 259 to 341 versus 94 cm H_2O • second per minute.[8,10] Values are five times higher when patients are in respiratory distress.[8,11]

INCREASED EXPIRATORY AIRWAY RESISTANCE

In healthy subjects, inspiratory and expiratory airway resistance are of similar magnitude.[6,12] In contrast, patients with COPD have greatly increased expiratory resistance.[12–14] In ventilated patients with COPD, the ratio of expiratory to inspiratory flow resistance ranges from 3.8 at low lung volumes to 1.6 at high lung volumes.[14] The increased resistance at low lung volumes is related to dynamic narrowing of the small airways during exhalation.[15] This narrowing is thought to result from damage to the elastic scaffold surrounding the airways[16] and as well as to the "wave speed limitation" of the expiratory flow—the tracheobronchial tree cannot adjust an airflow more rapidly than the velocity at which pressure travels along the airways.[15] Small-airway narrowing and wave-speed limitation reduce maximum flow during exhalation with the development of expiratory flow limitation (Fig. 31-2). Expiratory flow limitation occurs in 60% of stable patients during resting breathing,[17] and universally during episodes of acute respiratory failure.[18]

Patients with expiratory flow limitation experience air trapping whereby activation of the expiratory muscles increases alveolar pressure without decreasing the end-expiratory lung volume below the relaxation volume of the respiratory system (Vrel).[15] The inability to decrease end-expiratory lung volume below Vrel has several negative consequences. First, expiratory muscle contraction—a constrained response of the respiratory centers to increased ventilatory demands—does not achieve storage of elastic energy in the respiratory system at end exhalation.[4] Second, relaxation of the expiratory muscles at the onset of inhalation cannot assist the inspiratory muscles in expanding the respiratory system during inhalation. Third, the entire burden of breathing is borne by the inspiratory muscles. Fourth, recruitment of the expiratory muscles dissipates precious energy substrates. That is, expiratory muscle recruitment in COPD is harmful,[19] and it can account for 66% of the variation in Borg scale ratings of difficulty in breathing.[20]

DYNAMIC HYPERINFLATION AND INTRINSIC POSITIVE END-EXPIRATORY PRESSURE

The minimum time required to exhale from a given lung volume to Vrel is determined by the maximum expiratory flow.[15] When the time for exhalation (T_E) is less than this minimum time, inhalation will begin before the respiratory system has returned to Vrel—a state known as dynamic hyperinflation (Fig. 31-3).[16] Dynamic hyperinflation (a "volume"

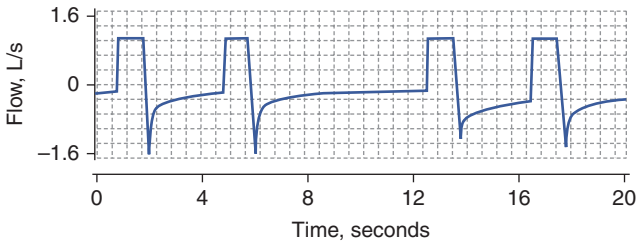

FIGURE 31-3 Persistent expiratory flow at end-exhalation. Recording of flow (*inspiration upward*) in a patient with chronic obstructive pulmonary disease (COPD) and respiratory failure receiving controlled mechanical ventilation. Whether the duration of exhalation is 3 seconds (first and third breaths) or 6 seconds (second breath), expiratory flow at end-exhalation is always present. Persistent expiratory flow at end-exhalation signifies that inhalation begins before the respiratory system has returned to its relaxation volume—dynamic hyperinflation.

phenomenon) is almost invariably associated with an increase in end-expiratory elastic recoil of the respiratory system (a "pressure" phenomenon).[15] This increase in end-expiratory elastic recoil has been called auto–positive end-expiratory pressure (auto-PEEP)[21] or intrinsic PEEP (PEEPi).[22] Dynamic hyperinflation and PEEPi have been reported in all ventilated patients with COPD.[23] Increases in dynamic hyperinflation during exacerbations are proportionally greater than increases in airflow obstruction.[24]

Dynamic hyperinflation and PEEPi can fluctuate widely as a result of several factors.[15] First, bronchospasm, mucosal edema, and sputum inspissation can abruptly worsen expiratory flow limitation. Second, patients are often tachypneic and, thus, T_E is shortened.[25] Finally, ventilatory demands can fluctuate because of sudden episodes of anxiety or deterioration of gas exchange.[15]

Acute worsening in dynamic hyperinflation is beneficial because it optimizes expiratory flow by limiting dynamic airway narrowing during exhalation[26] and by increasing the elastic recoil of the lung and, less so, of the chest wall.[18] It is detrimental because it decreases the effectiveness of the respiratory system through several mechanisms. First, at the start of inhalation patients have to first generate negative inspiratory pressure equal in magnitude to the value of PEEPi before inspiratory flow can be initiated (threshold inspiratory load).[8,27] In patients with COPD recovering from an episode of respiratory failure necessitating mechanical ventilation, Jubran and Tobin[8] reported that, during a spontaneous breathing trial, approximately 20% to 25% of the inspiratory muscle effort was required to overcome PEEPi. Second, dynamic hyperinflation impairs respiratory muscle function by worsening the length–tension relationship of the muscles (Fig. 31-4), by decreasing the zone of apposition,[28] and by interfering with inspiratory muscle perfusion.[29] Finally, dynamic hyperinflation increases end-inspiratory lung volume.[18] When excessive, increases in end-inspiratory lung volume can reduce lung compliance, increase the elastic work of breathing, and can cause alveolar overdistension. Alveolar overdistension can lead to hemodynamic compromise through several mechanisms. First, it can reduce right-ventricular preload as a result of impaired venous return.[21] Second, it can raise right-ventricular afterload by increasing pulmonary vascular resistance.[21] The increased right-ventricular afterload can increase the right ventricular end-diastolic volume and shift the interventricular septum toward the left ventricle. This shift can impair left-ventricular filling (ventricular interdependence). Finally, the threshold load imposed on the inspiratory muscles can increase left-ventricular afterload secondary to increased negative intrapleural pressure during inhalation.[21] All these phenomena can severely decrease cardiac output, effects exaggerated in COPD because the abnormally compliant lungs transmit a high fraction of alveolar pressure to intrathoracic vessels.[30]

Deterioration of Respiratory Muscle Function

RESPIRATORY MUSCLE WEAKNESS

Patients with COPD do not generate as much negative maximal inspiratory pressures as do healthy subjects.[4] This decrease in respiratory muscle strength may result from several factors, including greater protein degradation of muscle fibers,[31,32] malnutrition, sepsis, systemic steroids, and ventilator mode.[4,28] In some patients, however, the inspiratory weakness can be completely explained by hyperinflation-induced muscle shortening.[33] In addition, diaphragmatic myofibers of patients with COPD are also more susceptible to sarcomere disruption when subjected to an acute inspiratory load than are the diaphragms of healthy controls.[34]

Patients with COPD have an increased risk of coronary artery disease, and 20% to 30% have chronic heart failure.[35] Increased stress on the myocardium during acute respiratory failure could overwhelm an already impaired cardiac reserve.[36,37] An increased load resulting from interstitial edema secondary to acute left-ventricular failure together with decreased blood flow to the respiratory muscles may markedly impair respiratory muscle performance.[38]

RESPIRATORY MUSCLE FATIGUE

Contractile fatigue occurs when a sufficiently large respiratory load is applied over a sufficiently long period of time. Contractile fatigue can be brief or prolonged.[28] Short-lasting fatigue results from accumulation of inorganic phosphate, failure of the membrane electrical potential to propagate beyond T-tubules, and to a much lesser extent intramuscular acidosis.[28] In nine patients who developed acute respiratory failure during a weaning trial (four of whom had COPD), Brochard et al[39] reported electromyographic signs suggestive of incipient short-lasting diaphragmatic fatigue. Short-lasting fatigue appears to have a protective function, because it can prevent injury to the sarcolemma caused by forceful muscle contractions.[40] Long-lasting fatigue[41] is consistent with the development of, and recovery from, muscle injury.[28,40]

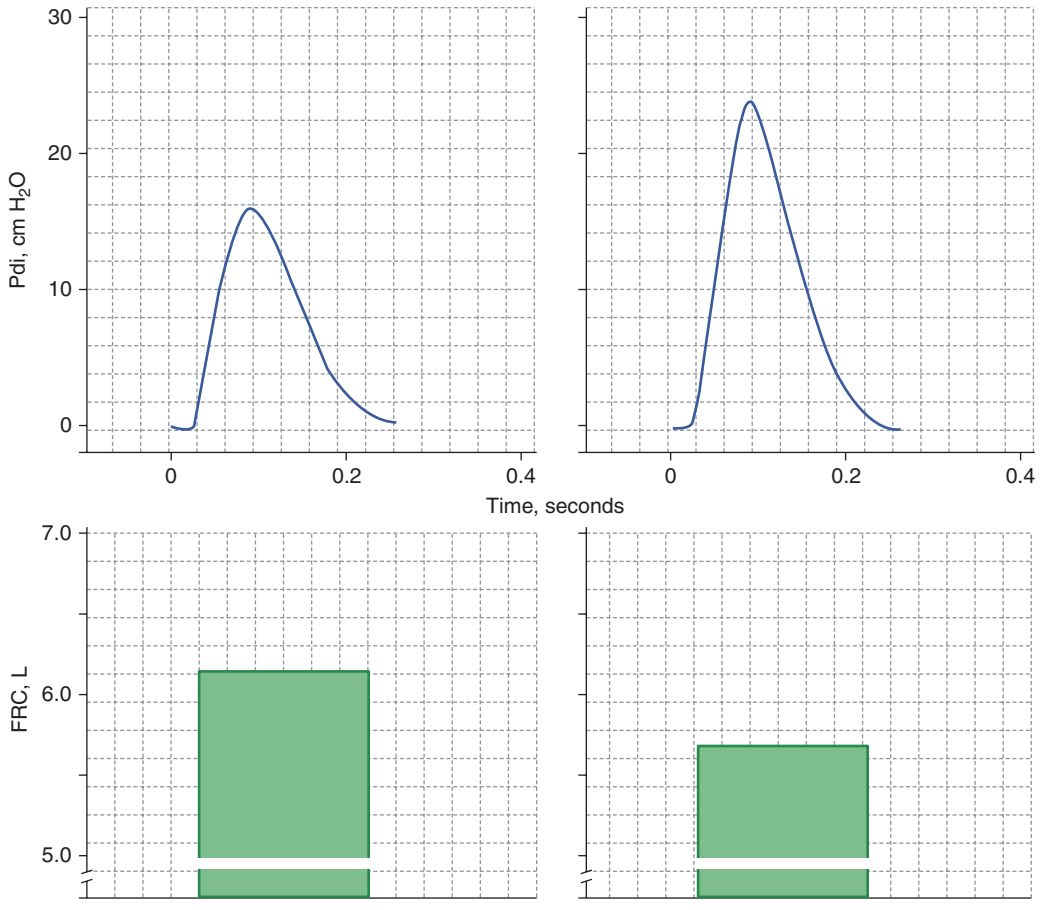

FIGURE 31-4 Twitch transdiaphragmatic pressure (*Pdi*) elicited by phrenic nerve stimulation (*upper panels*) and functional residual capacity (*FRC*; *lower panels*) in a patient with chronic obstructive pulmonary disease (COPD) before (*left*) and after (*right*) lung volume reduction surgery. The higher twitch Pdi after surgery was in part caused by decrease in operating lung volume as demonstrated by decrease in FRC. (Data from Laghi et al.[10])

To assess whether patients in acute respiratory failure develop long-lasting fatigue, Laghi et al[11] measured the contractile response of the diaphragm to phrenic nerve stimulation in sixteen patients being weaned from mechanical ventilation. In that study, no patient developed long-lasting fatigue of the diaphragm. The investigators concluded that patients displayed clinical manifestations of severe respiratory distress for a substantial time before they would develop fatigue.

Deterioration of Gas Exchange

Abnormal distribution of ventilation–perfusion ($\dot{V}_A/\dot{Q}$) ratios[42] and decreased mixed venous oxygen tension are common causes of hypoxemia during exacerbations.[43,44] In patients without alveolar pathologies (pneumonia, pulmonary edema) shunt is almost negligible.[43]

Hypercapnia is present in nearly half of patients admitted to a hospital with an acute exacerbation of COPD.[45] Hypercapnia plus respiratory acidosis is almost universal in patients with COPD requiring mechanical ventilation.[45]

Excluding patients who are on the verge of respiratory arrest, most patients with COPD in respiratory failure who develop hypercapnia experience a decrease in alveolar ventilation ($\dot{V}_A$) as a result of a change in the pattern of breathing and not as a result of decreased respiratory drive.[25] The dominant finding of this pattern of breathing is a shortening of inspiratory time (T_I) and T_E.[25] These combined changes lead to a marked increase in respiratory frequency and decrease in tidal volume (V_T)—rapid shallow breathing. The decrease in V_T results in increased dead-space-to-tidal-volume ratio (V_D/V_T) or dead space ventilation that is not compensated by the increase in minute ventilation. In a study of seventeen patients with COPD requiring mechanical ventilation, Tobin et al[25] reported that the combined changes in V_T and respiratory frequency accounted for 81% of increase in partial pressure of arterial carbon dioxide (Pa_{CO_2}) in the ten patients who developed respiratory distress when disconnected from mechanical ventilation. Whether rapid shallow breathing is an adaptive response to the mechanical constraints of acute dynamic hyperinflation that minimizes dyspnea and lessens the risk of respiratory muscle fatigue remains to be determined.

In some patients with COPD, hypercapnia can be worsened by the administration of supplemental oxygen.[45] This risk is significant when the inspired oxygen concentration exceeds 30%. Mechanisms that may contribute to CO_2 retention include a decrease in hypoxic ventilatory response consequent to the administration of oxygen; an increase in dead space consequent to release of hypoxic vasoconstriction and, thus, worsening of $\dot{V}_A/\dot{Q}$ relationships; and the Haldane effect (for any given amount of CO_2 bound to hemoglobin, Pa_{CO_2} is considerably higher in the presence of a high versus a low oxygen saturation).[16]

VENTILATOR ASSISTANCE

The many pathophysiologic defects considered above have direct bearing to the judicious administration of mechanical assistance in patients with COPD in respiratory failure. Physicians considering the need to implement mechanical ventilation in these patients have to answer five basic questions:

1. When should mechanical ventilation be started, and which goals should be pursued?
2. How should mechanical ventilation be delivered—noninvasive versus invasive?
3. What setting and mode of mechanical ventilation should be used?
4. When—and how—should mechanical ventilation be discontinued?
5. What can be done when weaning is difficult or impossible?

Ventilator Assistance: Indications

Most patients with mild exacerbations of COPD (70% to 90% of those hospitalized for an exacerbations)[5,45,46] can be cared for with oxygen and pharmacotherapy alone. The remaining 10% to 30% require ventilator assistance.[5,45–47]

INDICATIONS FOR NONINVASIVE POSITIVE-PRESSURE VENTILATION

Noninvasive positive-pressure ventilation (NIPPV) has become the first line intervention for most patients with COPD in acute respiratory failure (Table 31-1).[5] NIPPV decreases the need for endotracheal intubation and the rate of ventilator-related complications, intensive care unit (ICU) admissions, and in-hospital and 1-year mortality.[47–49]

In most studies, the rate of failure with NIPPV is inversely related to the severity of respiratory acidosis. When pH is 7.30 to 7.34 on admission, the rate of NIPPV failure is 10% to 20%;[47,50] when pH is 7.25 to 7.30, NIPPV failure is 30% to 40%;[51,52] and when pH is less than 7.25, failure is 50% to 60%.[53,54] These rates, however, have to be interpreted with caution. In some series, NIPPV failure in patients with very low pH (7.13 to 7.20) on admission was only 14% to 35%.[55–57]

TABLE 31-1: INDICATIONS AND CONTRAINDICATIONS FOR NONINVASIVE VENTILATION IN EXACERBATIONS OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Indications
Clinical observations
Moderate to severe dyspnea
Tachypnea
Accessory muscle use, abdominal paradox
Impaired gas exchange
Acute or acute-on-chronic hypercapnic respiratory failure (Pa_{CO_2} > 45 mm Hg, pH < 7.35)
Hypoxemia ($Pa_{O_2}/FI_{O_2} \leq 200$)[a]
Contraindications
Absolute
Bradypnea, respiratory arrest, immediate need for intubation
Life-threatening hypoxemia
Unable to fit mask
Upper airway obstruction
Undrained pneumothorax
Vomiting/severe upper gastrointestinal bleeding
Relative
Agitated, uncooperative
Severe hypercapnic encephalopathy (Glasgow Coma Scale score < 10)
Inability to protect the airway
Impaired swallowing or cough
Excessive secretions
Recent upper airway or upper gastrointestinal surgery
Multiorgan failure
Medically unstable
Uncontrolled cardiac ischemia or arrhythmia
Hypotensive shock

Abbreviations: FI_{O_2}, fractional inspired oxygen concentration; Pa_{CO_2}, partial pressure of arterial carbon dioxide; Pa_{O_2} partial pressure of arterial oxygen.

[a]Noninvasive ventilation should be used with caution in exacerbations of chronic obstructive pulmonary disease (COPD) accompanied with hypoxemia.

Failure with NIPPV usually occurs in the first hours of ventilator support.[58] Mask intolerance, uncontrollable leaks, and lack of improvement in gas exchange are the most common causes of failure.[59,60] Early improvement should not lull the physician into a false sense of security: Approximately 20% of initial responders (first 48 hours) experience a second episode of acute respiratory failure.[60] Late-onset deterioration is more likely in patients with worse clinical condition before admission, and more complications at admission.[60] Patients who experience late failure have a poor inhospital prognosis, particularly if they are not promptly intubated.[60]

INDICATIONS FOR NONINVASIVE NEGATIVE PRESSURE VENTILATION

Negative pressure ventilation (iron lung ventilation) has been successfully used in patients with COPD and severe respiratory acidosis (pH < 7.25).[61–63] (See Chapter 16.)

INDICATIONS FOR INVASIVE VENTILATION

NIPPV and negative pressure ventilation do not protect the upper airway in patients who are gasping, have respiratory arrest or have lost consciousness.[47] NIPPV and negative pressure ventilation are also unsafe and poorly tolerated in patients requiring high levels of inspiratory airway pressure (>25 to 30 cm H_2O) and inspired oxygen (FI_{O_2} > 0.60). These patients, as well as those who are hemodynamicaly unstable despite fluid resuscitation and vasopressors, and those who are agitated, uncooperative, or who fail noninvasive ventilation, require endotracheal intubation and invasive ventilation (see Table 31-1). Despite earlier concerns, severe hypercapnic encephalopathy (Glasgow Coma Scale score ≤8 to 10) should not—a priori—be considered an absolute contraindication to NIPPV.[55,57,64,65] If NIPPV is used in encephalopathic patients, opinions vary as to the advisability of inserting a nasogastric tube to decrease the risk of aspiration of gastric contents.[55,57,64]

Goals of Ventilator Assistance

The primary goals of ventilator assistance are to decrease inspiratory effort and respiratory distress, to minimize dynamic hyperinflation and PEEPi, to lessen respiratory acidosis, and to improve hypoxemia.

Most patients with COPD in respiratory failure are dyspneic and have clinical signs of increased work of breathing: nasal flaring, vigorous activity of the sternomastoid muscles, tracheal tug, recession of the suprasternal, supraclavicular and intercostal spaces, paradoxical motion of the abdomen, and pulsus paradoxus.[66] In these patients, invasive[67,68] and noninvasive[69–71] ventilation can decrease inspiratory effort and respiratory distress (Fig. 31-5).

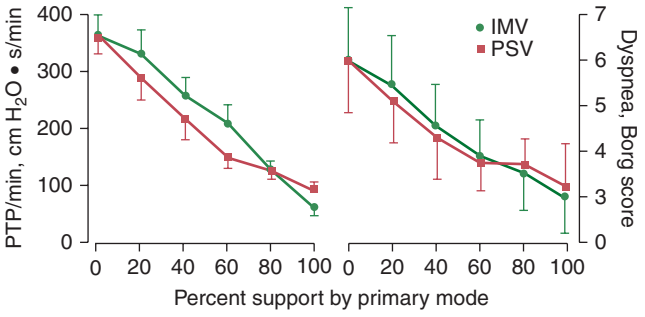

FIGURE 31-5 Inspiratory effort, quantitated as by esophageal pressure-time product per minute (*PTP/min*), and dyspnea, quantitated by Borg score in eleven ventilator-dependent patients with chronic obstructive pulmonary disease (COPD) while receiving pressure-support ventilation (*PSV*) and intermittent mandatory ventilation (*IMV*). *Left panel:* PTP decreased as the level of PSV or IMV was increased. At proportional levels of ventilatory assistance, PTP/min was not different during PSV and IMV ($p < 0.0005$ in both instances). *Right panel:* Dyspnea decreased with increasing levels of PSV or IMV ($p < 0.05$ in both instances). Bars represent ± standard error (SE). (Modified, with permission, from Leung et al.[67])

Mechanical ventilation can both worsen or improve dynamic hyperinflation and PEEPi.[15] Dynamic hyperinflation and PEEPi should be suspected in any patient with persistent expiratory flow (see Fig. 31-3) at end-exhalation.[15] The magnitude of end-expiratory flow, however, bears little relation to the magnitude of PEEPi.[30]

Mechanical ventilation improves hypercapnia by decreasing CO_2 production and, more importantly, by increasing $\dot{V}_A$. Vigorous increases in minute ventilation should be avoided, because of risk of iatrogenic dynamic hyperinflation. When dynamic hyperinflation is a concern, and provided that intracranial hypertension and overt hemodynamic instability do not exist, acceptance of acidemia (pH > 7.2) may be reasonable.[72]

In addition to worsening dynamic hyperinflation, overzealous ventilation can cause life-threatening alkalosis.[66] Severe alkalosis can cause coronary artery spasm, central nervous system hypoperfusion, myoclonus, asterixis, and seizures. Other effects of alkalosis include increase in hemoglobin affinity for oxygen, and, in the presence of increased shunt, a possible worsening of the $\dot{V}_A/\dot{Q}$ relationship (secondary to a decrease in hypoxic pulmonary vasoconstriction).[66] Excessive ventilation, over time, causes bicarbonate wasting by the kidney. In patients who retain CO_2 when clinically stable, this renal wasting of bicarbonate will increase ventilatory demands during weaning.

Choice of Ventilator Mode

A wide variety of ventilator modes are used in COPD. These include pressure-support ventilation (PSV), assist-control ventilation (ACV) that can be either volume-cycled or pressure-cycled (PCV), intermittent mandatory ventilation, and, more recently, proportional-assist ventilation and neurally adjusted ventilatory assist. Each of these modes is covered in detail in other chapters.

It is unknown whether one ventilator mode is superior to another in patients with COPD. I summarize here my own preferences, and the physiologic rationale behind my choices. In patients requiring NIPPV, I usually use PSV[5,73] based on two considerations. First, unlike volume-cycled modes (ACV, intermittent mandatory ventilation), PSV allows breath-by-breath titration of support. The hope is to improve patient comfort and thus achieve greater success with NIPPV. Second, PSV is equally as effective as volume-cycled modes in decreasing inspiratory effort (see Fig. 31-5). I add a moderate amount of external PEEP to counterbalance PEEPi—a combination that lowers inspiratory work more than the use of PSV or PEEP alone.[74,75] Persistent respiratory distress despite high levels of support can result from expiratory muscle recruitment.[76] This recruitment can be caused by inadequate "cycling-off" criteria of PSV: In patients with COPD the decay in inspiratory flow during PSV is less steep than in patients with normal respiratory mechanics.[76,77] When expiratory muscle recruitment does occur an increase in the threshold of peak

inspiratory flow to cycle off PSV can improve patient–ventilator interaction.[77,78]

Persistent respiratory distress despite high levels of support can result from excessive load on the respiratory muscles. In this situation, an increase in inspiratory pressurization rate—the time needed to reach the target inspiratory pressure—can decrease inspiratory effort.[79] Unfortunately, increases in pressurization rate during NIPPV are associated with increased air leaks and decreases a patient's tolerance of NIPPV.[79] When respiratory distress persists despite high levels of support, it may be more prudent to intubate a patient.

In intubated patients, I mostly use ACV[80] and, occasionally, PCV. I prefer ACV and PCV over PSV in intubated patients because these patients commonly receive sedation. Sedation can decrease respiratory motor output and thus promote alveolar hypoventilation. When using ACV I usually set the inspiratory flow waveform in the square pattern to facilitate monitoring of mechanics. When intubated patients with COPD display a high drive, I may use PCV. With this mode, patients have more control over the peak flow than with ACV. I avoid controlled mechanical ventilation because it is associated with the early development of respiratory muscle atrophy and damage.[81,82]

Proportional-assist ventilation and neurally adjusted ventilatory assist are two novel modes, but it is not known whether they will prove superior to traditional ventilator modes.

Intrinsic and External Positive End-Expiratory Pressure

The most valuable approach to reduce or eliminate PEEPi is to diminish minute ventilation,[30] even if this means development of alveolar hypoventilation—permissive hypercapnia.[83] In patients with PEEPi ventilated with volume-cycled modes, clinicians often increase inspiratory flow to decrease T_I. This is done hoping to prolong T_E. Increases in inspiratory flow, however, commonly lead to an increase in respiratory rate[84,85] and the anticipated reduction in T_E could increase PEEPi. Laghi et al[85] studied this phenomenon in ten patients with COPD while they were receiving ACV with a backup rate of 1 breath/min. As expected, an increase in flow from 30 to 90 L/min increased the respiratory rate from 16 ± 1 to 21 ± 2 breaths/min. Despite the rise in rate, PEEPi decreased from 7 ± 1 to 6 ± 1 cm H_2O. The decrease in PEEPi was the result of a paradoxical increase in T_E, which permitted extra time for lung deflation. The investigators reasoned that the shortened T_I secondary to the increase inspiratory flow combined with time-constant inhomogeneity of COPD caused overinflation of some lung units to persist into neural exhalation. Continued inflation during neural exhalation could stimulate the vagus, which prolongs expiratory time.[84,85]

In patients with COPD and flow-limited physiology, low levels of external PEEP can maintain a patent (or nearly patent) channel between the central airway and the alveolar compartment at the start of inhalation. In these patients, application of low-level external PEEP reduces the effort to trigger the ventilator,[14,86] improves patient–ventilator interaction,[14] and reduces the effort to start inspiratory flow during weaning from mechanical ventilation.[87] External PEEP of 5 cm H_2O or less often suffices to reach these goals.[88] In patients with PEEPi, intravascular fluid expansion can increase blood pressure and cardiac output.[21] Prompt disconnection from the ventilator can resolve hypotension secondary to PEEPi. If that is the case, mechanical ventilation should be restarted with lower minute ventilation.

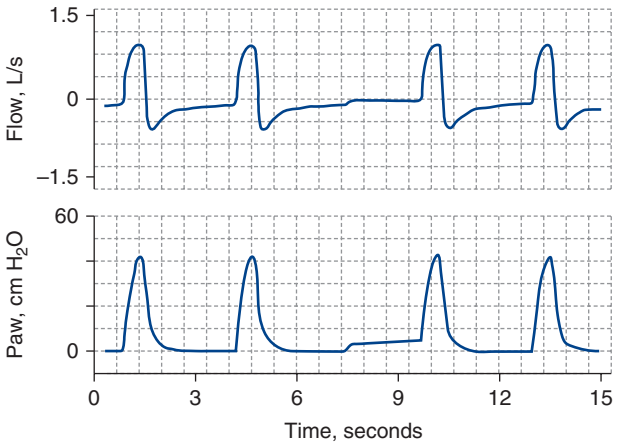

FIGURE 31-6 Measurement of static intrinsic positive end-expiratory pressure (PEEPi) by single-breath end-expiratory airway occlusion in a patient with chronic obstructive pulmonary disease (COPD) during controlled mechanical ventilation. End-expiratory airway occlusion is carried out at the time when the third ventilator breath should have taken place. The end of occlusion to preocclusion difference in airway pressure (Paw) is the static PEEPi. In this example, static PEEPi is 6 cm H_2O.

The selection of external PEEP should be guided by measurement of static PEEPi (Fig. 31-6).[15] When PEEPi is present, the rise in airway pressure during the occlusion maneuver should be maintained until a plateau is reached, usually in less than 4 seconds.[18] The delayed plateau in the airway pressure signal is caused by stress adaptation phenomena and by time-constant inequalities.[18] During controlled mechanical ventilation, application of a value of external PEEP at or above 50% of the static PEEPi improved ventilation–perfusion matching (Fig. 31-7)[89] and oxygenation without causing a decrease in cardiac output.[90]

When measuring static PEEPi with the occlusion method, it is impossible to detect any increased alveolar pressure distal to airways that are completely occluded during exhalation.[91] In other words, the occlusion method estimates only the end-expiratory alveolar pressure that is measurable in the upper airway during tidal breathing.[30] Consequently, some experts advocate the measurement of end-inspiratory plateau airway pressure as external PEEP is titrated as a more sensitive tool to monitor the potential perils of dynamic hyperinflation.[15,30,91]

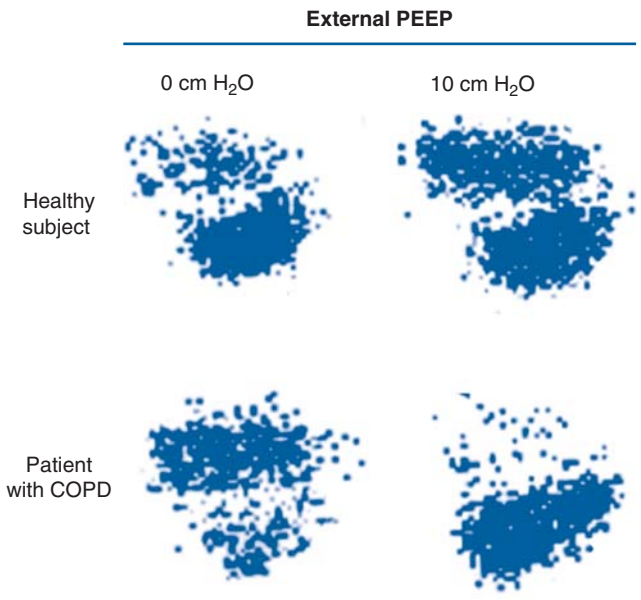

FIGURE 31-7 Ventilation scans (radioactive krypton) in a healthy subject (*upper panels*) and in a patient with chronic obstructive pulmonary disease (*COPD*) (*lower panels*) resting in the left lateral decubitus position while receiving positive end-expiratory pressure (*PEEP*) of 0 cm H_2O (*left panels*) and 10 cm H_2O (*right panels*). At a PEEP of 0 cm H_2O, ventilation was distributed predominantly to the dependent regions in the healthy subject (*left upper panel*) and in the nondependent regions in the patient (*left lower panel*). PEEP 10 cm H_2O restored ventilation to the dependent regions in the patient probably because it prevented collapse of the dependent airways. (Modified, with permission, from Shim et al.[89])

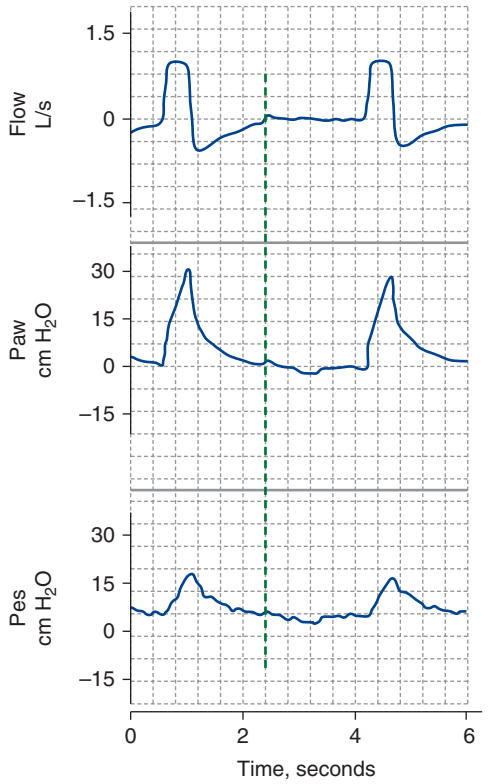

FIGURE 31-8 Inspiratory effort during end-expiratory airway occlusion maneuver. Recordings of flow (*inspiration upward*), airway pressure (*Paw*) and esophageal pressure (*Pes*) in a patient with chronic obstructive pulmonary disease (COPD) in respiratory failure receiving mechanical ventilation. Shortly after the start of airway occlusion (*green vertical line*), the patient exhibits an inspiratory effort (negative deflection in the Paw and Pes signals). Measurement of static intrinsic positive end-expiratory pressure during active inhalation is inaccurate.

The occlusion method is impractical and potentially inaccurate in patients who trigger most breaths during assisted ventilation (Fig. 31-8).[15] These patients can be instrumented with an esophageal balloon catheter system to measure the deflection in esophageal pressure from the beginning of inspiratory effort to the onset of inspiratory flow (counterbalance method) (Fig. 31-9).[15] This deflection is the so-called dynamic PEEPi. The counterbalance method is based on several assumptions.[27] First, the end-expiratory alveolar pressure represents the elastic recoil pressure of the relaxed respiratory system. Second, the change in esophageal pressure from the beginning of inspiratory effort to the onset of inspiratory flow reflects the inspiratory muscle pressure required to counterbalance the elastic recoil of the respiratory system at end-exhalation. Because of time constant inequalities between lung units, the end-expiratory elastic recoil may not be distributed homogeneously.[92] It follows that PEEPi measured with the counterbalance method represents the pressure required to start inspiratory flow in lung units with a short time constant and fast exhalation (minimum PEEPi). This characteristic of dynamic PEEPi raises several points. First, dynamic PEEPi underestimates the magnitude of static PEEPi, at times by as much as 90%.[93] Second, the true clinical impact of PEEPi can be misjudged if only dynamic PEEPi is considered.[15] Third, the difference between dynamic and static PEEPi—often reported as the ratio of dynamic to static PEEPi or "inequality index"[15]—can estimate the severity of time constant inequalities of the respiratory system.[93] In a study of paralyzed, ventilated patients, Maltais et al[93] reported a lower inequality index in patients with airway obstruction, 0.36 ± 0.06, than in patients without airway obstruction, 0.87 ± 0.05.

A final assumption with the counterbalance method is that exhalation is passive. If expiratory muscle contraction is present at end-exhalation, the decrease in esophageal pressure at the start of inhalation will reflect, in part, the relaxation of the expiratory muscles rather than inspiratory muscle contraction alone.[27] Several techniques to correct for this confounder have been proposed[74,94] with various success.[95,96] An additional confounding factor when measuring dynamic PEEPi is breath-to-breath variability in the duration of neural T_E.[94] This phenomenon causes a variable duration of lung emptying, which, in turn, can cause large fluctuations of PEEPi, even over short periods of time.[67,94] Systematic investigations of the effect of this additional confounder on the determination of dynamic PEEPi are not available.

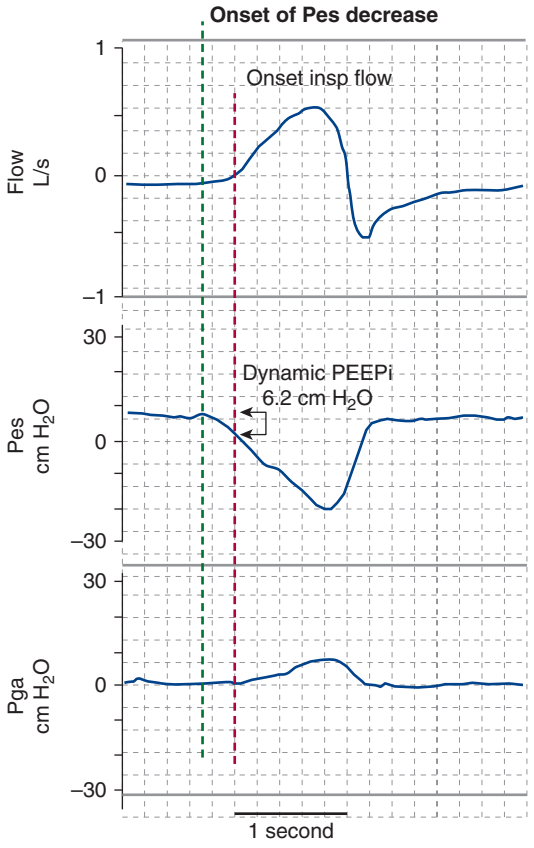

FIGURE 31-9 Recordings of flow (*inspiration upward*), esophageal pressure (*Pes*) and gastric pressure (*Pga*) illustrating the counterbalance method for measuring dynamic intrinsic positive end-expiratory pressure (*PEEPi*) during spontaneous respiration. The *green vertical line* indicates the onset of inspiratory effort and the *purple vertical line* indicates the onset of inspiratory flow. Dynamic PEEPi is measured as the negative deflection in Pes from the start of inspiratory effort to the onset of inspiratory flow. The Pga signal is flat during exhalation suggesting absent expiratory muscle recruitment.

In summary, the major goal of using external PEEP in patients with airflow obstruction who are triggering the ventilator is to decrease workload[14] and dyspnea[87] and to improve patient–ventilator synchrony.[67] Titration of external PEEP should continue until dyspnea has improved, respiratory motor output has decreased,[97] or until peak and plateau airway pressure demonstrate a sizeable increase (volume-cycled ventilation) (Fig. 31-10)[98] or tidal volume starts to decrease (PCV).[15]

Susceptibility to Ventilator Complications

Patients with COPD are particularly susceptible to ventilator complications. This susceptibility results from several mechanisms, including the pathophysiologic derangements that contribute to the need for mechanical ventilation in COPD (dynamic hyperinflation), side effects of medications, and complications that arise from the underlying lung disease (tissue destruction of the emphysematous lung).

DYSSYNCHRONIES

The complex abnormalities of lung mechanics in patients with COPD and respiratory failure make them particularly susceptible to develop patient–ventilator dyssynchrony. Dyssynchronies occur when there is inadequate matching between patient demand and ventilator support in terms of timing, volume, and flow. Dyssynchronies can occur at the onset of neural inhalation (ineffective trigger, trigger delay), during neural inhalation (double triggering, inadequate pressurization, inadequate flow or volume), at the offset of neural inhalation (premature or prolonged assist), and during neural exhalation (autotriggering) (Fig. 31-11).[16]

Ineffective triggering attempts occur in a quarter to a third of inspiratory efforts of patients with COPD receiving high levels of PSV or ACV (Fig. 31-12).[67] The number of ineffective triggering attempts increases in direct proportion to the level of ventilator assistance and result from premature inspiratory efforts that are insufficient to overcome the increased elastic recoil associated with dynamic hyperinflation.[67] Because there is no lung inflation during a failed triggering attempt, mechanical exhalation continues for a longer time and end-expiratory volume continues to fall until triggering becomes successful.

Trigger delays can be caused by factors intrinsic to the ventilator and factors intrinsic to the patient. Ventilator factors include the algorithms that control cycling and the electrical and mechanical processes in the machine.[99] Patients' factors include respiratory mechanics, respiratory drive, and inspiratory pressure output.[67,100–102]

A mismatch of the timing between a relatively long neural inhalation and a relatively short mechanical inflation (double triggering) (Fig. 31-13), or as a mismatch between patient flow demand and the flow delivered by the ventilator, can produce dyssynchronies during neural inhalation. Flow mismatch can be either in excess or in defect of the patient's demand. Excessive flow delivered by the ventilator will always raise peak airway pressure. If the patient is receiving NIPPV, an increase in peak airway pressure can cause air leaks around the mask. These leaks are uncomfortable and they diminish the patient's acceptance of NIPPV.[79] In addition, air leaks can decrease alveolar ventilation and worsen patient–ventilation interaction.

When the ventilator's inspiratory flow is insufficient for the patient's flow demands, two types of dyssynchrony can occur. First, the ventilator unloads the respiratory muscles unsatisfactorily or it may even impose an external elastic load on the respiratory muscles.[103,104] Second, the time required to deliver a given V_T will exceed the duration of neural T_I. In this case, mechanical inflation will continue during neural T_E. The sense of being unable to empty the lungs may cause patients to activate the expiratory muscles. This uncomfortable activation will cause a positive spike in the airway pressure signal at end-inhalation.

During ACV or PCV, when a patient's neural T_I is short, ventilator inflation may continue into neural exhalation and thus decrease the time available for lung emptying. This phenomenon increases the likelihood for dynamic

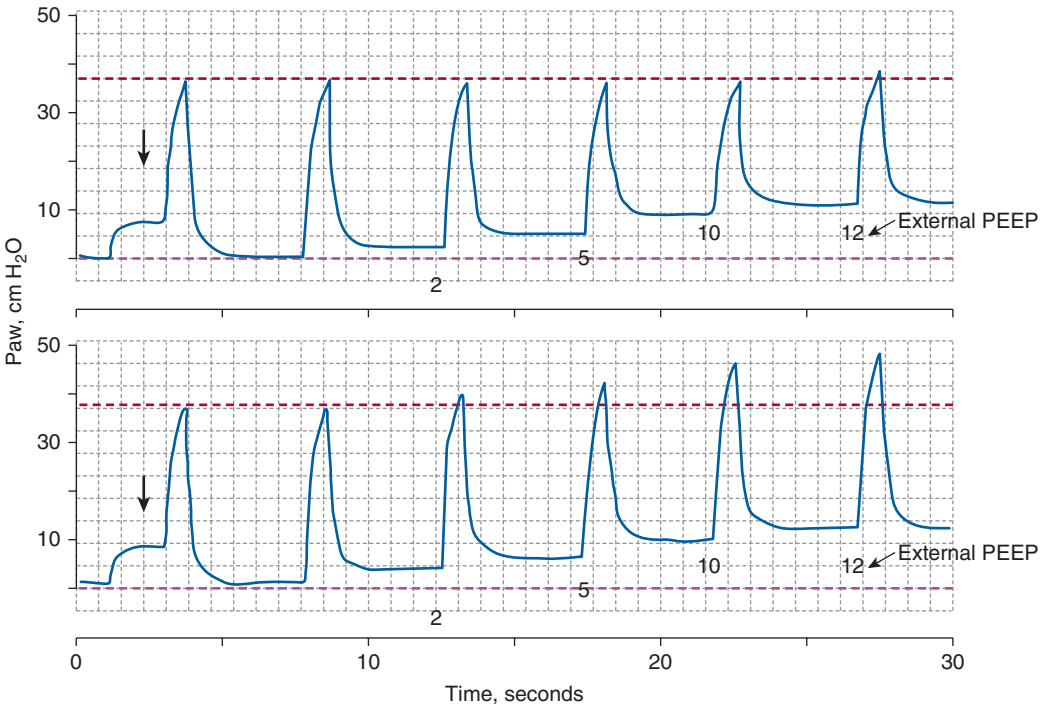

FIGURE 31-10 Schematic of airway pressure (*Paw*) versus time during controlled mechanical ventilation as external positive end-expiratory pressure (PEEP) is increased from 0 to 12 cm H_2O in a patient with expiratory flow limitation (*upper panel*) and in a patient without expiratory flow limitation (*lower panel*). In both patients, static intrinsic PEEP (PEEPi), determined by the end-expiratory airway occlusion technique (↓), is 10 cm H_2O. In the presence of expiratory flow limitation (*upper panel*), peak airway pressure increases only when external PEEP is 12 cm H_2O (*dotted red line*). In the absence of expiratory flow limitation (such as in patients with asthma; *lower panel*), application of external PEEP causes a proportional increase in peak airway pressure. The qualitative responses to external PEEP, seen with peak airway pressure, are expected to occur also with plateau pressure.

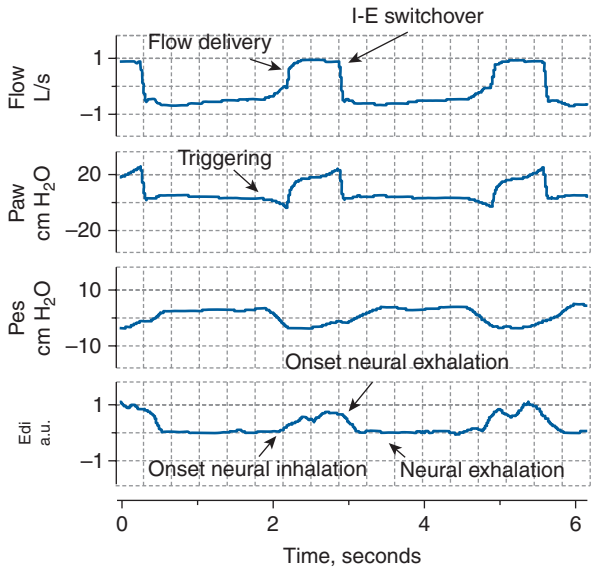

FIGURE 31-11 Points at which patient–ventilator dyssynchrony may arise: onset of neural inhalation (point of triggering, cycling-on function), during neural inhalation (inspiratory flow delivery, posttrigger inflation), onset of neural exhalation (switchover between inspiration and expiration, cycling-off function), and during neural exhalation (autocycling). *a.u.*, arbitrary units; *Edi*, electrical activity of the diaphragm; *Paw*, airway pressure; *Pes*, esophageal pressure.

hyperinflation (with attendant ineffective triggering) and activation of the expiratory muscles.

During PSV, dyssynchronies at the offset of neural inhalation are caused by the algorithm for "cycling-off" of mechanical inflation (see section Choice of Ventilator Mode above).[76,77,105] Air leaks between the mask and the patient's face and increased dead space make the synchronization between the offset of neural inhalation and the offset of mechanical inflation particularly tenuous when delivering PSV with NIPPV.[106,107] Strategies designed to improve synchronization include the use of a time-cycled expiratory trigger[107] and neurally adjusted ventilatory assist.[101,102,108]

Occasionally a ventilator delivers an assisted breath during neural exaltation. This phenomenon, known as *autotriggering* or *autocycling*, can cause severe respiratory alkalosis.[109] Autotriggering is relatively common when there is water in the ventilator circuit or when air leaks are present.[99,110] These leaks can occur around the endotracheal tube cuff,[111] around NIPPV masks,[99,112] and from chest tubes.[109] Oscillation of gas in the airways caused by cardiac contractions can also result in autotriggering (Fig. 31-14). Elimination of water from the ventilator circuit,[110] reduction of inspiratory trigger sensitivity, and minimization of leaks can reduce autotriggering.[99,109] An additional cause of autotriggering occurs when a stiff nasogastric tube placed on suction is erroneously passed into the airway rather than into the esophagus.[113]

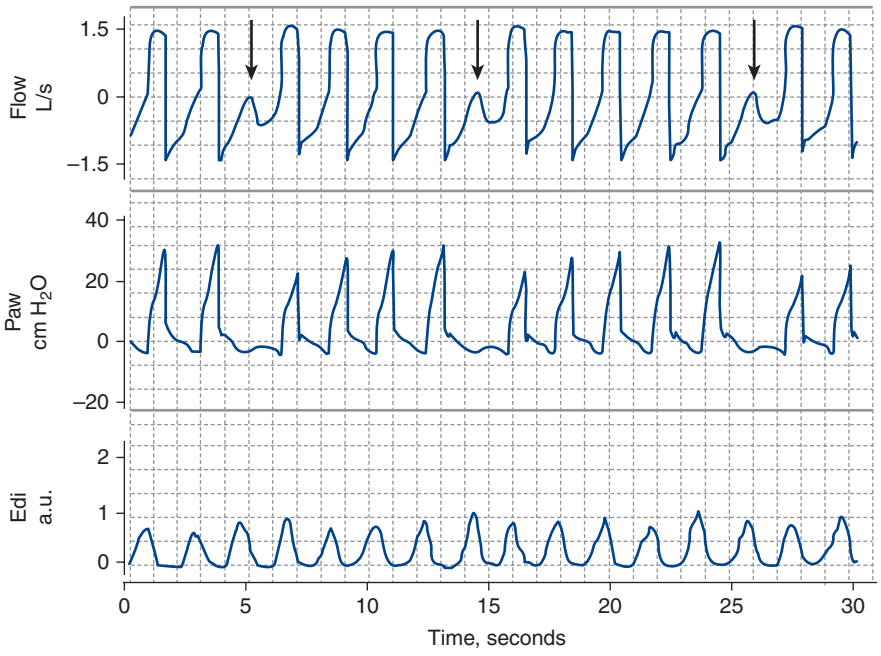

FIGURE 31-12 Failure to trigger the ventilator. Flow, airway pressure (*Paw*) and electrical activity of the diaphragm (*Edi*) in a patient with COPD who is receiving assist-control ventilation. Contractions of the inspiratory muscles during the failed triggering attempts (↓) cause brief deceleration of expiratory flow and decreases in Paw. The brief decelerations in flow are followed by brief accelerations of expiratory flow that coincide with the termination of the unsuccessful inspiratory effort. Of note, the peak airway pressure increases following each episode of failure to trigger the ventilator. This finding is caused by progressive air trapping. *a.u.*, arbitrary units.

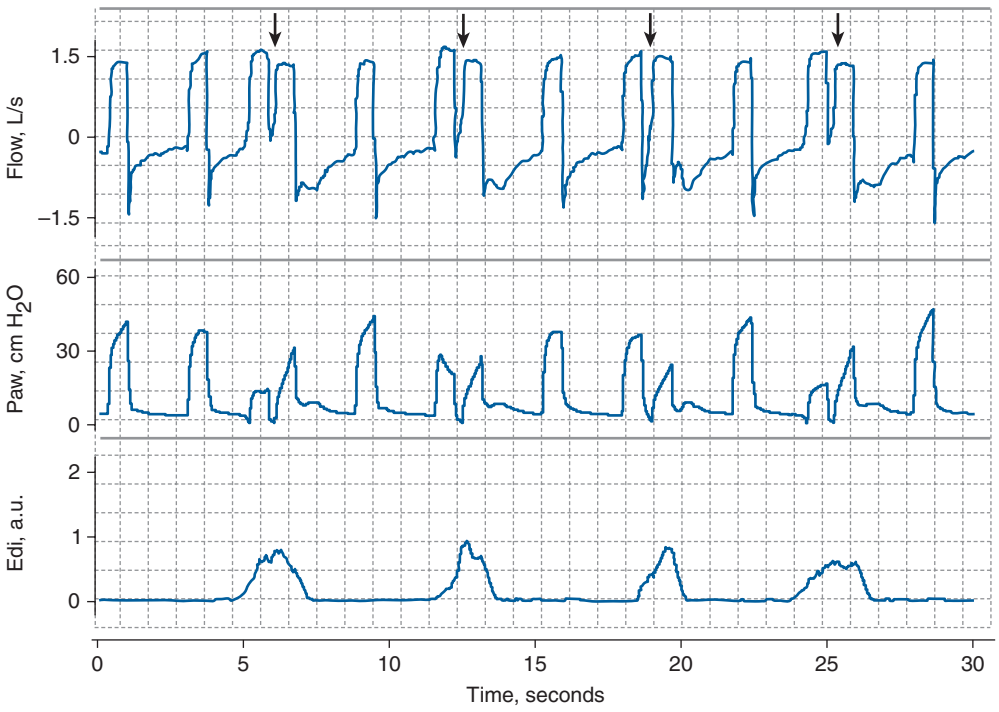

FIGURE 31-13 Double triggering caused by long duration of inspiratory effort. Four incidents of double triggering, each indicated by an arrowhead (↓). Flow, airway pressure (*Paw*) and electrical activity of the diaphragm (*Edi*) in a patient with chronic obstructive pulmonary disease (COPD) and pneumonia who was receiving assist-control ventilation. The patient generates only four neural inhalations (positive deflection in the Edi signal). The duration of each neural inhalation was substantially longer than the duration of mechanical inflation. This mismatch is responsible for double triggering. *a.u.*, arbitrary units.

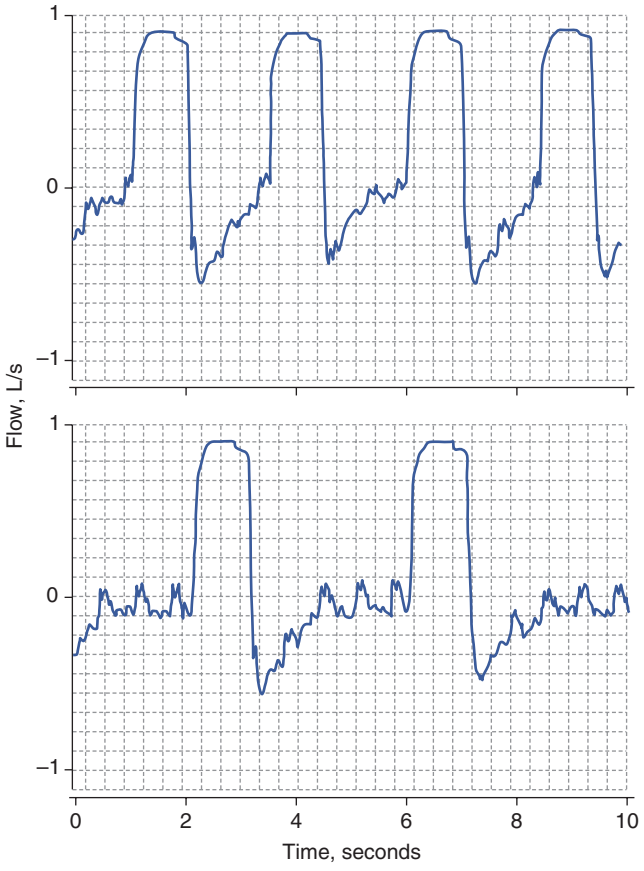

FIGURE 31-14 Autotriggering caused by cardiac oscillations. Recording of flow (*inspiration upward*) in a patient with chronic obstructive pulmonary disease (COPD) and aortic insufficiency. The patient was maintained on assist-control ventilation with a rate of 15 breaths/min and flow-triggering. *Upper panel:* The triggering sensitivity was set at 1 L/min. Despite the absence of clinically detectable inspiratory efforts, the ventilator rate was 24 breaths/min. *Lower panel:* When the triggering sensitivity was changed to 4 L/min, the ventilator rate decreased to 15 breaths/min, and large cardiac oscillations could be appreciated on the flow signal.

VENTILATOR-INDUCED HYPERINFLATION

In patients with COPD, mechanical ventilation itself increases the risk of dynamic hyperinflation through several mechanisms. First, ventilator settings (excessive minute ventilation, V_T, short time available for exhalation) can be unsuitable for the respiratory system resistance, elastance, and flow limitation of a given patient.[15] Second, the ventilator's circuit increases flow resistance. This increase in (external) resistance is caused by the combination of resistance of the endotracheal tube (particularly if the tube has concretions or is partially bent),[114] ventilator tubing, exhalation valves, and external PEEP.[15] Even in an intubated patient with healthy lungs, total expiratory resistance (across lungs, endotracheal tube, and exhalation valves) can exceed 10 cm H_2O/L/s (normal: <4 cm H_2O/L/s), enough to cause measurable PEEPi when the minute ventilation exceeds 20 L/min.[98]

VENTILATOR-ASSOCIATED PNEUMONIA

Ventilator-associated pneumonia is a common and potentially lethal complication of invasive ventilation. Factors that directly contribute the development of pneumonia include the presence of the endotracheal tube, contamination of the ventilator circuit and respiratory-therapy equipment with bacteria, ineffective cough, need of sedation, and development of acute sinusitis (see Chapter 46).

STEROID MYOPATHY

Most patients with exacerbations of COPD receive corticosteroids.[115,116] Administration of corticosteroids—with or without concomitant use of muscle relaxants—can trigger development of an acute myopathy characterized by loss of myosin heavy chains within muscle fibers.[28] Occasionally, corticosteroids cause acute rhabdomyolysis or myonecrosis.[28] In a prospective study of twenty-six patients with COPD exacerbation requiring invasive ventilation, Amaya-Villar et al[117] reported development of myopathy in nine patients (35%). Severity of illness (admission Acute Physiology and Chronic Health Evaluation [APACHE] II score), occurrence of sepsis and total dose of corticosteroids were higher in patients who develop myopathy than in those who did not develop it. Myopathy was associated with an increase in the duration of ventilation and lengths of ICU and hospital stay. An association between corticosteroid administration and development of myopathy in the ICU[118] or between myopathy and duration of mechanical ventilation[119] has been reported by other investigators.

In patients with steroid myopathy, acute weakness is likely caused by impaired muscle membrane excitability.[120] In contrast, prolonged weakness is more likely caused by proteolysis of myosin filaments, reduced myosin transcription, and decreased expression of the sarcoendoplasmic reticulum calcium-adenosine triphosphatase (SERCA)-type pumps (key protein pumps for calcium kinetics during muscle relaxation following contraction, which scavenge calcium from the cytosol).[28]

Two recent observations raise questions on the negative impact of (short-term) administration of corticosteroids during mechanical ventilation. In a study conducted in rats, Maes et al[121] reported that a single high dose of methylprednisolone protected diaphragmatic muscle function from the deleterious effects of controlled mechanical ventilation. According to the investigators, the most likely mechanism for this protective effect was a corticosteroid-dependent inhibition of the calpain proteolytic system. The second investigation was conducted in 340 patients with severe acute respiratory distress syndrome.[122] Patients were randomly assigned to receive, for 48 hours, either the neuromuscular blocking agent cisatracurium besylate (178 patients) or placebo (162 patients); 42% of all patients received corticosteroids for sepsis. Early administration of cisatracurium besylate—with or without corticosteroids—improved adjusted 90-day survival and increased the time off the ventilator without increasing muscle weakness.

Weaning from Noninvasive Positive-Pressure Ventilation

Most investigators decrease NIPPV when respiratory distress and tachypnea have resolved and FI_{O_2} requirement is less than 0.40.[55] At that point, inspiratory and expiratory pressures are decreased by 2 to 3 cm H_2O each hour as tolerated. When gas exchange is adequate and patients are comfortable with inspiratory pressure of 10 to 12 cm H_2O and external PEEP of 3 to 5 cm H_2O, clinicians can temporarily discontinue NIPPV. Periods of unassisted breathing are maintained until patients develop some degree of respiratory deterioration (tachypnea, dyspnea, increased use of accessory muscles).[123] Ideally, NIPPV is interrupted for progressively longer periods until patients can sustain unassisted breathing indefinitely.[51,55,123] In patients with exacerbations of COPD with an initial pH of 7.13 to 7.29 and who respond successfully to NIPPV, the mean duration of ventilator assistance—plus periods of interruption—can range from 2 to 9 days.[55,57,59,123,124] Occasionally patients require nocturnal noninvasive ventilation.

Weaning from Invasive Ventilation

Chapter 58 discusses ventilator weaning. In brief, my personal approach is to screen for early weanability with use of the ratio of respiratory frequency to tidal volume (f/VT).[125,126] When the result predicts weaning success, I proceed to a T-tube trial, usually lasting no more than 30 minutes. If a patient tolerates this trial without undue distress, I proceed to extubation.

ADJUNCTIVE THERAPIES

Several adjunctive therapies are administered in ventilated patients with COPD. These include therapies aimed at improving airflow (bronchodilators, helium–oxygen mixtures), decreasing inflammation (corticosteroids), and controlling infections (antibiotics).

Improvement in Airflow: Helium–Oxygen

Gas mixtures of helium and oxygen have lower density and slightly higher viscosity than standard air–oxygen mixtures.[127] This lower density decreases the Reynolds number of helium–oxygen mixtures.[127] A smaller Reynolds number can decrease resistance to gas flow through several mechanisms.[127] First, it will make flow laminar over a larger number of (medium-to-large) airway generations, over a greater fraction of the respiratory cycle, and over higher flow rates.[127] Second, when gas enters a bifurcated airway, laminar flow results in a lower airway resistance than does turbulent flow.[127] Third, for a given rate of laminar flow, a lighter gas mixture (smaller Reynolds number) results in a shorter entrance length. Entrance length is the length of a tube (bronchial tube) required to reestablish laminar flow after gas enters a bifurcated airway. For the portion of a tube over which laminar flow is becoming established, resistance will be higher as compared with when laminar flow has already been established.[127]

Several investigators have assessed the possibility to use those mixtures in patients with COPD.[44,51,128–132] In stable patients with severe COPD, Hussain et al[128] reported that patients who exercised while breathing helium–oxygen experienced less inspiratory muscle load, dyspnea, and dynamic hyperinflation, and could exercise for longer than when breathing air–oxygen alone (Fig. 31-15).[128] In patients with COPD and respiratory failure, NIPPV plus helium–oxygen decreases work of breathing and dyspnea and improves CO_2 clearance more than NIPPV alone.[129,130]

Two prospective trials have been conducted to assess whether NIPPV plus helium–oxygen could reduce the intubation rate and improve the clinical outcome of patients with COPD in respiratory failure.[51,131] In 123 patients, Jolliet et al[131] used a mixture of 78% helium and 22% oxygen. Intubation rates and ICU length of stay were comparable. In 204 patients, Maggiore et al[51] used a 65% helium and 35% oxygen mixture and found no differences in arterial blood gases, dyspnea, duration of NIPPV, ICU and hospital length of stay, and 28-day mortality.

At least two mechanisms may have contributed to the these negative results.[51,131] First, the trials were underpowered because of lower-than-expected intubation rates in the control groups. Second, helium–oxygen can improve gas dynamics by promoting the transition of flow from turbulent to laminar and by decreasing the driving pressure in areas where flow remains turbulent.[132] Turbulent flow is more likely when the increased resistance to airflow is located in the central airways than in the peripheral airways. If the increased resistance was mainly located in the peripheral airways of the patients in these two trials,[51,131] it would have been impossible for helium–oxygen to improve clinical outcomes.

Improvement in Airflow: Bronchodilators

Chapter 63 discusses bronchodilator therapy. My personal approach in patients receiving either NIPPV or invasive ventilation is to administer short-acting bronchodilators (albuterol and ipratropium) with a metered-dose inhaler and spacer. Occasionally I use nebulizers in patients receiving NIPPV.[133]

Corticosteroids

Administration of systemic corticosteroids in patients with exacerbations of COPD reduces dyspnea, treatment failure, and hospital stay.[115] Systemic corticosteroids are also associated with improvement of forced expiratory volume in 1 second and arterial blood-gases during the early treatment phase (to 72 hours) and at the end of treatment

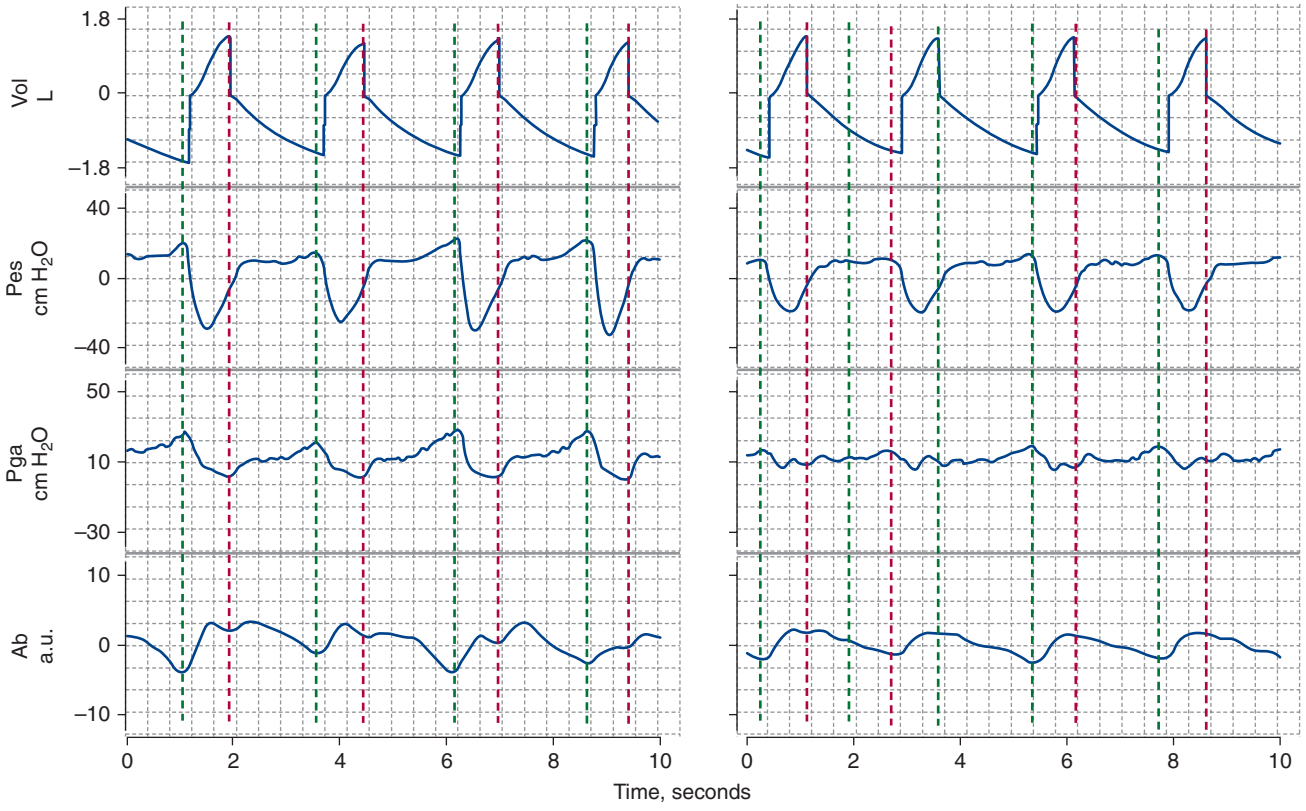

FIGURE 31-15 Helium–oxygen decreases inspiratory effort during exercise. Tracings of volume, esophageal (*Pes*) and gastric (*Pga*) pressures, and cross-sectional area of the abdomen (*Ab*) in a patient with severe chronic obstructive pulmonary disease (COPD) and severe hyperinflation during submaximal constant-load exercise test (cycle ergometer). The *green vertical lines* indicate the onset of inspiratory effort and the *red vertical lines* indicate the end of tidal inspiration. The patient exercised while breathing 30% oxygen (*left panel*) or a mixture of 70% helium plus 30% oxygen (*right panel*). Tidal volume was similar in the two conditions but tidal swings in Pes were decreased by almost half during helium–oxygen as contrasted with oxygen alone. In addition, expiratory muscle recruitment, reflected by positive deflection in the Pga signal and negative deflection in the Ab signal during exhalation, was less with helium–oxygen (*right panel*) than with oxygen alone (*left panel*). *a.u.*, arbitrary units. (Data from Hussain et al.[128])

(up to 15 days).[115] Systemic corticosteroids, however, predispose to hyperglycemia and do not decrease mortality.[115] Dose and duration of corticosteroid therapy continues to be debated.[115] In this regard, Lindenauer et al[116] compared the outcomes of nearly 80,000 exacerbations of COPD treated with low doses of corticosteroids administered orally (20 to 80 mg of prednisone) versus higher doses administered intravenously (120 to 800 mg prednisone equivalent). The risk of treatment failure, inpatient mortality, readmission for acute exacerbation of COPD was equivalent in the two groups. No benefit is derived by prolonging therapy beyond 2 weeks.[134] In patients with exacerbations of COPD, high-dose nebulized budesonide (1.5 to 2 mg every 6 hours) can be as effective as systemic corticosteroids, although much more expensive.[135]

Antibiotics

The use of antibiotics in the treatment of acute exacerbation of COPD is largely accepted.[136] In patients without pneumonia, inexpensive broad-spectrum antibiotics, such as ampicillin, doxycycline, and trimethoprim-sulfamethoxazole, are usually effective.[134] In a randomized, double-blind trial of 170 patients with an acute exacerbation of COPD requiring mechanical ventilation, trimethoprim-sulfamethoxazole was equivalent to a more expensive agent (ciprofloxacin).[136] In a recent review of eleven trials involving 917 patients, antibiotic administration in exacerbations of COPD was shown to reduce short-term mortality by 77% and the risk of treatment failure by 53%.[137]

Patients with COPD who have community-acquired pneumonia and who do not require ICU admission should be treated with a respiratory fluoroquinolone alone (levofloxacin, gemifloxacin, moxifloxacin) or with a β-lactam plus a macrolide.[138] Macrolides are attractive because they possess additional antiinflammatory and mucoregulatory properties.[139] Patients with COPD and pneumonia who require ICU admission should be treated with a β-lactam (cefotaxime, ceftriaxone, ampicillin-sulbactam) plus azithromycin or with a β-lactam plus a respiratory fluoroquinolone.[138]

Patients with recurrent exacerbations leading to frequent use of steroids and antibiotics are at increased risk of *Pseudomonas* pneumonia.[138] When these patients develop pneumonia, they should be treated with a β-lactam with

antipseudomonas and antipneumococcal properties (piperacillin-tazobactam, cefepime, imipenem or meropenem) plus ciprofloxacin or levofloxacin. An aminoglicoside plus azithromycin can be used as a alternative to ciprofloxacin or levofloxacin.[138] When community acquired methicillin-resistant *Staphylococcus aureus* is a consideration, vancomycin or linezolid should also be administered.[138]

Other Adjunctive Therapies

In patients with COPD and respiratory failure, mucolytics agents, respiratory stimulants, and methylxanthines are of uncertain benefit or no benefit or even harmful.[140,141] Chest physiotherapy is ineffective or even detrimental in patients with exacerbations of COPD requiring medical treatment alone or medical treatment plus invasive ventilation.[141] In patients treated with NIPPV, intrapulmonary percussive ventilation[56] and exhalation under positive-pressure (PEP mask)[142] may improve gas exchange, enhance removal of airway secretions and reduce duration of ventilator support and ICU length of stay.

Patients with COPD and acute respiratory failure often experience anxiety and agitation.[110] These symptoms can be caused by many factors including dyspnea, hypoxia, infection, fever, fear, and sleep deprivation. Identification and treatment of the underlying cause of anxiety does not always result in a satisfactory control of these symptoms. Anxiety and agitation can be sufficiently severe to interfere with the patient's adaptation to noninvasive or invasive ventilation. In these patients, the physician should consider the judicious use of sedatives.[110] The use of sedatives during NIPPV, however, is potentially dangerous and thus controversial.[110]

LONG-TERM OUTCOME FOLLOWING ACUTE RESPIRATORY FAILURE TREATED WITH MECHANICAL VENTILATION IN CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Patients with COPD who survive an episode of acute respiratory failure treated with NIPPV have significant morbidity and mortality following hospital discharge.[124,143] Chu et al[124] undertook a prospective study to assess the long-term outcome of 110 patients with COPD who survived an episode of acute respiratory failure treated with NIPPV. One year later, nearly half of the patients were dead, mostly because of respiratory failure. It is uncertain whether domiciliary nighttime NIPPV could improve the long-term outcome of these patients.[144]

Long-term use of nocturnal NIPPV has also been proposed for stable patients with severe COPD and chronic ventilatory failure,[145–147] including those with recurrent admissions for acute respiratory failure.[148] In two Italian studies, long-term nocturnal NIPPV plus oxygen was associated with small improvements in dyspnea,[146,147] daytime hypercapnia, and health-related quality of life.[147] More recently, the investigators of the Australian trial of noninvasive Ventilation in Chronic Airflow Limitation (AVCAL)[145] concluded that nocturnal NIPPV in stable oxygen-dependent patients with hypercapnic COPD may improve survival while worsening quality of life (see Chapters 18 and 68).

In a recent multicenter study conducted in France and Tunisia, Girault et al[149] reported the outcome of more than 200 patients with COPD who had been intubated for an episode of acute respiratory failure. In the study, 76% of patients survived hospitalization. At discharge, 81% of the survivors were able to maintain spontaneous respiration completely unassisted, 12% were discharged on noninvasive ventilation, and 4% required invasive ventilation through a tracheostomy.

Tracheostomized patients discharged from an ICU may be transferred to a long-term weaning facility.[150,151] In approximately one-third of patients transferred to these facilities, mechanical ventilation can be successfully discontinued after early trials of spontaneous respiration.[151] In the remaining patients, the weaning process is slow (average of 33 to 44 days).[150,151] Eventually, 55% to 75% of patients in whom the weaning process is slow are successfully weaned and decannulated.[150,151] The remaining 18% to 45%, however, die during the admission to the weaning facility or remain ventilator dependent.[150,151]

The long-term outcome of patients with COPD who are ventilator dependent is poor.[150] In a small series of patients with COPD who required prolonged mechanical ventilation, Nava et al[150] reported death rates of 50% at 6 months and 78% at 2 years in patients who could not be weaned. In contrast, death rates in patients who were weaned were 20% at 6 months and 32% at 2 years ($p < 0.01$).

CONCLUSION

Few groups of patients have benefitted more from the intelligent use of mechanical ventilation than have patients with COPD. Forty years ago, pulmonologists commonly employed little more than palliative care in the management of patients with COPD who had developed acute respiratory failure. Pulmonologists were reluctant to intubate such patients because of their increased susceptibility to complications and the fear that subsequent extubation would be well-nigh impossible. All that has changed. Expert use of mechanical ventilation helps the vast majority of patients with COPD to successfully battle an episode of acute respiratory failure, and patients are typically weaned and extubated without undue difficulty. Indeed, ventilator assistance is mostly achieved noninvasively, without recourse to intubation. Success with use of NIPPV has not been achieved to the same extent with any other group of patients.

The successes achieved by mechanical ventilation are the consequences of major advances in understanding of respiratory pathophysiology that began during World War II and continued in the subsequent decades. Harnessing this knowledge to better engineering of ventilator machinery

combined with more sophisticated methods of patient monitoring has resulted in more intelligent use of mechanical ventilation and fewer complications. Selecting the most appropriate mode of ventilator assistance and settings in a given patient with COPD is predicated on careful evaluation of that patient's pathophysiology. Few other illnesses managed in an ICU depend on the same level of physiologic understanding as does the management of a patient with COPD in acute respiratory failure—the reason why I have devoted the bulk of this chapter to discussion of the pathophysiology of COPD.

32 MECHANICAL VENTILATION IN NEUROMUSCULAR DISEASE

Ahmet Baydur

The earliest application of assisted ventilation in patients with neuromuscular disease was with the iron lung during the poliomyelitis epidemic in the 1940s and 1950s, which enabled patients with severe respiratory insufficiency to recover, become ventilator-free, and go on to lead productive lives.[1] In most cases, the device was used for a few weeks to up to 2 years, with eventual recovery of ventilatory function. Many polio patients with disability continue to reside in iron lungs in the community after several decades.[2] Others have converted to tracheostomy-assisted positive-pressure ventilation, achieving mobility and the ability to clear airway secretions. With appropriate weaning techniques, some have switched to noninvasive positive-pressure ventilation (NIPPV).[3] NIPPV is now preferred to support most patients with chronic neuromuscular disorders and is used increasingly to support patients with acute ventilatory insufficiency, such as with Guillain-Barré syndrome and myasthenia gravis. Table 32-1 lists neuromuscular conditions associated with respiratory impairment and failure.

OVERVIEW OF PERTINENT PATHOPHYSIOLOGY

The primary muscle of inspiration is the diaphragm, which is innervated by the third through fifth cervical nerves. In addition, the external intercostal muscles provide stability to the rib cage during inspiration. With ascending paralysis, such as with Guillain-Barré syndrome or traumatic quadriplegia above the T10 level (Fig. 32-1),[4] there are reductions in vital capacity and other volume subdivisions, as well as rib cage distortion with inspiratory effort. These changes result in regional ventilation–perfusion mismatching, particularly in the dependent portions of the lungs. An early increase in the alveolar-arterial oxygen (O_2) difference can be found in some patients with neuromuscular impairment long before hypercapnia develops.[5,6] Gas exchange worsens during sleep secondary to alveolar hypoventilation, inhibited intercostal and accessory muscle activity, and dead space ventilation induced by rapid shallow breathing.[6–8] Long-term episodic hypoxia in dystrophic mice leads to dysfunction of myofibrillar contractility as there is no change in diaphragmatic collagen content and dry-to-wet ratio.[9] Expiratory muscles in muscular dystrophies are more impaired than inspiratory muscles.[10] Despite this finding, cough effort can still be preserved if inspiratory volume and respiratory elastic recoil are maintained.[11]

Patients with Duchenne muscular dystrophy with a vital capacity above 1.8 L remain normocapnic.[12] Below this value, nocturnal hypercapnia is likely to ensue. Many factors contribute to hypercapnia including respiratory muscle weakness,[13] central hypopneas during rapid-eye movement sleep,[14] upper airways obstruction,[15] sleep fragmentation,[16]

TABLE 32-1: NEUROMUSCULAR DISEASES ASSOCIATED WITH RESPIRATORY IMPAIRMENT OR FAILURE

1. Muscle diseases
   a. Dystrophies (Duchenne, fascioscapulohumeral, limb girdle)
   b. Myotonias
   c. Autoimmune/inflammatory myopathies (dermatomyositis, polymyositis)
   d. Metabolic myopathies (hypophosphatemia, glycogen-storage disorders, disturbed lipid metabolism)
   e. Endocrine myopathies (hypothyroidism, hyperthyroidism)
   f. Periodic paralysis
   g. Toxic myopathies (alcohol)
2. Peripheral neuropathies
   a. Autoimmune/inflammatory (Guillain-Barré, Chronic demyelinating inflammatory polyneuropathy)
   b. Toxic (heavy metal, organophosphates, nitrofurantoin, hexacarbons)
   c. Acute intermittent porphyria
   d. Tick paralysis
   e. Shellfish poisoning
   f. Hereditary (Charcot-Marie-Tooth)
   g. Endocrine (hypothyroidism, hyperthyroidism, diabetic)
3. Neuromuscular junction (myasthenia gravis, botulism)
4. Motor neuron disease
   a. Poliomyelitis
   b. Amyotrophic lateral sclerosis
   c. Spinal muscle atrophies
5. Intensive care unit-related weakness
   a. Critical illness polyneuropathy (sepsis, multisystem organ failure)
   b. Neuromuscular blocking agent-related neuropathy
   c. Status asthmaticus-associated neuromyopathy (high-dose steroids, aminoglycosides, paralytic agents)
6. Spinal cord injury

obesity,[14] respiratory muscle asynchrony,[17] and decrease in respiratory compliance.[18,19] Thoracic scoliosis, often associated with disorders such as poliomyelitis and muscular dystrophy (Fig. 32-2), further reduces respiratory compliance, resulting in an increase in inspiratory drive, altered force-length and force-velocity relationships,[20,21] and, ultimately, diaphragmatic fatigue.

Body position influences regional ventilation in individuals with neuromuscular disease. Furthermore, use of positive-pressure ventilation and an abdominal belt results in greater global and regional ventilation in the supine position than in the right and left lateral positions.[22] Intermittent positive-pressure breathing sessions (30 consecutive deep breaths at pressures up to 30 cm H_2O) improve regional ventilation by approximately 30%, more so in the anterior regions.[22,23]

Measurement of maximal static mouth pressures (Pmax) provides a guide to the degree of respiratory muscle weakness and is an adjunct in assessing the need for assisted ventilation. In stable neuromuscular disease, maximal expiratory mouth pressures are lower in myopathy than in polyneuropathy and in proximal than in distal muscle weakness.[10,24]

Weakened abdominal muscles reduce the ability to cough, as reflected by decreased peak expiratory flow rates. Patients with peak expiratory flows of less than 160 L/min need cough assistance to prevent accumulation of airway secretions.[25,26] Cough impairment is worsened by inspiratory muscle weakness and glottic dysfunction. Bulbar muscle involvement impairs swallowing and speech and increases risk of aspiration and upper airway collapse.

Dysregulation of breathing in muscular dystrophy and myotonic dystrophy has been attributed to abnormal feedback from respiratory muscle receptors and abnormal central ventilatory control, respectively.[27,28] Sleep-disordered breathing can be related to respiratory muscle weakness, chest wall deformities, obesity, craniofacial abnormalities, bulbar dysfunction, and abnormalities in control of ventilation.[14,29] Loss of rib cage and bulbar muscle tone, particularly during rapid-eye movement sleep, results in hypoventilation, decreased inspiratory flow, fragmented sleep, and daytime symptoms, well described in myotonic dystrophy, diaphragmatic paralysis, Duchenne muscular dystrophy, and amyotrophic lateral sclerosis.[30–34] Despite muscle weakness, central drive in patients with neuromuscular and chest wall disorders is often increased.[35]

CLINICAL AND PHYSIOLOGIC INDICATIONS TO INITIATE ASSISTED VENTILATION

Altered mental status, cardiac or respiratory arrest, shock, arrhythmias, gas-exchange abnormalities, and bulbar dysfunction are absolute indications for endotracheal intubation. Such acute changes are frequently seen in patients with Guillain-Barré syndrome, myasthenia gravis, and almost always in cervical spinal cord injury. Lawn and Wijdicks[36] advocated the use of a pulmonary function score, the sum of the vital capacity, maximum inspiratory pressure ($P_I$max), and maximum expiratory pressure ($P_E$max), to predict prolonged ventilation and the need for tracheostomy in patients with Guillain-Barré syndrome.

The patient developing slowly progressive respiratory impairment will experience dyspnea, increased use of accessory neck muscles, paradoxical breathing, cough after swallowing (indicative of aspiration), tachycardia, sweating, and inability to say more than a few words in a row. Some patients may complain of headaches or sleep disturbances or exhibit cognitive impairment associated with daytime hypercapnia with partial compensation. Those with generalized muscle weakness often experience orthopnea whereas patients with quadriplegia prefer the supine position because the diaphragm assumes a greater resting length and force generation.[4]

Serial measurements of forced vital capacity provide a simple and reliable means of assessing disease progression, and may predict difficulties with cough and secretion clearance[37] although as much as 50% reduction in respiratory

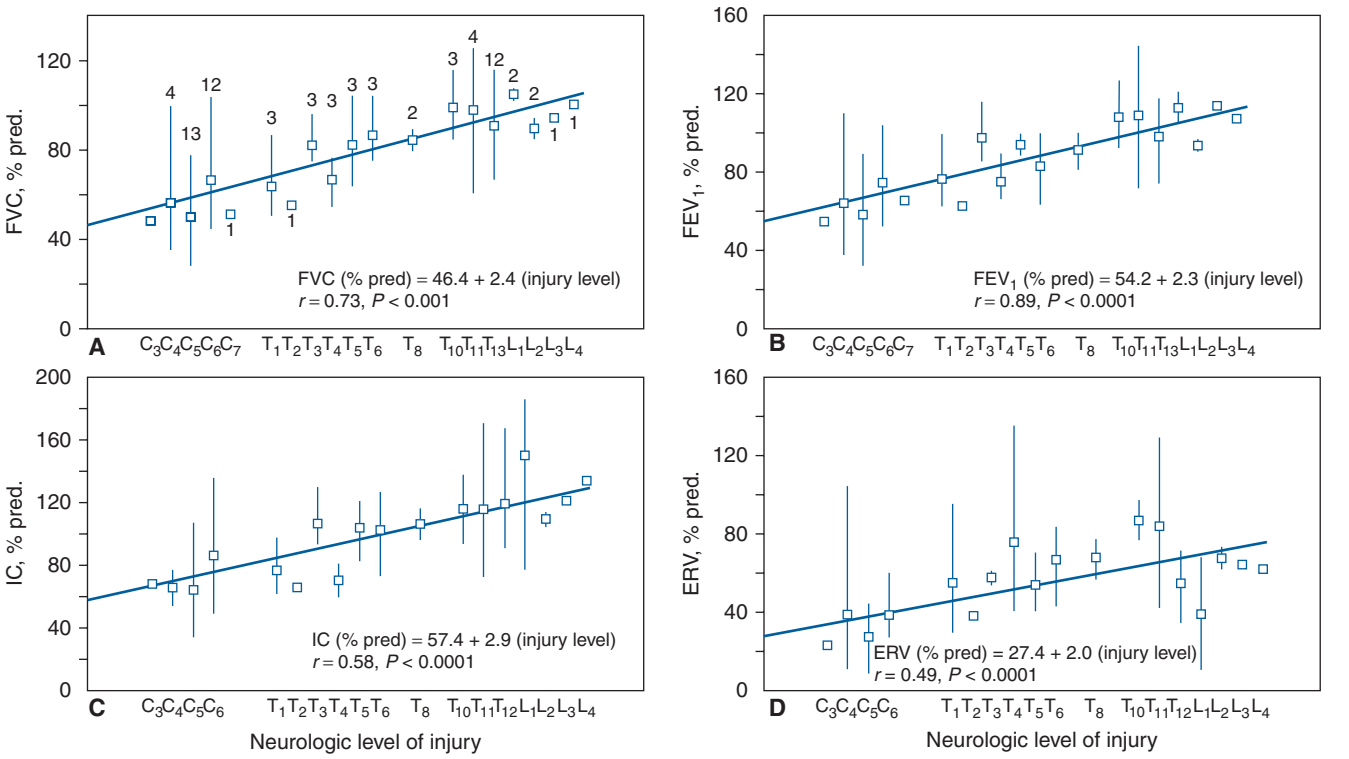

FIGURE 32-1 Spirometric variables in seated spinal cord-injured subjects distributed according to lesion level. **A.** Forced vital capacity (*FVC; n* = 74). **B.** Forced expiratory volume in 1 second (FEV_1; *n* = 74). **C.** Inspiratory capacity (*IC; n* = 73). **D.** Expiratory reserve volume (*ERV; n* = 73). Values are means and ranges of percent predicted (*% pred*) values for healthy persons. Numbers above squares in A are numbers of subjects at each injury level and are the same for B to D. (Used, with permission, from Baydur et al.[4])

muscle strength occurs before these values are reduced.[38] In general, patients with less than 10% of predicted (or <1 L) vital capacity have little tolerance off assisted ventilation.[2,3] In patients with bulbar involvement who have difficulty holding a mouthpiece in place, a full face mask can be used to perform spirometry. Facemask measurements tend to produce vital capacity values larger than those recorded by mouthpiece, in some cases by as much as 1.2 L in the seated position.[39] A more useful guide to diaphragmatic weakness is the comparison of the vital capacity measured in the seated and supine positions. Reductions in vital capacity of 12% to 65% have been recorded in patients with neuromuscular disease[3,4,40,41] (except in those with traumatic quadriplegia[4,42,43]) on assuming the supine position.

Measurements of $P_I$max and $P_E$max are noninvasive and have established normal values for adults and children. They require, however, maximal effort and coordination, and are uncomfortable to perform. Low values may be difficult to interpret.[44,45] Poor effort or air leaks around the mouthpiece give rise to submaximal measurements. Sniff esophageal pressure (Pes-sniff) and twitch transdiaphragmatic pressure (Pdi) tests are more precise but somewhat invasive (Fig. 32-3).[46–48] Sniff nasal inspiratory force avoids the need for use of a mouthpiece and is easily performed by most patients, but may be tiring because of the need for repetition.[49,50] A sniff nasal inspiratory force less than

FIGURE 32-2 Patient with Duchenne muscular dystrophy and severe scoliosis.

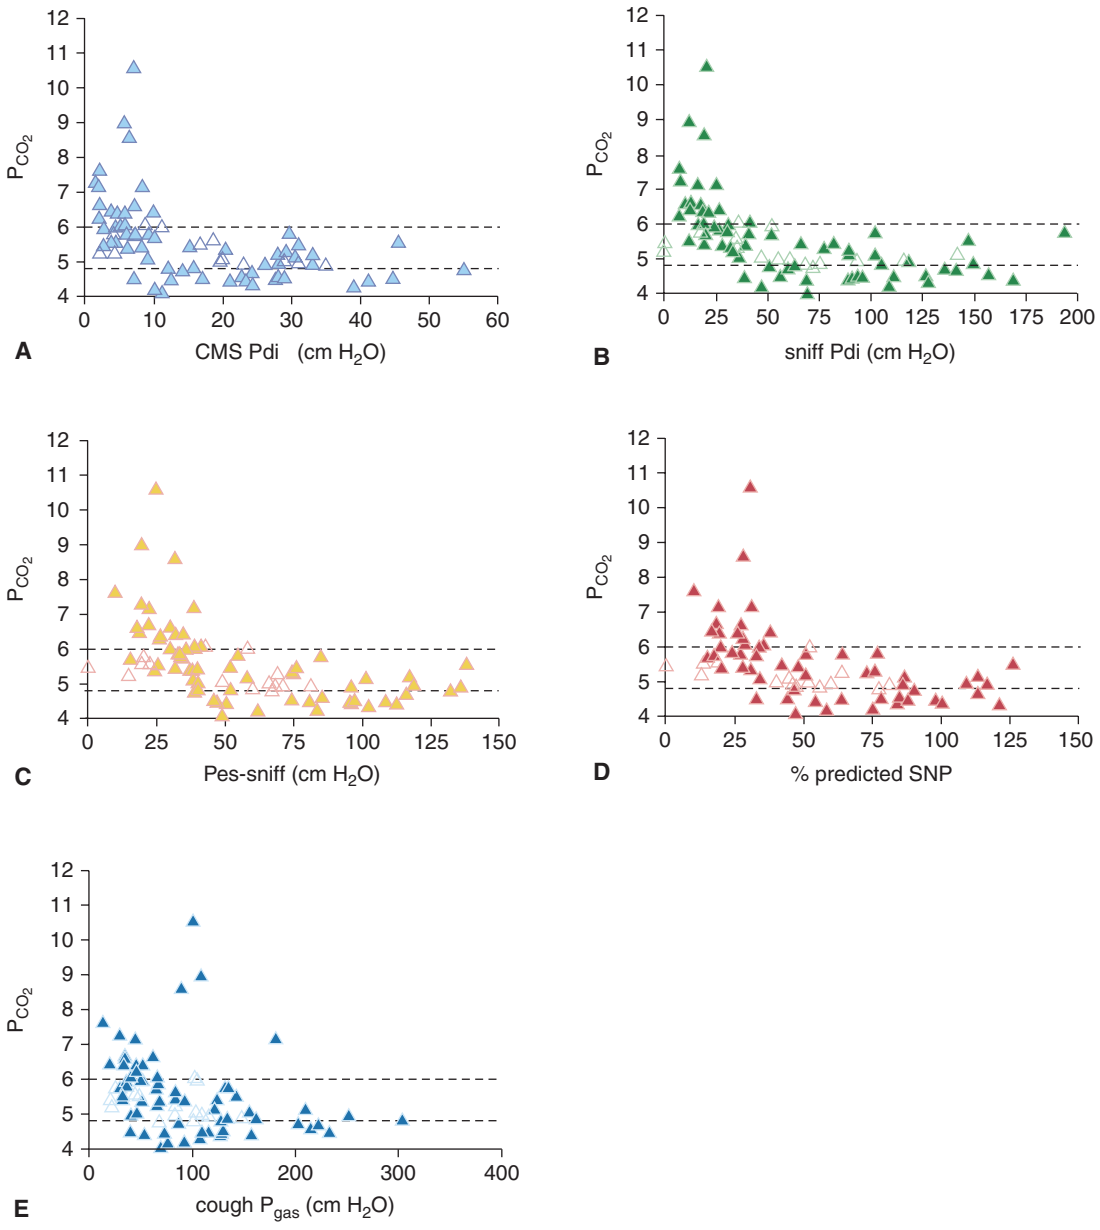

FIGURE 32-3 Relationship between tests of respiratory muscle strength (RMS) and P_{CO_2}. Each graph shows earlobe blood gas P_{CO_2} in kPa on the *y*-axis and RMS on the *x*-axis. *Open symbols* represent the bulbar patients and *closed symbols* the limb patients. The *dotted lines* represent the lower and upper limits of normal for earlobe blood gas P_{CO_2} (4.8 to 6.0 kPa). *CMS Pdi,* transdiaphragmatic pressure after bilateral cervical magnetic phrenic nerve stimulation; *cough* P_{gas}, cough gastric pressure; *sniff Pdi,* maximal sniff transdiaphragmatic pressure; *Pes-sniff,* maximal sniff esophageal pressure; *SNP,* maximal sniff nasal pressure. (Used, with permission, from Lyall A, Donaldson N, Polkey MI, Leigh PN, Moxham J. Respiratory muscle strength and ventilatory failure in amyotrophic lateral sclerosis. *Brain.* 2001;124:2000–2013, with permission of Oxford University Press.)

40 cm H_2O_2 has a sensitivity of 97% and specificity of 79% for predicting 6-month mortality in amyotrophic lateral sclerosis.[51] The use of individual tests tends to overdiagnose respiratory muscle weakness by approximately 27%, while the combination of tests increases precision and reduces the diagnosis of respiratory muscle weakness by 19% to 56% (Fig. 32-4).[52] Supine forced vital capacity, upright forced vital capacity, $P_I$max, $P_E$max, and Pdi-sniff are associated with tracheostomy-free survival, more so than Pa_{CO_2} (Fig. 32-5).[41]

Table 32-2 lists physical and functional findings used in the evaluation of patients with impending respiratory failure secondary to neuromuscular disease.

VENTILATOR TARGETS IN NEUROMUSCULAR DISEASE

The chief goals are to reverse altered mental status, correct gas exchange, and improve quality of life (see Table 32-2). With the use of nighttime NIPPV, daytime hypercapnia in

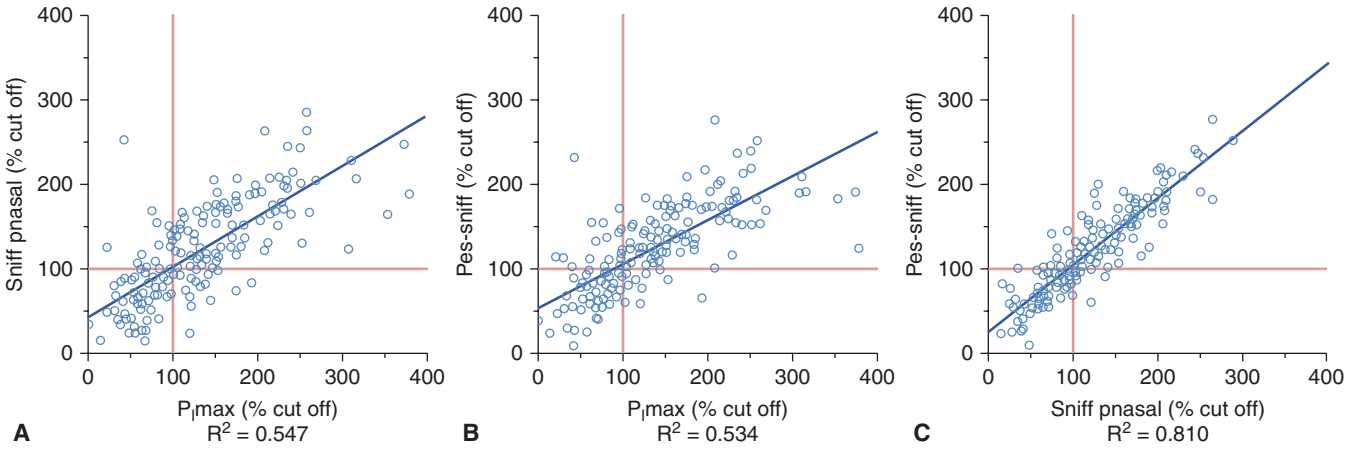

FIGURE 32-4 Correlation between (**A**) maximum inspiratory pressure ($P_I max$) and sniff nasal pressure (*Pnasal*), (**B**) $P_I max$ and sniff esophageal pressure (*Pes*), and (**C**) *Sniff Pnasal* and *Pes-sniff*. Duchenne muscular dystrophy is delayed by 4 to 5 years[53] and survival improves by 5 to 10 years.[54,55] Application of a few hours of daytime NIPPV reduces breathlessness and increases endurance capacity in Duchenne muscular dystrophy more effectively than nocturnal NIPPV alone (Fig. 32-6).[55] Similarly, NIPPV improves survival and quality of life in amyotrophic lateral sclerosis, even in those with bulbar dysfunction.[56,57]

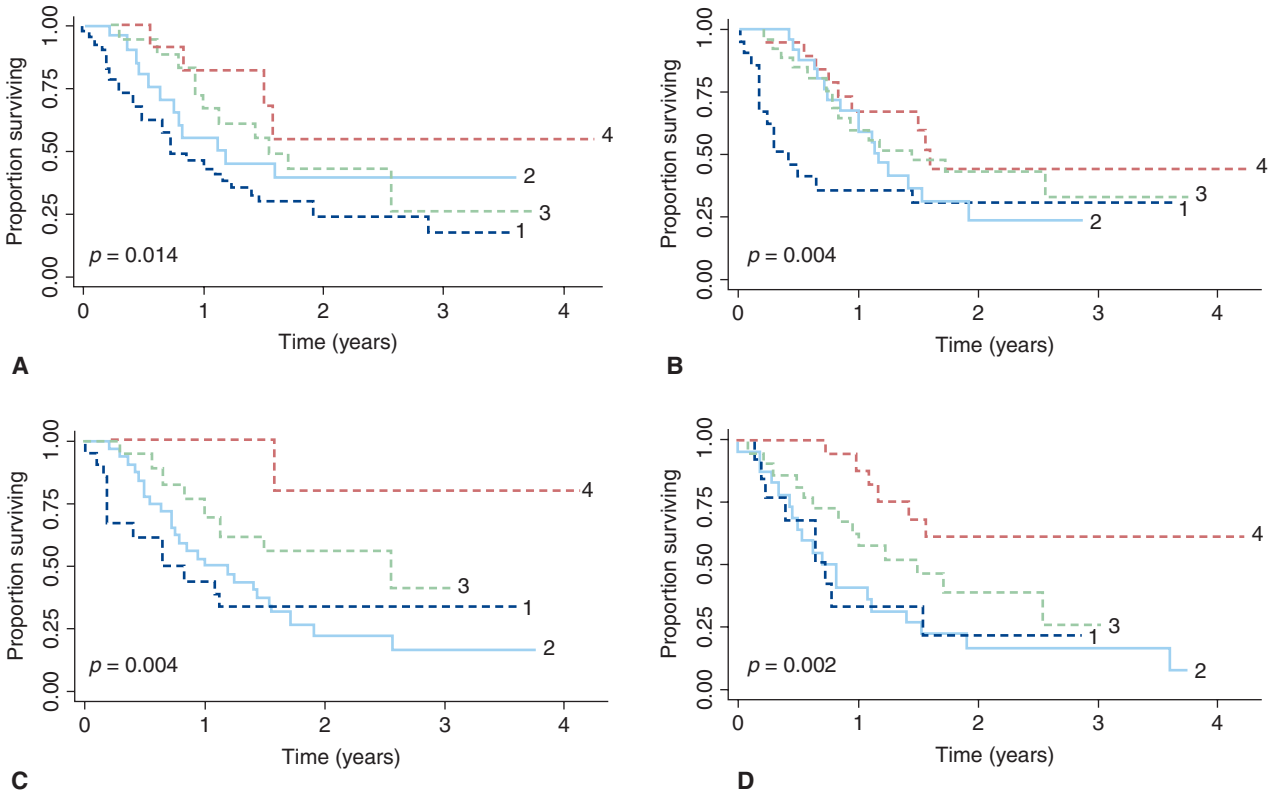

FIGURE 32-5 Kaplan-Meier curves showing differences in survival based on values of supine forced vital capacity (FVC) (**A**), upright FVC (**B**), maximal inspiratory pressure ($P_I max$) (**C**), and maximal expiratory pressure ($P_E max$) (**D**). The categories of FVC are as follows: FVC ≤50% (line 1); FVC = 51% to 65% (line 2); FVC = 66% to 80% (line 3); FVC >80% (line 4). The $P_I max$ categories are as follows: $P_I max$ greater than −25 cm H_2O (line 1); $P_I max$ = −25 to −50 cm H_2O (line 2); $P_I max$ = −51 to −70 cm H_2O (line 3); $P_I max$ less than −70 cm H_2O (line 4). The $P_E max$ categories are as follows: $P_E max$ <25 cm H_2O (line 1); $P_E max$ = 25 to 50 cm H_2O (line 2); $P_E max$ = 51 to 70 cm H_2O (line 3); $P_E max$ >70 cm H_2O (line 4). The *p* values compare differences in survival between the four categories of each pulmonary test by the Wilcoxon test. (Used, with permission, from Schmidt et al.[41])

TABLE 32-2: INDICATIONS FOR INITIATING MECHANICAL VENTILATION IN NEUROMUSCULAR DISEASES

- Relative subjective symptoms (orthopnea, frequent arousals from sleep, morning headaches, daytime somnolence/napping, impaired cognitive function [memory, concentration], fatigue)
- Cor pulmonale
- Vital capacity <25% of predicted
- Maximal inspiratory mouth pressure <25 cm H_2O
- Nasal "sniff" pressure <25 cm H_2O
- Changes in gas exchange indicating progressive respiratory failure:
  - Daytime Pa_{CO_2} >45 mm Hg
  - Sustained nocturnal hemoglobin desaturation (>5 minutes or >10% of total study time)
- Recurrent acute respiratory failure episodes requiring intervention
- Failure to respond to continuous positive pressure alone in patients with documented sleep apnea syndrome before neuromuscular weakness is detected

EXPERIENCE WITH TRADITIONAL MODES OF VENTILATION

Many patients with poliomyelitis were supported with negative-pressure devices such as oscillating beds (Fig. 32-7), iron lungs (Fig. 32-8), cuirasses, and "ponchos" (Figs. 32-9A and B). Subsequently, individuals with other neuromuscular disorders received tracheostomies for positive-pressure support (Fig. 32-10). Disadvantages of tracheostomies include the necessity of teaching the patient and caregivers how to maintain the tracheostomy, and complications such as stomal infections, airway erosions (from repeated suctioning), tracheal stenosis, and difficulty with speech and swallowing (that can be overcome with proper speech and bulbar training and use of a one-way speaking valve). Airway-vascular fistulas (with fatal hemorrhage) and tracheobronchomalacia are infrequent but devastating complications that can occur even with uncuffed tracheostomies.[58] Tracheostomies can be performed with local anesthesia during NIPPV support in hypercarbic patients with neuromuscular disease (vital capacity <20% predicted).[59]

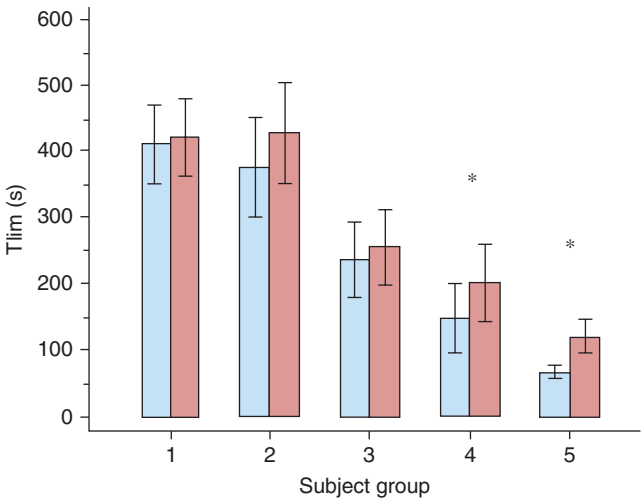

FIGURE 32-6 Endurance capacity (*Tlim*) in the five groups of patients with Duchenne muscular dystrophy. Columns represent mean values; errors bars represent 1 standard error of the mean (SEM). *Blue columns:* Evening Tlim; *red columns:* morning Tlim; $*p < 0.05$ (paired t test, evening vs. morning). Group 1, no assisted ventilation and 24/24 hours normocapnia; group 2, nocturnal hypercapnia before the start of noninvasive positive-pressure ventilation (NIPPV) implementation; group 3, nocturnal NIPPV with no breathlessness; group 4, nocturnal NIPPV with breathlessness; group 5, full-time NIPPV. (Used, with permission, from Toussaint M, Soudon P, Kinnear W. NONINVASIVE POSITIVE-PRESSURE VENTILATION

Not all patients elect to undergo tracheostomy for ventilation. The use of oral, lip (Fig. 32-11), nasal, or full-face (Figs. 32-12 to 32-14) interfaces in neuromuscular disorders

FIGURE 32-8 An iron lung (negative-pressure) ventilator.

FIGURE 32-10 A poliomyelitis survivor receiving tracheostomy positive ventilation.

enables avoiding tracheostomies. They also have been used to wean patients off tracheostomy-assisted ventilation.[3] An open mouthpiece circuit can be used in respiratory-dependent neuromuscular patients with a portable volume ventilator. Only volume-cycled ventilators with negative-pressure triggering should be used, however, because flow-triggered volume ventilators autocycle when used with an open-circuit mouth-positive system.[3,60]

Delivery of effective ventilation is dependent on many factors, including ventilator type, mode, settings, presence of leaks (Fig. 32-15), upper airway resistance, expiratory valve, type of triggering (Fig. 32-16), pressurization rate, cycling pattern, and positive end-expiratory pressure (PEEP) level.[60] Patients with increased respiratory elastance (e.g., scoliosis) are likely to benefit more from a volume-cycled ventilator than from a bilevel positive airway pressure machine.

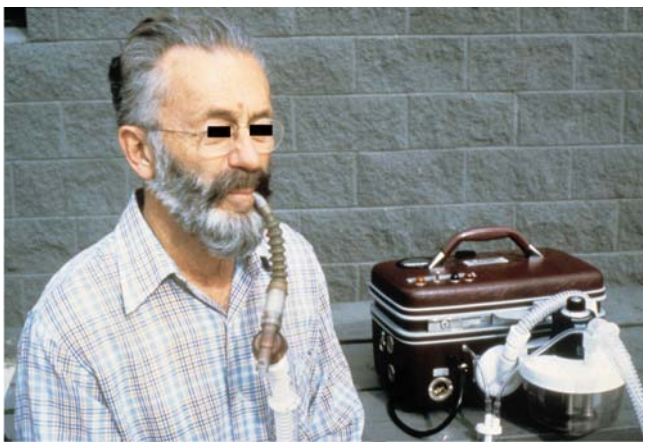

FIGURE 32-11 An individual with late effects of poliomyelitis receiving mouth positive ventilation through a mouthpiece.

FIGURE 32-12 A full-face mask used in noninvasive ventilation. (With permission from Hans Rudolph, Inc.)

FIGURE 32-14 Nasal adaptor ("pillows") used with noninvasive ventilation. (Used, with permission, from Swift™FX © ResMed 2012.)

Volume-cycled ventilators have the advantage of delivering higher volumes and can provide air "stacking" to maximum insufflations via an oral interface.[3,26] Leaks are best handled with pressure-targeted ventilators.[60]

With a close working relationship between the patient and caregivers, machine tolerance can be achieved in virtually all patients with neuromuscular diseases, including those with hypercapnic amyotrophic lateral sclerosis.[61] The prognosis in the latter group is particularly poor if they do not accept mask ventilation (death usually within less than a year). One study found a survival disadvantage in patients treated early with NIPPV for Duchenne muscular dystrophy,[62] but this finding may have resulted from the exclusion of hypercapnic patients.

FIGURE 32-13 A silicone nasal interface used with noninvasive positive-pressure ventilation.

Current evidence concerning the benefits of NIPPV is consistent, suggesting relief of symptoms of hypoventilation in the short-term and, for the most part, improvement in survival[56,57] and quality of life.[47,56] Development of a home protocol in which oxygen desaturations are prevented or reversed using NIPPV and manual and mechanically assisted coughing techniques results in fewer and shorter hospitalizations than if such a protocol were not used.[3] Early respiratory evaluation improves patient outcomes, particularly in patients without bulbar dysfunction, and increases survival time.[57] Bulbar involvement worsens survival and increases intolerance of NIPPV.[56,57,61] Initiation of NIPPV in the hospital also improves tolerance through nocturnal adaption, and increases the likelihood of adhering to the home-ventilation program following discharge[57,61]

ROLE FOR NEWER MODES OF VENTILATION

Although pressure-cycled ventilation is the most common mode of providing ventilatory assistance in the long-term setting, patient–ventilation asynchrony sometimes occurs.[63] Proportional-assist ventilation improves patient–ventilatory synchrony by providing inspiratory flow and pressure in proportion to the patient's effort.[64] In a crossover study of fourteen patients with chronic ventilatory insufficiency (ten with restrictive thoracic disorders) comparing pressure-cycled with proportional-assist ventilation, both modes were shown to result in similar tolerance and were equally effective in reducing daytime

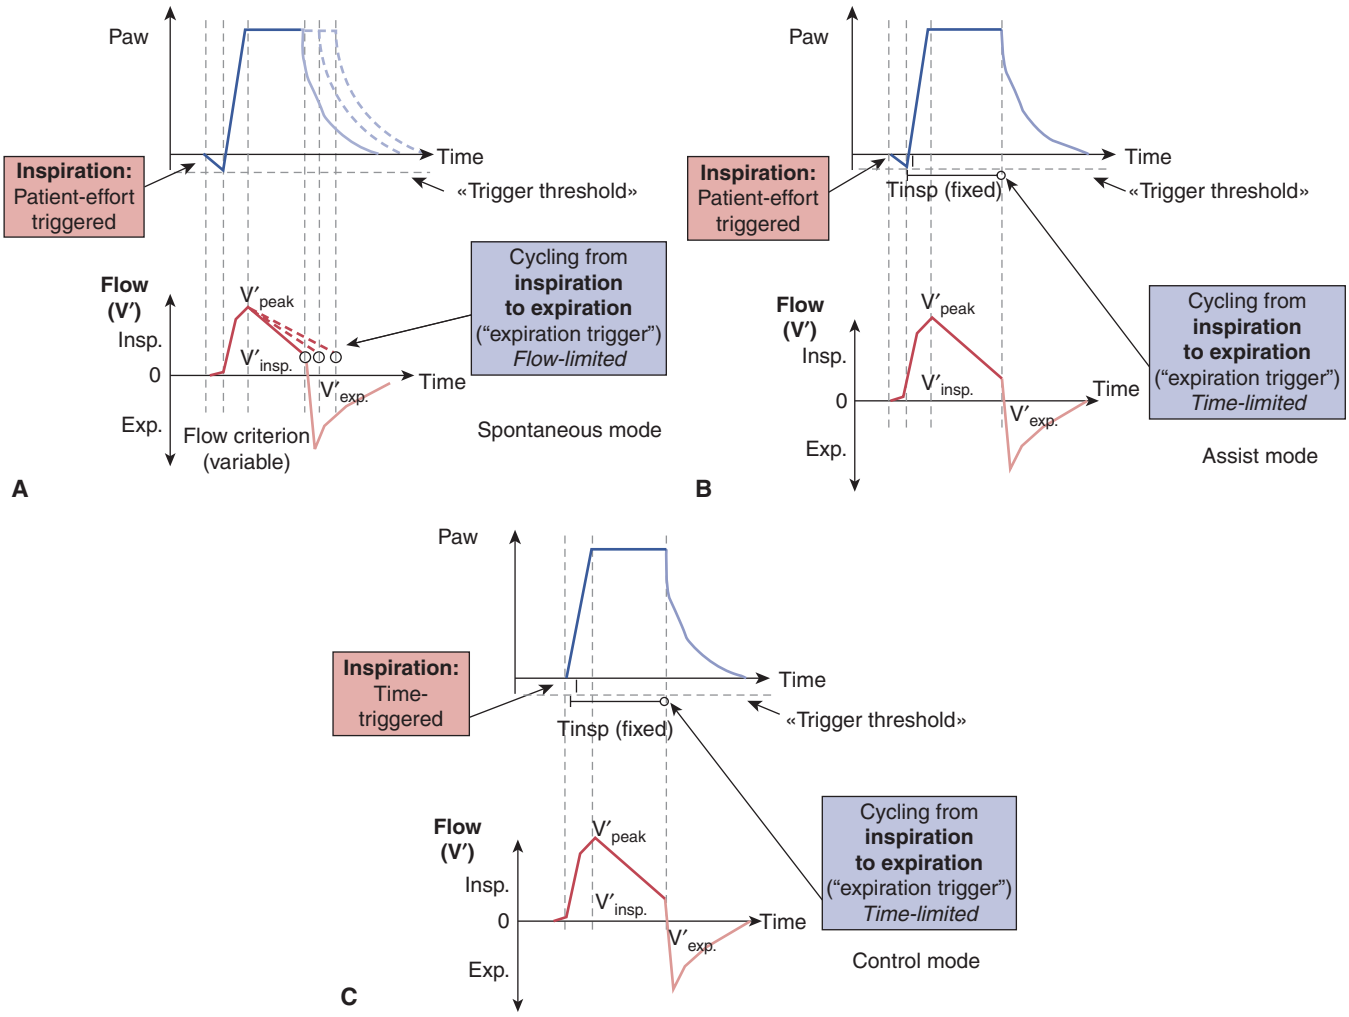

FIGURE 32-15 Impact of leaks on inspiratory-to-expiratory (I to E) cycling during pressure support ventilation (S in bilevel devices) mode (**A**) without leaks and (**B**) with leaks. Note that during leaks the flow increases to compensate for them, prolonging the inspiratory time (*dashed lines*) and switching to time-limited if maximal inspiratory time ($T_I$max) is available. Interestingly, $T_I$max is adjustable in most recent noninvasive ventilation devices. *Paw,* pressure in the airways. hypercapnia and improving nocturnal saturation and symptoms.[65]

Recently, average volume-assured pressure-support ventilation (AVAPS) (Fig. 32-17) has gained use. This mode guarantees any tidal volume compatible with the physician-set upper pressure limit. It applies the benefits of pressure control while avoiding its potential complications. It is an ideal mode for individuals with low respiratory compliance, such as those with morbid obesity, scoliosis, and atelectasis. AVAPS can also reduce the leak related to the interface and reduce the rate of asynchrony related to the underlying disease process. In the only randomized, crossover trial in patients with a chest wall disorder (obesity-hypoventilation syndrome), the addition of AVAPS to bilevel pressure ventilation reduced hypercapnia as well as improved sleep quality and health-related quality of life.[66]

ROLE FOR POSITIVE END-EXPIRATORY PRESSURE

PEEP is used primarily to improve oxygenation in patients with severe and refractory hypoxemia. PEEP should recruit gas exchange units in neuromuscular weakness as most patients have reduced functional residual capacities and dependent alveolar units that fail to open during inspiration.

The most practical application of PEEP is in the form of the expiratory positive airway pressure delivered by bilevel positive airway pressure. Although pressure-cycled ventilators can compensate partially for mask leaks, excessive leaks can prolong the inspiratory phase and worsen intrinsic PEEP and patient–ventilator asynchrony. The latter problem can be corrected with the use of time-cycled expiratory triggers better than with flow-cycled expiratory triggers.[67]

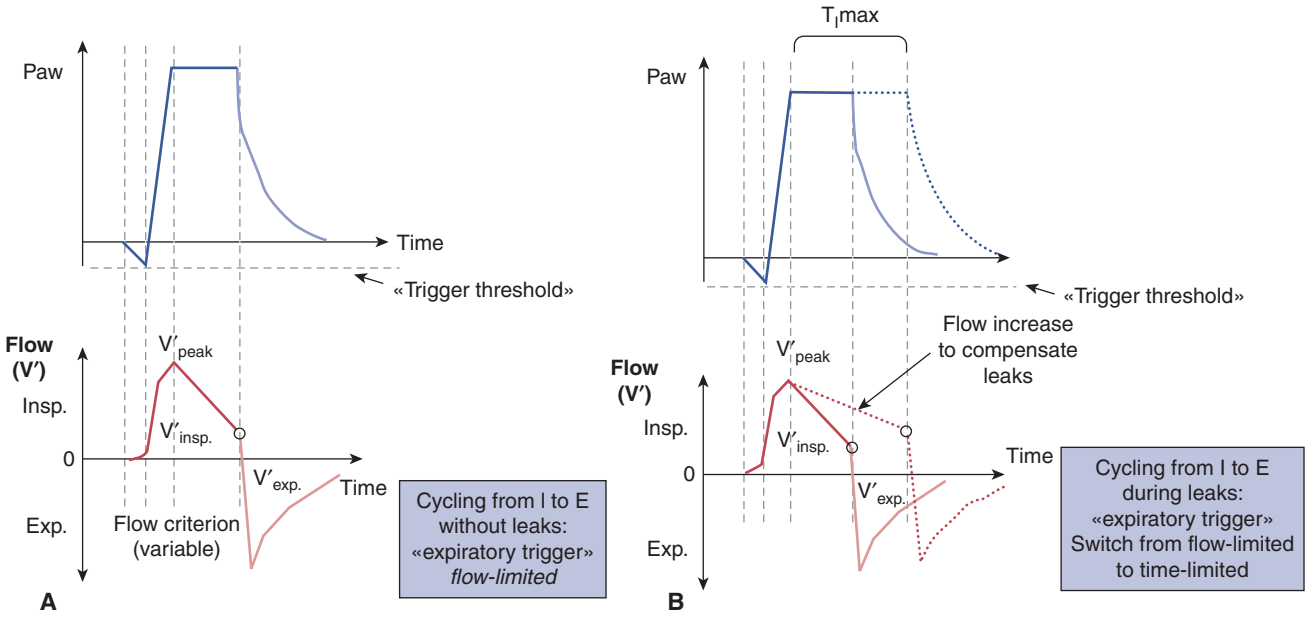

FIGURE 32-16 Different modes of inspiratory and expiratory triggering. **A.** Spontaneous mode. The patient controls the beginning and end of inspiration. Inspiration starts when the ventilator is triggered by the patient, and cycling from inspiration to expiration occurs when the inspiratory flow reaches a predetermined percentage of peak inspiratory flow. This mode is also called "pressure support" and, in some ventilators, "spontaneous (S) mode." **B.** Assisted mode. The patient controls the onset of inspiration but the end of inspiration is time triggered. When a backup respiratory rate (RR) is preset, this mode is called assist or control. In this last mode, if the patient's RR is lower than the preset ventilator backup RR, the system moves to control mode. **C.** Control mode. There is a preset automatic cycle based on time. The ventilator controls the beginning and end of inspiration and thus the RR. In some ventilators, this mode is also called "timed (T) mode." *Paw,* pressure in the airways. (Reproduced with permission from BMJ Publishing Group Ltd from Rabec C, Rodenstein D, Leger P, Rouault, Perrin C, Gonzalez-Bermejo, and on behalf of the SomnoNIV group. Ventilator modes and settings during non-invasive ventilation: effects on respiratory events and implications for their identification. *Thorax.* 2011;66:170–178.)

As in any patient with impaired left-ventricular function receiving high levels of PEEP, excess pressures can lead to a decrease in cardiac output, a potential problem in dystrophic cardiomyopathies.

SELECTING VENTILATOR SETTINGS

For most patients who present with findings of respiratory impairment, as shown in Table 32-2, ventilator assistance usually is begun nocturnally. Bach[3] recommends that most patients be started on a volume-cycled ventilator to achieve air "stacking" for maximum insufflations and for eventual daytime use. Occasional patients will benefit more from a pressure-cycled ventilator if they have glottic incompetence and cannot stack breaths.[3,60] If they do use a pressure-cycled device, the pressure spans must be high enough to generate adequate volumes. The expiratory positive airway pressure should be set as low as possible (e.g., 2 cm H_2O) unless the patient has underlying lung disease or documented sleep apnea. The spontaneous-timed mode is recommended. Patients with oral leaks can be switched to a full-face mask or, if this is uncomfortable, to chin straps, or mouth or lip seals. Because such interfaces result in an open system, and patients can take in as much volume as they want, the set volume should be able to compensate for leaks (starting at 600 to 1000 mL, with eventual increases to 800 to 1500 mL).[3]

In patients with severe respiratory muscle weakness, patient–ventilator dyssynchrony may result in hypoventilation, particularly at night, when changes in the pattern of recruitment of the respiratory muscles may occur during different sleep stages and disrupt sleep. Settings of NIPPV chosen on an empirical basis while the patient is awake may not predict ventilator asynchrony during sleep, and improper titration of inspiratory support or PEEP may impede the trigger of the mechanical breath. These abnormalities can be reduced when a physiologic setting, based on recordings of inspiratory muscle efforts, is applied.[68]

Noninvasive ventilation may be initiated in the hospital, a sleep laboratory, the outpatient office, or the patient's home, depending on the resources available. Ideally, the procedure should be initiated with the patient alert, under the guidance and supervision of experienced personnel. The goals should be to familiarize and encourage the patient with the technique and to establish initial ventilator settings (determined by optimizing both by physiology and patient comfort). Once gas-exchange and patient-comfort goals have been reached, transition to nocturnal use is initiated. Evaluations should be conducted using nocturnal oximetry and daytime arterial gases (Fig. 32-18). Polysomnography (and where available continuous percutaneous or end-tidal CO_2 monitoring) are recommended in patients in whom sleep hypoventilation is suspected.[69,70,103]

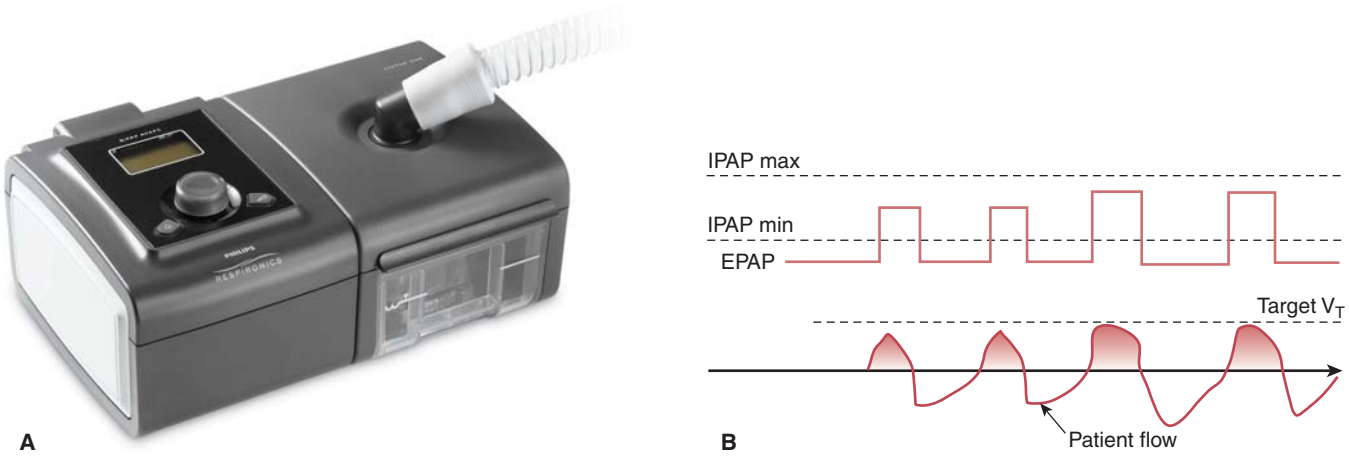

FIGURE 32-17 **A.** Average volume-assured pressure-support (AVAPS) ventilator with humidifier. **B.** Tracings taken from AVAPS mode. Based on a sensitivity algorithm performance, the device estimates the patient's tidal volume (V_T) with each breath and compares it with the target tidal flow/volume. If necessary, the algorithm slowly increases or decreases inspiratory pressure for each breath (0.5 to 1 cm H_2O/min) so as to achieve the preset V_T. (Image provided by Philips Respironics, Murrysville, PA.)

VULNERABILITY TO VENTILATOR COMPLICATIONS

Many patients tend to have ventilation increased, especially during an acute respiratory infection, and neglect to restore their settings to their original values. Reducing the ventilation of chronically hyperventilated patients results in immediate dyspnea and demands to restore the previous ventilator settings.[71,72] In contrast to tracheostomy-assisted ventilation, NIPPV provides an open system of ventilation with maintenance of more optimal levels of partial pressure of carbon dioxide (P_{CO_2}), allowing restoration of the ventilatory drive.[3] The correction should be done with small decrements in tidal volume and/or respiratory rate over time. Periodic assessments of blood gases or end-tidal or rebreathe P_{CO_2} values[73] should be done to optimize ventilation. Progressive weight loss in patients with chronic neuromuscular disorders may also necessitate a decrease in tidal volume requirements.

Adverse effects of the interface, although not life-threatening, can lead to serious discomfort and the possibility of discontinuation. They include skin and eye irritation, drying of mucus membranes, aerophagia, leaks around the nasal and full-face interfaces, and abdominal distension with colic.[74]

Volume-cycled ventilation in control mode may result in a decrease in effective ventilation secondary to glottic closure.[3,60,75,76] Mechanical dysfunction and power outages occur occasionally, leaving the ventilator-dependent patient vulnerable to acute or progressive respiratory failure. The physician may have to exert influence as the patient's advocate to persuade third-party payors to provide reimbursement for a backup ventilator.

Other respiratory aids such as rocking beds, pneumobelts, diaphragmatic pacing, and negative pressure ventilators are discussed elsewhere in this book. In general, they are not as effective as NIPPV, particularly in patients with severe scoliosis and bulbar dysfunction. Negative pressure ventilators and diaphragmatic pacers can promote obstructive apneas, whereas the disadvantages of diaphragmatic pacers also include their high cost, lack of alarms, and potential to fail.

ADJUNCTIVE THERAPY

Glossopharyngeal Breathing

Originally taught to persons with poliomyelitis, glossopharyngeal breathing (GPB) may be useful in other neuromuscular diseases in maintaining ventilation. In individuals with weak inspiratory muscles and no tolerance off the ventilator, GPB is a nonmechanical form of breathing that can be handy in the case of sudden ventilator failure or to augment spontaneous breathing.[77] With each closure of the glottis (a "gulp"; 40 to 200 mL) can be inhaled and then exhaled to augment breathing. GPB can be used to stack breaths (up to 1.6 L) and promote cough.[3]

Assisted Coughing

Respiratory complications are the principal causes of morbidity and mortality in advanced neuromuscular diseases, in particular, inability to eliminate airway secretions because of ineffective coughing. Clearance of secretions with assisted coughing can prevent respiratory failure and delay or avoid the need for a tracheostomy. Effectiveness of secretion clearance depends on the peak expiratory flow rate. A peak cough flow of 160 to 270 L/min is an indication to provide manually or mechanically applied cough assistance.[26,78] These values should be used as guidelines and not as absolute cutoffs because some patients may develop difficulty eliminating secretions despite higher peak flows.

Manually assisted coughing requires cooperation and coordination between the patient and caregiver. The patient achieves a maximal inspiratory capacity, preferably with use of a positive-pressure device (such as with a resuscitator bag, or ventilator, or mechanical insufflation–exsufflation device) and breath "stacking," closes his or her glottis, and then "lets go" with the help of an externally applied upward and inward abdominal thrust.[79] A mouth pressure of 60 cm H_2O or more during relaxation at peak insufflation against a closed shutter usually indicates a recoil pressure adequate to generate a good cough flow.[79]

Patients with quadriplegia can contract the clavicular portion of the pectoralis major to compress the rib cage during forced expiration and cough.[80] They have decreased ability to increase intrathoracic pressure, however, because of paralysis of expiratory rib cage and abdominal muscles. Electrical or magnetic stimulation can increase intrathoracic pressure inversely and may be used to augment dynamic airway compression and clearance of airway secretions.[81]

Mechanical Insufflation–Exsufflation Devices

A mechanical insufflation–exsufflation device is a positive-pressure generator that produces a deep inspiration followed by a powerful sucking action that achieves a high expiratory flow rate (see Fig. 32-19). Minimum pressures of 35 to 40 cm H_2O are required to expel secretions but should be increased gradually over time according to the patient's comfort level.[82] Such pressures would be required to overcome small lungs and stiff chest walls, as in scoliosis. The mechanical insufflation–exsufflation device can be used with tracheostomies and full-face masks, avoiding the mucosal trauma that results from suctioning. Frequency of use can vary depending on the amount of secretions produced. Many patients note that they can breathe more easily after using the mechanical insufflation–exsufflation device. These devices are useful in patients with most neuromuscular conditions, including amyotrophic lateral sclerosis.[83,84] Children with neuromuscular disorders exhibit pressure-dependent short-term improvements in inspiratory and expiratory pressures and flows, associated with

FIGURE 32-19 (**A**) A mechanical insufflation-exsufflation device shown ready to use with a full-face mask (**B**) shown in use through a tracheostomy. (Image provided by Philips Respironics, Murrysville, PA.)

expired volume measured during the mechanical insufflation–exsufflation maneuver with good tolerance.[85] For optimal results, use of the mechanical insufflation–exsufflation device can be augmented with application of manual cough technique and proper positioning of the patient to promote drainage of airway secretions.

The mechanical insufflation–exsufflation device can also function as an alternative to intermittent positive-pressure breathing. By increasing lung volume during assisted cough, it can generate a higher peak cough flow than unassisted cough. It can improve other respiratory variables, including oxygen saturation and dyspnea, in neuromuscular diseases.[86]

Complications with mechanical insufflation–exsufflation devices are rare and include nausea, bradycardia, tachycardia, and abdominal distension. The most common reason for intolerance of the mechanical insufflation–exsufflation device is inadequate caregiver training regarding its application. As with any respiratory device used for life support, education of the patient and caregivers is important to ensure best results.

Bronchoscopy is useful only in selected cases of atelectasis caused by mucus plugging and should be tried after other methods of secretion removal have failed.

BULBAR DYSFUNCTION AND NUTRITIONAL SUPPORT

Patients with severe dysphagia require a gastrostomy for continued nutritional support. The gastrostomy is often placed in patients with an artificial airway under general anesthesia. Avoiding intubation and general anesthesia decreases the risk of respiratory complications and can prolong noninvasive ventilator management. Bach et al[87] reported placement of gastrostomies in sixty-two patients with neuromuscular disease while receiving NIPPV supplemented by mechanically assisted coughing. Normal gas exchange was able to be maintained and there were no complications.

As with any patient in a critical care setting, the patient with neuromuscular disease must be guarded against overfeeding. Because of progressive muscle wasting, caloric replacement based on ideal body weight (assuming intact muscle mass) can lead to rapid weight gain, reductions in lung volume and respiratory compliance, and an increase in work of breathing.

TIMING OF TRANSFER FROM INTENSIVE CARE UNIT TO THE COMMUNITY

Patients may be hospitalized for a number of acute consequences of respiratory muscle weakness, including pneumonia, atelectasis, hypoventilation, and sleep apnea. After the complication has resolved, the patient must be prepared for discharge into the community using a multidisciplinary approach incorporating potential caregivers in the planning. During this period, there should be clarification of the patient's advance directives, particularly with regard to interventions for long-term survival. If the patient is supported with NIPPV, attention must be given to maintenance of appropriate ventilator settings, the oral–nasal interface, seating, mobility, and nutrition (including gastrostomy or jejunostomy feeding).[3,60] Caregivers must be trained in techniques of manual and mechanical cough assistance. Only if such measures are unsuccessful in clearing secretions (as in severe bulbar involvement with amyotrophic lateral sclerosis or postpolio syndrome) should tracheostomies be resorted to. As yet, professional organizations do not provide guidelines for extubating patients with neuromuscular diseases and critical care neuropathy-myopathy. The use of assisted coughing can be used to transition from tracheostomy-assisted ventilation to noninvasive ventilation in suitable patients who meet certain criteria, the main ones including being oxygenation and absence of hypercapnia, being fully alert and cooperative, and a peak expiratory flow of at least 160 L/m.[3] Many patients have expressed a preference to NIPPV, even after many years of having lived with tracheostomies.

LONG-TERM SURVIVAL AND QUALITY OF LIFE

Home NIPPV improves survival in amyotrophic lateral sclerosis[61,88,89] and Duchenne muscular dystrophy,[90–92] as well as quality of life in most patients.[47,56,61] Yet clinical practice remains variable among physicians,[93–96] most likely because of a perception that mechanical ventilation may prolong suffering in progressive disease. In general, health care workers tend to underestimate quality-of-life scores of life satisfaction.[97]

Patients appreciate having meaningful discussions about assisted ventilation throughout the course of their illness, and they should begin before the onset of respiratory impairment. Care should be conducted in a multidisciplinary setting involving neurologists, pulmonologists, psychologists, social workers, physical and occupational therapists, speech pathologists, nutritionists, and respiratory therapists.[98–102] In some respects, working closely with the family and other caregivers is even more vital than working with the patient, but the workload associated with supporting home-ventilated patients can be considerable. Despite patients and caregivers receiving competency training before discharge, regular reeducation is required. Urgent calls to a dedicated respiratory support system may be reduced by a more flexible problem-solving approach. Reports in which no technical fault is found may indicate declining health and require clinical reevaluation.[102]

IMPORTANT UNKNOWNS AND THE FUTURE

Although it is agreed that NIPPV is the preferred means of managing ventilatory impairment and failure in neuromuscular disease, many patients have difficulty in tolerating mask ventilation. Inability or unwillingness to use the ventilator detracts from quality of life as well as survival. Glottic closure, patient–ventilator asynchrony leading to increased work of breathing in those patients with remaining respiratory muscle function, a sensation of suffocation, and facial pressure points and abrasions contribute to this lack of success. Increased use of spontaneous-timed ventilator mode ventilation and of oral or lip seals may circumvent some of these problems. Well-designed, randomized, controlled trials and cost-effectiveness studies would help to increase the acceptability of NIPPV at an earlier stage of respiratory impairment, enabling the patient to increase its use with disease progression. Ethical issues also present problems, for example, by not comparing hospitalization rates of an untreated group with the hospitalizations of patients who have avoided tracheostomy through the use of NIPPV, respiratory muscle aids, and cough-assist techniques. Such studies also would increase physician acceptance of the use of NIPPV as a routine means of improving quality of life and survival. A change in physician attitudes will lead to greater acceptance among patients who, unfortunately, still face indifferent and even negative attitudes concerning life support.

SUMMARY AND CONCLUSION

Noninvasive ventilation is now the accepted form of respiratory support for people with neuromuscular and chest wall disorders. Improvements in ventilator modes, interfaces, and adjunctive secretion-removal techniques have facilitated care and increased the quality of life in such individuals. An interdisciplinary approach aimed at not only the patient but also the family and other caregivers is essential for coping with the rigors of providing care under potentially stressful conditions. Close involvement by third-party payors and private community-based and governmental agencies is also crucial to ease the cost of home care.

CHRONIC VENTILATOR FACILITIES

Stefano Nava
Michele Vitacca

Chronic ventilator facilities (CVFs) are meant to be "protected" environments for the treatment of patients who require prolonged mechanical ventilation. Numerous words are included under the umbrella of CVFs: long-term acute care facilities, respiratory special care units, chronic ventilator-dependent units, regional weaning centers, ventilator-dependent rehabilitation hospitals, prolonged respiratory care units, noninvasive respiratory care units, high-dependency units, and respiratory intensive care units. And this is without even considering nursing homes and hospice care.

A 16-year study showed that the number of acute care hospital beds in the United States has decreased over time, but the number of critical care beds has increased progressively in both absolute and proportional terms. Indeed, the total number of non–critical care beds decreased by 31%, whereas critical care beds increased by 26%[1]; nevertheless, admissions to an intensive care unit (ICU) are very strongly influenced by bed shortages. Most beds in an ICU are occupied by patients requiring mechanical ventilation. A subset of patients receiving mechanical ventilation may have weaning difficulties, so that the duration of ventilation may be abnormally prolonged (commonly defined as greater than 15 days). Several reports indicate that these ICU patients are affected by complex cardiopulmonary disease or multisystem problems and have a relatively poor outcome.[2–6]

Of 6,469,674 hospitalizations in six American states, 180,326 (2.8%) received invasive mechanical ventilation. A total of 44.6% had at least one major comorbidity condition. The most common comorbidities were diabetes (13.2%) and pulmonary disease (13.2%), and only 30.8% of patients were discharged to home from the hospital, while the others ultimately required care in a skilled care facility.[7]

Increased life expectancy has dramatically increased the age of patients requiring critical care. Medical ICU admission is associated with a high long-term mortality even in healthy elderly patients, while most of the oldest survivors undergo prolonged mechanical ventilation, which is often a marker not only of respiratory system insufficiency, but also a multisystems insufficiency caused by many factors, including a chronic underlying disease, infections, malnutrition, complications, invasive procedures, and medications.[8,9]

Prolonged mechanical ventilation is not just a "medical" problem; it also has social and economic impact. Costs for mechanical ventilation in the United States are estimated to be $27 billion, representing 12% of all hospital costs. Incidence, mortality, and cumulative population costs rise significantly with age.[7] Each year in the United States, approximately 300,000 patients receive prolonged life support in an ICU, and this number is likely to double within a decade, with associated costs of more than $50 billion.[10]

These patients, once discharged from the ICU, have a readmission rate of 67% and spend an average of 74% of all days alive in a hospital or in an acute care facility, or receiving home health care. Indeed, patients who survive for 1 year are left with a serious burden of pervasive and persistent disability despite aggressive care that cost

306,135 $ for cohort members.[11] The burden of prolonged mechanical ventilation also affects the families because of financial implications, disruption of family routine, and uncertainly of the future, as well as community financial resources. Even after these "chronically ill" patients are discharged from the ICU, which occurs once the precipitating cause of their acute episode of respiratory failure has been reversed, they still require mechanical ventilation. Thus, they either require transfer to a long-term care or rehabilitation facility.[12]

RATIONALE

At the time of ICU discharge, patients who still need dedicated care or mechanical support are usually in a phase of clinical stability, but they have several "open" problems that prevent them being transferred to a regular ward or directly to home. Several reasons justify their transfer to a dedicated CVF.

First, weaning from prolonged mechanical ventilation is a complex, time-consuming process that involves not only the selection of the best ventilation method for a particular patient, but comprehensive procedures, such as protocol-driven weaning, have the potential for improving clinical outcome through increased use of efficacious weaning methods, such as daily weaning screening, spontaneous breathing trials, and management of the ventilator and sedation.[13] Rapid turnover in a busy ICU and its clinical burden does not always allow devoting the necessary time for these procedures, and discontinuation of mechanical ventilation is not always a priority.[14]

Second, given the nature of critical illnesses and the modalities used to manage them, prolonged bed rest, with well-known adverse physiologic effects, is the rule in the ICU. Rehabilitation has the potential to restore lost function. Yet, with few exceptions,[15] it traditionally does not start until after ICU discharge. Critically ill patients are often viewed as "too sick" to tolerate physical activity in the early phase of their illness, frequently prolonging immobilization.

Third, psychiatric symptoms are quite common in chronic patients who survive an ICU stay and in their relatives at the time of ICU discharge, as well as 90 days later.[16] Open visiting hours for family members and comfort among patients and caregivers may be enhanced by return to a more physiologic circadian rhythm as opposed to that found in a typical ICU. Delirium, probably the most common psychiatric problem in critically ill patients, may still occur after discharge from an ICU, albeit with a lower incidence. The environment and the strategy of care adopted in CVFs seems to positively affect the recovery from a delirious state.[17]

Fourth, sleep disruption is a well-documented problem during ICU stay and it persists at ICU discharge.[18] Sleep deprivation can have significant consequences and has been shown to impair cognitive function, increase protein catabolism, decrease immune function, and alter respiratory mechanics that could eventually impact weaning from mechanical ventilation. A more "natural setting," like a CVF, may minimize the number and intensity of some environmental factors, involved in the genesis of poor sleep, such as noise and light intensity.[19]

Fifth, aspiration is common in patients with tracheostomies receiving prolonged ventilation and with advanced age the risk of aspiration increases. Swallowing problems are seldom assessed with the appropriate technique (i.e., videofluoroscopy) in the ICU, and the most important specific rehabilitative therapy is rarely started. Figure 33-1 illustrates the incidence and types of swallowing dysfunction in a cohort of 188 patients admitted to a CVF after ICU discharge.

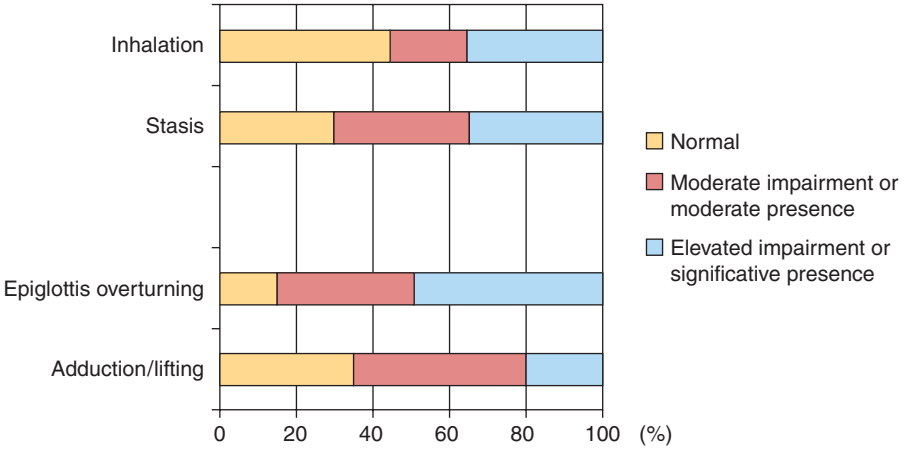

FIGURE 33-1 Incidence and types of swallowing dysfunction in a cohort of 188 patients admitted to a chronic ventilator facility after discharge from an ICU (Ceriana et al, unpublished data). Epiglottic overturning refers to the backward movement of the epiglottis during closure of the laryngeal vestibule. Adduction/lifting refers to the adduction of the vocal folds and movement of the larynx observed during inspection when the patient is requested to phonate and swallow.

Sixth, the number of tracheotomies has dramatically increased over the last few years, not only because of increasing numbers of difficult-to-wean patients, but also because of early timing of the procedure. The vast majority of these patients are discharged with a tracheal tube still in place, even when they no longer need ventilator support. A Spanish study shows that lack of tracheostomy decannulation in the ICU is associated with markedly increased ward mortality, at least in a large subset of these patients. The increased ward mortality may have resulted because the care of a tracheotomy is suboptimal outside a specialized environment.[20] Ceriana et al[21] highlighted the possibility of safely removing the tracheotomy cannula from almost 80% of patients breathing autonomously among a group of seventy-two patients recovering from weaning in a CVF, while decannulation was achieved in approximately 40% of patients transferred to a similar environment in the United States.[22]

Seventh, the interaction between ICU physicians and patients or their surrogates is far from optimal, especially when discussing the problem of prolonged ventilation including its outcome. A lack of prognostication, discordance between surrogates and physicians about potential outcomes, and unreasonably optimistic expectations of surrogates are potentially modifiable factors in surrogate–physician interactions. A less stressful environment than the ICU, combined with fewer sedative drugs and more comprehensive teamwork—nurses, respiratory therapists, psychologists, and clergy—typical of a CVF, may improve the patient–clinician relationship so that expectations and outcomes may be better defined and discussed.[23]

Overall, the disproportionate number of days of care required by chronically ventilated patients contributes to overcrowding despite the limited availability of ICU beds.[24] As Figure 33-2 shows the number of ICU beds, in several countries. The demand for ICU beds far exceeds their availability in many European and non-European countries, so that many patients are denied ICU admission because the ICU beds are already fully occupied.[25] Consequently, many critically ill patients are cared for in non-ICU beds throughout the hospital. The outcome of patients who fit ICU admission criteria but who are hospitalized in regular wards was assessed in a study performed in Israel.[26] Early survival advantage in an ICU suggests that a window of critical opportunity exists for these patients. Given economic constraints and the dearth of ICU beds, it is possible that increased turnover of patients in an ICU, thus providing an opportunity for more needy patients to avail of the early benefits of intensive management, may be advantageous. This study highlights both the risk of not admitting critically ill patients to the ICU and the advantages of early discharge from the ICU for the subset of patients not in immediate life-threatening situations, but yet not ready for discharge to a nonprotected environment.[26]

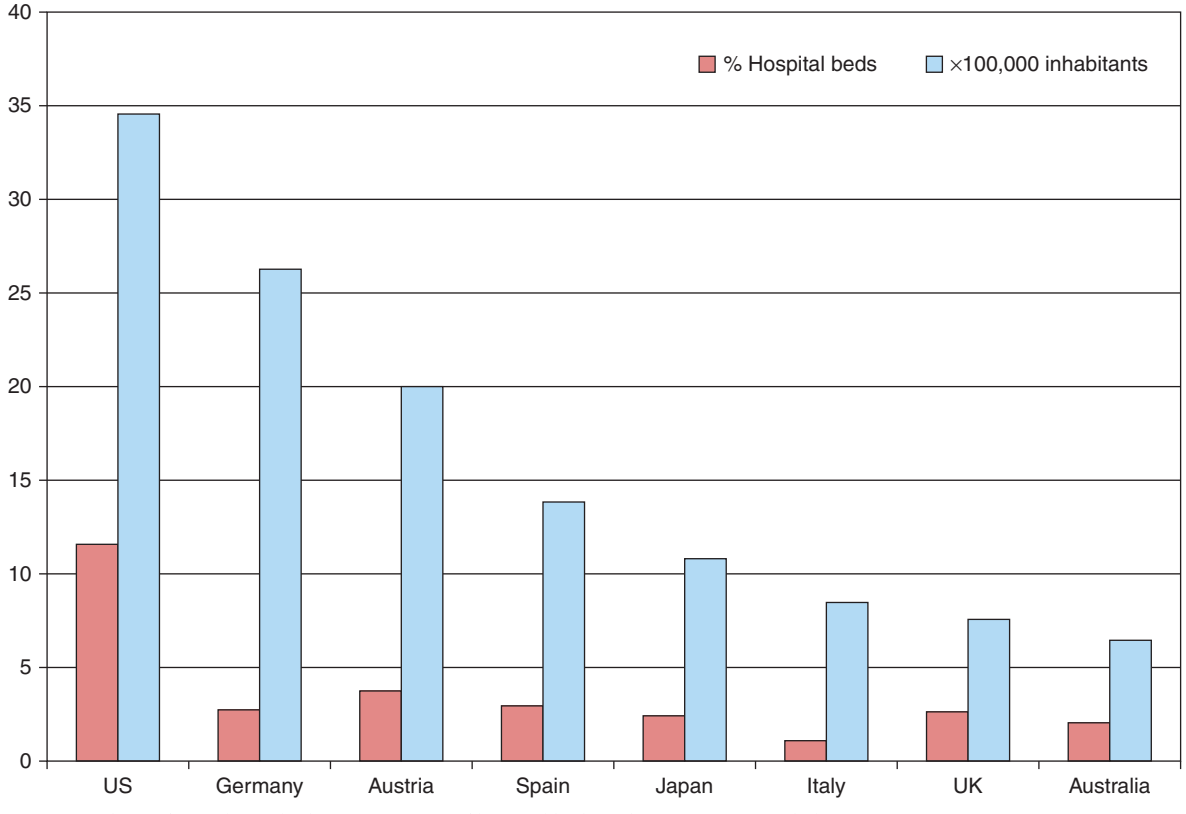

FIGURE 33-2 Numbers of actual ICU beds as percentage of hospital beds and as per 100,000 inhabitants.

The paucity of ICU beds is not as dramatic in the United States as in Europe, but discharge of chronic ventilator patients is still problematic. There has been an increase in the number of facilities specializing in the care of chronically ventilated patients. In Massachusetts, for example, the estimated prevalence of prolonged ventilation increased from 2.8 per 100,000 inhabitants in 1983 to 7.1 per 100,000 inhabitants in 2006, and most of these ventilator-dependent patients are in long-term acute care facilities, large urban teaching hospitals, and at home. The number of long-term acute care hospitals in the United States increased at a mean rate of approximately 9% per year, from 192 in 1997 to 408 in 2006, which resulted in an increased incidence of long-term acute care utilization after critical illness from 38.1 per 100,000 in 1997 to 99.7 per 100,000 in 2006.[27]

ORGANIZATION OF CHRONIC VENTILATOR FACILITIES

The term *CVF* is not necessarily synonymous with the so-called intermediate care unit or high-dependency unit, which are meant for patients who do not require full ICU care but are thought to need more care than usually can be offered in a general ward.[28–32] Not all patients in the latter units may be ventilator-dependent, but they may require either noninvasive monitoring or noninvasive mechanical ventilation. There is no agreement about the classification of facilities for patients needing prolonged mechanical ventilation because of geographic differences, lack of consensus regarding the appropriate timing of transfer from the ICU, and different criteria of admission. For example, the American College of Critical Care Medicine states in its guidelines for admission to and discharge from adult intermediate care units that "medically stable ventilator patients for weaning and chronic care" are the ideal candidates for these environments.[33] Unfortunately, these units were described only generically as "progressive-care units or single-organ subspecialty floors or chronic ventilator respiratory-care units." Details were not provided on how these units should be organized or financially reimbursed.

Timing of discharge from the ICU is also critical. Long-term ventilator patients are often old (i.e. >75 years) and have various underlying chronic comorbidities that may complicate or exacerbate their respiratory condition at any time after discharge from the ICU.[34,35] The 6-month rate of readmission to an acute care hospital is close to 40%, and readmission is often within the first 2 months after discharge from the ICU.[36] Surprisingly, this rate is not influenced by the initial discharge disposition; that is, it does not differ for patients discharged to a nursing home, a CVF, or their own home. These findings indirectly suggest that not all CVFs are presently prepared to cope with the burden of a new "acute exacerbation" in such patients. For example, Nasraway et al[37] found that despite a 31-fold increase in the number of all adults transferred from ICUs to extended care facilities in the Boston area between 1990 and 1996, the level of care of these facilities varied greatly depending mainly on the availability of skilled nurses.

There is still disagreement about the definition of a ventilator-dependent patient. The ninth revision of the *International Classification of Diseases*[38] defines long-term ventilation patients as those who have received 5 or more days of ventilation. Various authors, however, have used limits as short as 48 to 72 hours and as long as 40 days.[39–41] Realistically, approximately 20% of patients in an ICU require mechanical ventilation for more than 1 week, and about half of them are weaned successfully over the following few days.[42] Therefore, a limit of 2 weeks has been chosen by most authors to define the threshold for ventilator dependency. The Health Care Financing Administration[43] has expanded this limit to 21 days of mechanical ventilation for at least 6 hours a day. A definition based only on time, however, does not consider that for a particular patient to be regarded as ventilator-dependent (and therefore eligible for transfer to a chronic care facility), the precipitating cause of the respiratory failure must have been reversed.

CVFs have been described in the literature only in North America,[44] Europe,[45] and Asia.[46] Substantial differences exist in their organization, location, and criteria of admission. An editorial entitled, "The Challenge of Prolonged Mechanical Ventilation: A Shared Global Experience,"[47] stressed the need for common international consensus. Yet international guidelines and/or "position papers" are lacking.

Given the confusion of terminology, we submit that the most logical classification of CVFs is one based on the location of the different facilities, specifically whether the facility is inside or outside a so-called acute care hospital. Figure 33-3 illustrates the possible sites of care for patients who are chronically ventilator-dependent. It should be borne in mind that access to these different environments may differ internationally or even regionally within the same country.

Facilities within Acute Care Hospitals

Mechanical ventilation is initiated outside the hospital in a relatively small proportion of patients; ventilation is mostly started and stabilized in an ICU.[48] The timing of discharge of ventilator-dependent patients from the ICU is linked strictly to the criteria of admission of each single CVF, which are described in Chapter 34.

In the late 1980s, CVFs started to emerge in acute care hospitals as an attempt to provide an alternative therapeutic environment for ICU patients requiring prolonged mechanical ventilation. Krieger et al[49,50] probably were the first to establish a CVF within an acute care hospital (Central Respiratory Monitoring Unit at Mount Sinai Medical Center, Miami, FL). They were followed shortly after by Elpern et al[51,52] (Noninvasive Respiratory Care Unit of St. Luke's Medical Center, Chicago, IL). These units were devoted mainly to patients requiring prolonged mechanical ventilation. In 1990,

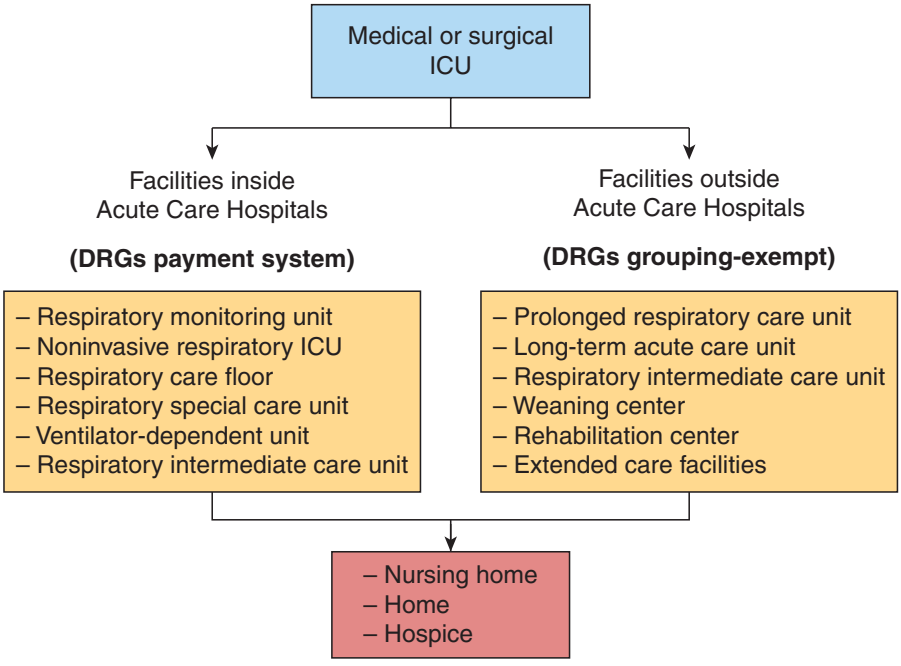

FIGURE 33-3 Potential sites of care for ventilator-dependent patients when discharged from an intensive care unit (ICU). *DRG*, diagnostic-related grouping.

the Mayo Clinic opened a ventilator-dependent unit inside Saint Mary's Hospital.[53–56] Its mission was to create an environment conducive to the rehabilitation of patients with respiratory failure and also to lower the costs of ventilator-dependent patients.[57] Shortly thereafter, new CVFs were opened. These went under different names at Saint Vincent's Hospital and Medical Center in New York, (NY)[58] (Nonmonitored Respiratory Care Floor) and at Cleveland Clinic Foundation in Cleveland, Ohio[59] (Respiratory Special Care Unit). As discussed later (see "Outcomes and Effectiveness" below), the overall rate of weaning success was high (>50%), with a mortality rate below 40%.

In Europe, the first report on this subject was published in 1995 by Smith and Shneerson[60] from England. Rather than opening a special unit for patients requiring prolonged ventilation, they described the institution of a progressive-care multidisciplinary program carried out within the ICU by a dedicated team of respiratory physicians and nurses. As soon as patients were judged ready for discharge from the ICU, they were transferred to a respiratory unit, where they continued the multidisciplinary program. The program was very successful with regard to discharge to home (80% of the patients) and 1-year survival (76%). A survey[45] of the European Respiratory Society on respiratory intermediate care units (RICUs) showed that during 1999, most (58%) of the 11,890 patients admitted to fifty-five RICUs received invasive mechanical ventilation. These units almost always (>90%) were inside an acute care hospital. Unfortunately, no data were available on how many of these patients actually were ventilator-dependent. Nevertheless, an Italian survey published in 2001[61] reported that 61% of patients receiving invasive mechanical ventilation in Italian RICUs were tracheotomized and therefore considered ventilator-dependent. The percentage is similar to that reported in Britain and Germany, where most patients survived to leave hospital, most having been weaned from the ventilator. Survivors were younger and spent less time ventilated in the referring ICU.[62,63]

Irrespective of location on either side of the Atlantic, the organization and staffing of CVFs inside acute care hospitals appear to be homogeneous and more similar to that of an ICU than to that of a CVF located outside an acute care hospital.[64,65] Most of these CVFs provide noninvasive monitoring, the nurse-to-patient ratio is usually 1:2 to 1:4,[45,51,53,58,59] and a lead respiratory therapist is assigned permanently and is present in the unit. General medical care is provided around the clock by medical house staff under the direction of an attending physician in either critical care or pulmonology. The nursing staff usually is specially trained through orientation and in-service programs to address the needs of this particular patient population. The approach to the patients is multidisciplinary, involving dieticians, psychologists, physical therapists, speech therapists, social workers, and clergy as needed. Because these CVFs are located within an acute care hospital, all the diagnostic (e.g., computed tomographic scans, nuclear magnetic resonance imaging) and therapeutic (e.g., major surgery) options are readily available. In Europe, the nurse-to-patient ratio varies slightly according to the three levels of care of RICUs.[29,45] Because of the different education and responsibilities of the respiratory therapists (rarely present around the clock), an attending physician is always present in the units.[66,67]

Facilities outside Acute Care Hospitals

This classification consists of several CVFs going under names such as regional weaning centers, prolonged respiratory care units, long-term acute care units, and RICUs inside rehabilitation hospitals. The need for these special facilities outside the acute care health system was recognized a long time ago in North America, but only recently in Europe. For example, the Comprehensive Critical Care of the British Department of Health[68] stated that "the effectiveness of specialist weaning and progressive care programs for long-term ventilation of patients has been demonstrated by research, and NHS Trusts should review the need for provision of such services."

The first experience of a CVF dedicated to the problem of ventilator-dependent patients was reported by Indihar,[69–71] who described 10 years of activity, starting in 1979, of a unit located in Bethesda Lutheran Medical Center. In the late 1980s there was substantial growth of regional weaning centers in the United States. Examples include the Barlow Respiratory Hospital in Los Angeles,[72,73] the Medical Center of Central Massachusetts,[74] and the Hospital for Special Care, New Britain, Connecticut.[75,76] Later, there was an impressive burgeoning of new long-term acute care units. By 1997, these had a capacity of about 15,000 patients per year.[77] These units were established either as free-standing hospitals, as in the case of most regional weaning center, or within an acute care hospital but operating with total independence. As such, their governance is independent of the host hospital, and reimbursement is not based on a diagnosis-related grouping (DRG) system.

CVFs within a rehabilitation hospital are also popular in the United States and Europe, especially in Germany and Italy, where approximately 15% of RICUs are located inside rehabilitation centers.[45,62,78,79]

Unlike CVFs located within acute care hospitals, CVFs located outside appear to have a rather heterogeneous organization and staffing. This heterogeneity occurs despite these facilities espousing a program based on the common ideal of providing comprehensive medical, nursing, and respiratory care to ventilator-dependent patients. For example, New England[37] has several "extended care facilities" outside acute hospitals; the skills and level of care vary dramatically among different centers. Despite the personnel being fully licensed health care practitioners, they may not all be completely familiar with the complexities of ventilator-dependent patients. Patient outcome is likely to depend on the different levels of care provided.

In most North American centers, the nurse-to-patient ratio is approximately 1:4 during the day and 1:8 at night and on weekends. A full-time respiratory therapist[72,80] usually is present. The primary physicians are either internists or specialists in pulmonary and/or critical care medicine, whereas nighttime coverage commonly is provided by junior doctors. The comprehensive care team includes physical therapists, occupational therapists, speech and swallowing therapists, and clinical psychologists. Screening for admission is performed either by an attending physician or by a nurse in consultation with an attending physician.[80] Weaning protocols and selection of ventilator settings during this process are implemented by respiratory therapists.[81] Discharges are planned by nurses or social-work care managers. With the exception of a few facilities, which may have operating rooms for minor surgery, most CVFs located outside acute care hospitals cannot offer surgery or sophisticated diagnostic procedures.

In Europe, CVFs outside acute care hospitals are run mainly by full-time attending physicians who are specialists in respiratory and/or critical care medicine.[29,45,61] These physicians are in charge of the admission and discharge of patients and the weaning protocols. They are on duty 24 hours a day. The doctor-to-patient ratio is at least 1:8. The nurse-to-patient ratio is usually similar to that of North American centers. Because of their different educational training, respiratory therapists in Europe tend to be involved mainly in rehabilitation programs, for approximately 8 hours a day (excluding Sundays and holidays), rather than in the weaning process.[21] In common with North American facilities, most European CVFs do not offer major surgery.

Irrespective of their geographic location, CVFs located outside acute care hospitals are intended to provide privacy, rest, and longer visiting hours for relatives and friends. Above all, they provide physical and pulmonary rehabilitation, which has been shown to help in freeing patients from mechanical ventilation and restoring them to an acceptable level of autonomy.[82]

Nursing Homes

A small percentage of ventilator-dependent patients are discharged from an ICU[36] directly to a nursing home. Nursing homes, however, are more likely to receive such patients once they have left a CVF. In 1991, a survey by the American Association for Respiratory Therapists[83] found that nearly 30% of ventilator-dependent patients remained in CVFs for nonmedical reasons, such as reimbursement obstacles to discharge or lack of postdischarge placement options. Indeed, approximately 20% of patients cared for in a ventilator-dependent unit are transferred to a nursing home simply because they are not ready to go home.[36]

Nursing homes have been established all over the United States,[84] either as independent units inside larger facilities or as stand-alone facilities. To the best of our knowledge, in Europe specialized units for the care of ventilator-dependent patients are very few.[85] Apparently, there is no standardization of admission criteria, staffing, or organization of these units apart from the person needing "24-hour nursing care for a cognitive or a physical impairment."[86] Nurses working in this specialized area should be trained by respiratory therapists to perform specific procedures such as suctioning, tracheotomy care, and monitoring of ventilator parameters. In some cases, for example, Lakeside Hospital in Wisconsin, Eau Claire[87] weekly care rounds led by a pulmonary physician with the participation of the care

team, including not only the certified nurses but also respiratory therapists, dieticians, social workers, and, when possible, family members, have been introduced. In the very few observational studies performed in this kind of facility, weaning outcomes are very promising.[87] Further studies are needed to define the characteristics of ventilator-dependent patients who are most likely to benefit from admission to this environment.

CRITERIA FOR ADMISSION

Table 33-1 lists criteria for defining the "ideal" candidate for a CVF. The concept of ventilator dependency is the primary criterion for selecting admissions to a CVF. Accordingly, most centers accept only tracheotomized patients because tracheotomy per se is assumed as evidence of ventilator dependency. Significant differences on the best location of care at the time of ICU discharge between patients with and without tracheostomy has been demonstrated.[88] Indeed, the dramatic increase in tracheotomies performed over the last 10 years[89] suggests that ICU physicians tend to perform an early tracheotomy before trying to complete weaning. This change may reflect attempts to decongest busy ICUs more rapidly by allowing transfer of ventilator-dependent patients to extended care facilities. To avoid this problem, some units request proof that a patient has failed at least two weaning trials before being admitted.[55] Other centers, however, accept patients based mainly on the availability of resources (bed and nursing staff) rather than on the basis of perceived ability to wean.[62]

Another criteria used for selecting patients for admission to CVFs are the clinical stability and the potential to benefit from a rehabilitation program.[53,59] The clinical stability is defined as reversal of the precipitating cause of respiratory failure, hemodynamic stability (not needing invasive measurements of blood pressure or pulmonary artery pressure, not requiring vasoactive drug infusion before transfer) and absence an arrhythmia requiring telemetry. Patients with multiorgan failure often are not admitted. Patients receiving hemodialytic support are usually accepted, particularly if the unit is inside an acute care hospital. When transferring a patient from the ICU, because errors in discharge reports are frequent, it is necessary to double check to avoid errors. It has been shown, for example, that of 123 transfer reports, seventy-six (62%) were affected by at least one error, with 28% of the errors being potentially harmful to the patients.[90]

The idea of the ability to benefit from rehabilitation or other comprehensive program is subjective and depends strongly on the judgment of the proposing or accepting physician. In some facilities, the proposing physician must make a written statement where the physician states that the patient is either capable of being weaned from the ventilator or is likely to return to the community despite receiving ventilator assistance.[54] Other facilities specifically ask that a patient be returned to the referring hospital once the patient has been weaned successfully or when it becomes obvious that weaning will not be possible. To ensure that all parties understand this policy, a letter of confirmation may be required from the referring physician, countersigned by the patient or the patient's surrogate.[91] A more liberal attitude is shown by other facilities, for example, the Worcester County Ventilator Unit, Worcester, Mass[74] where "specifically no admission decision is based on prognosis, weaning or rehabilitation potential." Also, at the Long-Term Acute Care Unit of the University of Chicago,[80] "patients are accepted regardless of the severity of their illness, provided they are stable for transfer." The latter institution theoretically accepts patients requiring positive end-expiratory pressure of more than 10 cm H_2O or a fractional inspired oxygen concentration (FI_{O_2}) of greater than 60%. Finally, methods have been proposed for identifying patients suitable for admission to CVFs based on severity-of-illness scores or activity of treatments.[92–95]

With few local differences, the classification of ventilator-dependent patients admitted to CVFs follows that illustrated[96] in Table 33-2.

TABLE 33-1: CRITERIA FOR DEFINING THE IDEAL CANDIDATE TO A CHRONIC VENTILATOR FACILITY

Patients ventilated for more than 14 days, necessitating prolonged weaning
Presence of a tracheostomy
Potential weaning possibility
Defined diagnosis
Single-organ failure
Hemodynamically stable (no pressor infusion)
No sepsis or active infections
Absence of surgical problems
No need of continuous sedation
Absence of chronic renal failure necessitating hemodialysis
$Pa_{O_2}/FI_{O_2} > 200$ and need for external PEEP <10 cm H_2O
Need for aggressive rehabilitation program
Potential to benefit from a rehabilitation program

Abbreviations: FI_{O_2}, fractional inspired oxygen concentration; Pa_{O_2}, partial pressure of arterial oxygen; *PEEP*, positive end-expiratory pressure.

OUTCOMES AND EFFECTIVENESS

Comparisons with Intensive Care Units

Commenting on the rationale for opening an intermediate care unit, Vincent and Buchardi[97] stated they "would recommend that instead of fragmenting ICU facilities by separating 'intensive' from 'intermediate,' with the potential risk of reduced staff morale and less adequate patient care, intensive and intermediate care beds should be combined in one unit." As stated earlier, intermediate care units are not necessarily equivalent to CVFs. Despite the lack of strong scientific evidence, specific facilities for ventilator-dependent patients

TABLE 33-2: CLASSIFICATION OF PATIENTS ADMITTED TO A CHRONIC VENTILATOR FACILITY

- Acute lung injury
  - Acute respiratory distress syndrome
  - Pneumonia
  - Aspiration injury
  - Burns
- Chronic lung disease

  - Kyphoscoliosis
  - Critically ill polyneuropathy
  - Guillain-Barré syndrome
- Cardiovascular disorders
  - Chronic congestive heart failure
  - Ischemic cardiomyopathy

do have some clinical and financial advantages over ICU care (they are not, however, "in competition").[31,98–101] Table 33-3 lists the main differences between ICUs and CVFs located inside or outside acute care hospitals.

A retrospective review[101] of 429 ICU patients tracheotomized for respiratory failure and needing prolonged mechanical ventilation showed that only 57% of survivors had been free from mechanical ventilation by the time of discharge from the ICU. Patients who were finally weaned and had their tracheostomy tubes removed had better survival than patients who did not. Improved survival, however, came at higher hospital cost and a longer ICU stay. This study illustrated the need to compare the clinical outcomes and financial burdens of these "difficulties to wean" patients when treated exclusively in a traditional ICU or transferred during hospitalization to a CVF. The study also demonstrated that the emotional status of these patients at ICU discharge was generally good, whereas physical function was quite limited.[101]

The only randomized, controlled study directly comparing the outcomes of chronically ill patients, most of them ventilator-dependent, managed entirely in the ICU or transferred when clinically stable to a special care unit (SCU), managed mainly by specialized nurses, was performed by Rudy et al.[102] The SCU had a case-management approach for clinical problems, a full rehabilitation program, weaning protocols, and control of resource use. A total of 220 patients were assigned randomly to either the SCU or the ICU. Overall mortality rates were similar in the two groups, but the rate of readmission was lower and hospital stay shorter in the SCU group. The average cost of delivering care was $5000 less per patient in the SCU than in the ICU, and the cost to produce a survivor was $19,000 less. It makes sense that specialized care may achieve better outcomes. It is difficult, however, to draw up standardized recommendations based on a relatively small single-center study where the two groups were not fully comparable in either number or baseline conditions.

Using a retrospective chart review and questionnaires, Seneff et al[103] analyzed 6-month mortality and hospital costs in fifty-four acute care referral hospitals and twenty-six long-term acute care institutions. Hospital costs included the amount of uncompensated care incurred by the ICU under the Medicare prospective payment DRG system. The authors compared 432 patients ventilated for an average of 3 weeks who were referred but not transferred to

CVFs (Vencor) with 1702 patients who were referred and transferred to CVFs. Six-month mortality was not adversely affected by transfer to a CVF. Because patients had long hospital stays and consumed much resources, overall cost of care was very high. Acute care hospitals, however, theoretically can reduce the amount of uncompensated care for these patients by timely referral to an appropriate CVF. Only approximately 10% of the two groups were discharged directly home; most patients were transferred to a nursing home or another CVF.

The latter study[103] leaves three major unsolved issues. First, the "appropriate" timing of transfer has not been clearly defined because some CVFs accept sicker patients with "overt" nonpulmonary dysfunction, whereas others only accept patients with the "single-organ failure." Second, although the authors showed that transfer to a CVF is associated with a reduction of ICU uncompensated costs of care, the issue of best reimbursement system for the CVF was not assessed. Third, even after patients were transferred to a CVF, the rate of discharge home was disappointingly low; there is an urgent need to identify the best location of care for these patients once they are discharged from a CVF.

One of the most important rationales for using a CVF is the expected reduction in ICU stay. Otherwise, the marginal variable cost of the ICU is relatively small compared with the average total cost.[104] For this reason, interventions that reduce ICU length of stay and duration of mechanical ventilation may not result in significant actual cost savings.[104]

Observational Studies

The patient populations admitted to CVF, as reported by recent observational studies from the United States and Europe, span a wide range of ages and admission diagnoses, and generally have significant comorbidities. Table 33-4 summarizes outcome indices for patients admitted to an acute care setting for weaning. Although comparisons between studies is difficult, the rate of weaning success ranges from 25% to greater than 90%. Variability of hospital mortality is equally great, ranging from 10% to 50%.

A U.S. study showed that, over time, patients transferred to CVFs had a higher number of comorbidities (5 in 1997 to 2000 vs. 5.8 in 2004 to 2006) and were more likely to receive mechanical ventilation at the long-term acute care hospital (16.4% in 1997 to 2000 vs. 29.8% in 2004 to 2006). One-year mortality after long-term acute care hospital admission was high throughout the study period: 50.7% in 1997 to 2000 and 52.2% in 2004 to 2006.[27] Similar data were recently reported in Europe: Over a period of 15 years, there were increases in the number of comorbidities per patient (from 1.8 to 3) and the duration of previous ICU stay (from 25 to 32 days). Given, the greater severity of disease among patients, the overall weaning success rate decreased from 87% to 66%, and the discharge destination changed over time: Fewer patients were discharged to home (decrease from 22% to 10%) and more were discharged to chronic care facilities (increase from 3% to 6%), acute hospitals (increase from 6% to 10%) and rehabilitative units (increase from 70% to 75%). The mortality rate also increased over time (from 9% to 15%).

A total of 1419 patients were enrolled in the United States for the Ventilation Outcomes Study. Patients were old (i.e. >75 years) and averaged 6.9 procedures and treatments during hospitalization with a median length of stay of 40 days (range: 1 to 365 days). The patients had very poor functional status at admission; nearly all were totally bedridden as a result of prolonged critical illness. The prevalence of penetrating or indwelling catheters, each breaching host defenses against infection, was striking. Discharge disposition included 28.8% to home, 49.2% to rehabilitation and extended care facilities, and 19.5% to short-stay acute care hospitals.[106]

Bigatello et al[14] noted that many patients are able to be separated from the ventilator at the time of admission to a CVF, which implies that discontinuation of mechanical ventilation was not a top priority in the referring ICU. Their data show that a number of patients may wean rapidly once ventilator management becomes the focus of care in a specialized CVF, confirming a similar observation by Vitacca et al[107] in patients with chronic obstructive pulmonary disease (COPD) and a tracheostomy.

Table 33-5 summarizes the outcome indices for patients admitted to nonacute settings for weaning. There is overall agreement that a rehabilitation-based weaning unit can assist with weaning and maximal functional independence and prepare the family for the discharge of the ventilated patient to home.[74]

Clinical outcome of patients requiring prolonged ventilation depends on the underlying disease. Weaning success is highest in postoperative patients (58%) and patients with acute lung injury (57%), and lowest in patients with COPD or neuromuscular disease (22%).[74] Chronically ventilated patients with respiratory failure caused by COPD have a worse prognosis than patients with respiratory failure from other causes.[75] This observation is consistent with the findings of Schonhöfer et al[62] that long-term survival rate was worse in patients with severe COPD than in other patients. In a homogeneous group of forty-two patients with COPD, Nava et al[78] observed a successful weaning rate of 55% when a rehabilitation program was continued for a long period outside the ICU.

Physical function is limited and reduced in most patients[60,116,117] but it is sometimes good or improved after discharge.[60,80,111,117] Quality of life is defined as good, quite good, reasonable, or normal, although severe impairment is reported in a minority of studies;[60,80,111,117] often it is improved 1 year after discharge.[118] Ambrosino et al[117] conducted a prospective, controlled cohort study in a respiratory intermediate ICU in sixty-three patients with COPD requiring mechanical ventilation. Perceived health status and cognitive function were worse in patients recovering from acute-on-chronic respiratory failure (requiring mechanical ventilation) than in stable patients receiving long-term

oxygen therapy who never required ICU admission. After discharge, cognition and mobility improved to levels found in stable COPD patients on oxygen therapy.

PROBLEMS UNIQUE TO CHRONIC FACILITIES

Finances

Comparison between studies of different centers and different periods may be inappropriate because weaning success seems strongly related to patient complexity and comorbidities, hospital organization and personnel expertise, availability of early physiotherapy, use of weaning management techniques, patient autonomy, and family preparation for home discharge with a ventilator. Published data based on small samples, different clinical histories, costs based on patients in a single hospital, different reimbursements, variations in care habits among different countries, and differences in interventions, equipment, and staff involvement reduce the generalizability of cost assessment. In all studies, lower costs principally arise from a lower staffing ratio; other reductions are related to decreased room charges, lower overheads, simpler (usually noninvasive) monitoring, and changes in the pattern of diagnostics and therapeutics.

Costs are likely to change across years, particularly for admissions and related provisions because reimbursement based on DRG does not necessarily reflect real costs of individual treatment. In this respect, CVFs have a peculiar system of reimbursement that deserves special attention.[119] As shown in Table 33-6, most observational studies estimate that the daily cost of care for ventilator-dependent patients is lower in a CVF than in an ICU. Indeed, the difference in health care systems between the United States and most other industrialized countries (i.e., near universal health insurance coverage)[122] makes any comparison between different countries futile.

Proposed modalities of reimbursements in the United States include: (a) single payment for all patients within a DRG with specific weight severity; (b) payment according to variability of units dedicated to prolonged mechanical ventilation; (c) reduced payment for short length of stay; (d) ability to balance with very long stay costs; and (e) bonuses for unweanable patients.

Familiarity with correct reimbursement codes for documentation of time spent caring for patients and appropriate documentation has been advocated for physicians involved in CVFs[123] because of the complexity of the encounter with subsequent different payments. To address the problem of underreimbursement, some CVFs are now licensed as DRG-grouping-exempt,[56] and are required by the Health Care Financial Administration to maintain a mean length of stay more than 25 days and usually fewer than 90 days. In the United States, long-term acute care facilities are reimbursed under regulations of the Tax Equity and Fiscal Responsibility Act (TEFRA)[124] for care provided to Medicare patients. Charges are reimbursed up to the annual maximum cap for the facility, calculated during a 12-month period designated as the base year. Hospitals incur penalties when charges for Medicare exceed the discharge target amount and receive incentives if charges are reduced in the subsequent years. This policy, unfortunately, has led, as it did for rehabilitation hospitals, to substantial extra costs, including increases in payments to hospitals and doctors and numbers of hospital days for the average patient.[124] In most European countries, the health care system is funded primarily by government. Therefore, the vast majority of public hospitals and some private hospitals receive most of their funds through a national health service. Most beds are devoted to the treatment of acutely ill patients, independent of the baseline disease (i.e., medical or surgical), and are reimbursed through

TABLE 33-6: COSTS PER DAY FOR A VENTILATOR-DEPENDENT PATIENT ADMITTED TO AN INTENSIVE CARE UNIT OR TO A CHRONIC VENTILATOR FACILITY

Authors (Ref)	Year of Publication	Year of Analysis	Type of Unit	Daily Costs
Sheinhorn[72]	1994	?	WC (outside acute care H)	$980
Latriano[58]	1996	?	Nonmonitored care floor (inside acute care H)	$453
Bagley[74]	1997	1995	WC (outside acute care H)	$630
Nava[120]	1997	1995	RICU (outside acute care H)	$865
Gracey[56]	2000	1998	CVDU (inside acute care H)	$1084
Engoren[116]	2000	?	Cardiac stepdown unit (inside acute care H)	$439
Seneff[103]	2000	?	ICU	$4174
Linsday[87]	2004	?	Nursing home	$303
Halpern[1]	2004	2000	Daily cost per patient admitted to a critical care bed	$2647
Pilcher[62]	2005	1997 to 2000	Cost per day	€1350
O'Connor[21]	2009	2002 to 2003	Cost per day	$1054
Carpene[121]	2010	2008 to 2009	Mean cost saving per patient	€39.8452
Kahn[27]	2010	1997 to 2006	Mean cost per patient	$21.766

Note: Reference 1 is the actual daily cost of a critical care bed in year 2000 in the United States.

Abbreviations: CVDU, chronic ventilator-dependent unit; *H*, hospital; *RICU*, respiratory intensive-care unit; *WC*, weaning center.

a DRG-based system. A minor share is devoted to the care of chronically ill patients. The latter beds are located inside rehabilitation wards of acute care hospitals or within independently structured rehabilitation hospitals. For acute care, the DRG-based reimbursement *per case* is applied. For chronic care, reimbursement is on a *per diem* basis, allowing for some increase according to DRG classification. This *per diem* fee applies for only a limited number of days (40 to 60), after which the fee is curtailed drastically.

Mean duration of stay in CVFs differs considerably between patients with an impressively high standard deviation. Nasraway et al[37] reported the duration of hospital stay to range from 1 to 2125 days. Because the time spent in CVFs differs so greatly, it is clear that exemption from the DRG-based payment system is granted to avoid massive losses. The *per diem* reimbursement up to relatively small ceiling of days, however, may not achieve reasonable reimbursement.

Staffing

CVFs, especially those outside acute care hospitals, are still characterized by heterogeneous staffing. Most of the centers share common views about the equipment to be used (i.e., ventilators and monitoring systems) and the overall multidisciplinary organization, aimed at improving the autonomy of patients, privacy, and environment. There is, however, considerable discrepancy concerning the training of personnel, especially of nurses. The availability of skilled nurses in extended care facilities in the Boston area, as determined by an informal survey.[37] Marked differences exist in the care that each center provides to long-term ventilated patients. The authors[37] state that "some facilities may accept ventilator-dependent patients but may not be able to provide for all their needs, especially when serious infections or other setbacks ensue." Nurses working in a CVF should be specifically trained not only in acute lifesaving procedures, such as resuscitation, but also in specific "chronic" procedures, such as bronchial toilet, prevention of sores at the tracheotomy site, and positioning of the tracheal cannula.

Vitacca et al[125] studied the allocation of nursing time in a respiratory unit belonging to a rehabilitation center. In the first 2 days after admission, time devoted to care of a ventilator-dependent patient consumed approximately 45% of a nursing shift.

Respiratory therapists should be skilled in weaning protocols that shorten the duration of mechanical ventilation. The hospital team should be trained in clinical tests (i.e., bronchoscopy, fluoroscopy, assessment of respiratory muscle function) that may help the clinicians decide whether or not a patient can have the tracheotomy removed.[21] Special attention should be paid to the diagnosis of ICU-acquired neuromuscular abnormalities, which increase the time to weaning. Diagnosis may require electrophysiologic studies and needle electromyography of the limb and respiratory muscles.[126,127]

The global economic crisis in recent years may induce administrators to reduce the number of hospital employees, especially outside critical care settings. In the past, however, a reduction of hospital staff caused a worsening in clinical performance. For example, studies show a lower mortality and length of stay with high-intensity physician staffing.[128] Dara and Afessa observed a longer stay during the periods with less intensivists in a medical ICU.[129] Differences in the intensivist-to-ICU-bed ratio, ranging from 1:7.5 to 1:15, were not associated with differences in ICU or hospital mortality, although a ratio of 1:15 was associated with an increased ICU length of stay.[129] An Italian multicenter study revealed a progressive decrease in the doctor-to-patient ratio secondary to a reduction of medical personnel consequent to the recent restriction in the reimbursement policy of the National Health Care System.[115] The negative influence of reduced medical staff availability on weaning success rate, home discharge, and length of stay has been previously demonstrated,[115] providing empirical evidence for a link between organization and outcome in dedicated weaning facilities.

CONCLUSION

Over the past 15 years, the availability of ICU beds, new technology, and improved levels of care have produced a new population of patients termed *survivors of catastrophic illness.* These patients commonly require prolonged weaning.

The rate of achieving complete ventilator independence in specific and dedicated weaning units is generally high. It has been demonstrated that these units are cost-saving alternatives to an ICU for carefully selected patients. Survivors have an acceptable long-term quality of life. Weaning success, however, does not in itself solve other severe problems, such as the heavy financial and human burdens that the high level of dependency imposes on families, caregivers, and health service organizations once these patients are discharged from a protected environment.

Long-term acute care hospitals play an increasingly important role in patients with chronic critical illness. Yet few data exist to guide decision making about transfer or to inform policy decisions about whether to support or restrict this rapidly growing cost center.[27] The different international medical systems need to adopt new organizational innovations and highlight the need for a diverse program of comparative effectiveness research to determine the optimal organization of care for patients recovering from critical illness, including the best way to maximize survival and control costs for this high-risk patient group.[27] For these reasons, rigorous studies on structural factors relating to the outcome of patients with mechanical ventilation are mandatory. With increased efforts to reduce health care costs, patients will be shifted away from ICUs toward other clinical settings, such as dedicated weaning facilities, to care for more, and increasingly complex, patients.[130] It is imperative that we critically evaluate these changes as they occur. More research is needed on the impact of weaning facilities on costs and outcomes. In particular, the following questions should be assessed: (a) whether weaning facilities best operate as units within hospitals or as

stand-alone hospitals; (b) the optimum nurse, physician, and ancillary staffing of weaning facilities; and (c) the spillover effects of weaning facilities on critical care.[130]

In conclusion, the main benefits of chronic ventilator facilities are (a) the possibility of relieving congestion of ICU beds, (b) maintaining a high level of nursing assistance, (c) responding to sudden changes in a patient's clinical condition, (d) allowing enough time for a multidisciplinary rehabilitation approach, and (e) acting as a bridge to home-care programs or other forms of continuous chronic assistance (e.g., telemedicine or dedicated long-term units).

NONINVASIVE VENTILATION ON A GENERAL WARD

Mark W. Elliott

In any discussion about location of a noninvasive ventilation (NIV) service, it is important to note that the model of hospital care differs between countries and that there may be significant differences even between hospitals within the same country. There will be variations in staffing levels; the skills of doctors, nurses, and paramedical staff; and the sophistication of monitoring. The terms *intensive care unit* (ICU), *high-dependency unit* (HDU), and *general ward* have a different meaning to different people. Care therefore must be taken when extrapolating experience and results obtained in one environment to other hospitals and countries.

The United Kingdom's King's Fund panel[1] defines intensive care as "a service for patients with potentially recoverable diseases who can benefit from more detailed observation and treatment than is generally available in the standard wards and departments." The definition of HDU is less clear, with some HDUs allowing invasive monitoring, whereas in others only noninvasive monitoring is performed. In some countries, specific respiratory ICUs and intermediate ICUs have been developed.[2,3] Specifically, within the King's Fund definition is the consideration of intensive care as a service rather than a place; critical care is provided within a continuum of primary, secondary, and tertiary care, and patients are categorized on the basis of their needs[4] (Table 34-1). Movement through the different levels usually means transfer from one location to another. Critical care outreach teams can advise on care as patients cross organizational boundaries and also facilitate transfer when this is needed.[5,6] Although most acute NIV services are situated in a specific clinical area, a peripatetic model has been described and has some advantages.[7,8]

For the purposes of this chapter, the following definitions are used:

- *Intensive care.* High ratio of staff to patients, facility for invasive ventilation and sophisticated monitoring.
- *Intermediate respiratory ICU or HDU.* Continuous monitoring of vital signs, with a staffing ratio intermediate between an ICU and a general ward, in a specified clinical area. Intubated patients (unless with tracheostomy) usually are not cared for in this environment.
- *General ward.* Takes unselected emergency admission, and although most wards will have a particular speciality interest, it is likely that because of the unpredictability of demand, patients with a variety of conditions and degrees of severity will be cared for in the same clinical area. Nurse staffing levels vary, but the intensity of nursing input available in HDUs and ICUs is not possible. Only basic monitoring is available.

Another important issue when considering NIV in different locations is the severity and acuteness of the insult leading to ventilatory failure. Ventilatory failure can be considered *acute* when it occurs on a background of normal function, *acute-on-chronic* when there is a sudden deterioration on a background of impaired function, or *chronic* when there is ventilatory failure but with no precipitating acute event. Assisted ventilation can be considered *necessary* when

TABLE 34-1: CLASSIFICATION OF INDIVIDUAL PATIENT DEPENDENCY

Level 0: Patients whose needs can be met through normal ward care in an acute hospital

Level 1: Patients at risk of their condition deteriorating or patients recently relocated from higher levels of care whose needs can be met in an acute ward with additional advice and support from the critical care team

Level 2: Patients requiring more detailed observation or intervention, including support for a single failing organ system or postoperative care, and those stepping down from higher levels of care

Level 3: Patients requiring advanced respiratory support alone or basic respiratory support, together with the support of at least two organ systems. This level includes all complex patients requiring support for multiorgan failure

without it death will ensue over a few hours or *desirable* when the primary aim is to improve quality of life and also to improve survival over the longer term.

EVIDENCE AND RATIONALE FOR NONINVASIVE VENTILATION ON A GENERAL WARD

For additional information about noninvasive ventilation, see Chapter 18.

Acute Noninvasive Ventilation

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

NIV first became established as a viable technique for patients with acute respiratory failure secondary to an exacerbation of chronic obstructive pulmonary disease (COPD) in the ICU. The most striking finding from the early randomized, controlled trials (RCTs) comparing NIV with conventional therapy was a reduction in the need for intubation,[9,10] which in the largest study translated into improved survival and reduced length of both ICU and hospital stays.[9] Complications, particularly pneumonia and other infectious complications, were reduced markedly.[9,11–15] It is striking that NIV was administered for only a relatively small proportion (mean: 6 hours) of each day[9] or at modest levels for a longer period.[10] With NIV, paralysis and sedation are not needed, and ventilation outside the ICU is an option. Given the considerable pressure on ICU beds in some countries, the high costs, and that for some patients admission to ICU is a distressing experience,[16] this is an attractive option.

There have been seven prospective, randomized, controlled studies of NIV outside the ICU either on general wards, in an intermediate unit, or in the emergency department.[17–23] A more rapid improvement in abnormal physiology is a consistent finding, but it was only in the largest,[22] adequately powered, study that a benefit in terms of outcome was seen. Plant et al[22] recruited 236 patients with an acute exacerbation of COPD, who were still hypercapnic, with a pH less than 7.35, and respiratory rate greater than 23 breaths/min on arrival on the ward. A proportion of patients will improve just with medical therapy. In a 1-year-period prevalence study[24] of patients with acute exacerbations of COPD, 20% of 954 patients were acidotic on arrival in the emergency department; of these, 25% had completely corrected their pH by the time of arrival on the ward. There was a weak relationship between partial pressure of arterial oxygen (Pa_{O_2}) on arrival at hospital and the presence of acidosis, suggesting that, in at least some patients, respiratory acidosis had been precipitated by high-flow oxygen therapy administered on the way to hospital.

The study was performed on general respiratory wards in thirteen centers. NIV was applied, by the usual ward staff, using a bilevel device in spontaneous mode according to a simple protocol. "Treatment failure," a surrogate for the need for intubation, defined by a priori criteria, was reduced from 27% to 15% by NIV. In-hospital mortality was reduced from 20% to 10%. This study suggests that with adequate staff training, NIV can be applied with benefit outside the ICU by the usual ward staff and that early introduction of NIV in a general ward results in better outcomes than providing no ventilator support for acidotic patients outside the ICU. A recent national audit in the United Kingdom,[25] however, raised significant concerns about the provision of NIV in the "real" world. Although it was not recorded in the audit, it is likely that the majority of patients received NIV outside of ICUs, mostly on general wards. Two hundred and thirty-two hospital units collected data on 9716 patients of whom 1077 received NIV. Of concern 30% of patients with persisting respiratory acidosis did not receive NIV. The mortality was higher in all acidotic groups receiving NIV than in those treated without. Patients who had late-onset acidosis had a particularly poor prognosis confirming the results of an earlier case series.[26] Interestingly, 11% of acidotic admissions had a pure metabolic acidosis. There is a challenge in translating the results of RCTs into everyday clinical practice, especially when the particular technique involves significant technical expertise. It reinforces the need for ongoing audit to ensure that standards are maintained.

CONDITIONS OTHER THAN CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Trials in acute exacerbations of COPD provide the biggest body of evidence on NIV. NIV, however, is also used in other conditions, often on the basis of what has been learned in COPD.

Hypoxemic and Hypercapnic Respiratory Failure.

Obesity. Obese patients may present with acute or acute-on-chronic respiratory failure. In numerical terms this patient group is increasing; the number of patients requiring home ventilation because of obesity-hypoventilation syndrome

is increasing year on year, and in one study, patients with obesity now comprise the largest single group.[27] For obese patients requiring ventilator support acutely, the outcome from invasive ventilation is generally poor.[28] There are major practical problems associated with nursing critically ill obese patients, often requiring many pairs of hands and specialized lifting equipment for basic tasks. There are no RCTs of the use of NIV in patients with ventilatory failure secondary to obesity. A case series in which patients who received NIV were compared with those who refused it showed a survival advantage for those receiving NIV (97% vs. 42%)[29]; this was not controlled and there may have been other reasons for the difference. Very obese patients may have upper airway obstruction during sleep and because the impedance to inflation may be very high may require different ventilator modes.[30]

Neuromuscular Disease and Chest Wall Deformity. Patients with acute respiratory failure secondary to neuromuscular disease and chest wall deformity are not widely studied because they are small in number. Because of markedly reduced respiratory reserve, however, these patients are often challenging to wean from invasive ventilation and endotracheal intubation is best avoided if possible. Ideally, at-risk patients should already be under follow-up in a specialist unit and have been warned of the symptoms of evolving respiratory failure and of the necessity to present to hospital early in case of changes in their condition. Some patients will already have experienced a trial of domiciliary NIV. As such they represent good candidates for NIV outside the ICU. In addition to staff skilled in the delivery of NIV, therapists with expertise in secretion clearance techniques, including the use of mechanical insufflators or exsufflators,[31,32] are vital in the management of these patients.

Cardiogenic Pulmonary Edema. Cardiogenic pulmonary edema (CPE) represents a special case because the onset and recovery are usually both rapid. Most patients present to the emergency room, but some develop CPE in the ward. There have been seven systematic reviews (meta-analyses) on noninvasive ventilator assistance in CPE published since 2005.[33–40] Overall, there was a significant reduction in mortality for those patients treated with continuous positive airway pressure (CPAP) and a trend toward improved survival with NIV.[34] Both CPAP and NIV showed benefit when intubation was an outcome. There was no difference in any outcome when CPAP and NIV were compared. There was a trend toward an increase in myocardial infarction rate with NIV, but this was largely caused by the weighting of one study.[41] Two recent trials may result in the reappraisal of the role of NIV in acute CPE.[42,43]

In the 3CPO trial,[42] a multicenter, open, prospective RCT, patients were randomized to standard oxygen therapy, CPAP, or bilevel ventilation. There was no difference between 7-day mortality for standard oxygen therapy (9.8%) and NIV (CPAP and bilevel ventilation, 9.5%; $P = 0.87$). The combined end point of 7-day death or intubation rate was similar irrespective of NIV modality (11.7% vs. 11.1%, CPAP vs. bilevel ventilation respectively; $P = 0.81$). In comparison to standard oxygen therapy, NIV was associated with greater reductions in breathlessness scores, heart rate, acidosis, and hypercapnia at 1 hour. There were no treatment-related adverse events. There were no differences in other secondary outcomes, such as myocardial infarction rate, intubation, length of hospital stay, or ICU admission rate.

In another trial,[43] 120 patients were enrolled in three French emergency departments to either CPAP or NIV. There was no difference between interventions for any outcome. Respiratory distress and physiology improved in both arms. Only 3% of patients required intubation and one died within the first 24 hours.

These outcomes are different from the outcomes in the above meta-analyses, despite similar improvements in physiologic and gas exchange variables. The 3CPO trial was adequately powered and recruited more patients than the total of all the studies included in the meta-analyses. The discrepancy between results from one large, multicenter RCT and previous pooled data are not unique and the limitations of meta-analysis are well known.[44] Individual trials were composed of small treatment group sizes that varied between nine and sixty-five patients with recruitment rates of only 10% to 30% (compared to 62% randomized in the 3CPO trial). In the meta-analyses, the small total number of outcome events was well below the recommended threshold of 200,[45] limiting the generalizability of the findings.

The 3CPO trial may have failed to reveal a difference because the intervention was ineffectively delivered. Mean pressures for both CPAP (10 cm H_2O) and noninvasive positive pressure ventilation (IPAP 14/EPAP 7 cm H_2O) are comparable with previous studies, and improvements in physiologic variables are similar. There was crossover between interventions in all three arms of the 3CPO trial and these were analyzed on an intention-to-treat basis. There were differing reasons with respiratory distress and hypoxia being more likely in the control arm and lack of patient tolerance in the two intervention arms. After these patients were removed from primary outcome analysis, there remained no significant difference between groups, although mortality rates were lower.

Previous trials have indicated that the physiologic improvement seen with NIV is translated into a reduction in tracheal intubation rates.[33,34] In contrast, the 3CPO trial found no benefit in reducing intubation rates by NIV. Reasons for this are unclear but may reflect the differing patient populations, concomitant therapies, and thresholds for intubation and mechanical ventilation. Intubations rates in the standard therapy arms vary from 35% to 65% in early trials to 5% to 7% for recent trials in emergency department settings, despite similar severity of illness. Intubation rate in the intervention arms have fallen considerably over time, with some initial trials reporting intubation rates of up to 35% whereas recent reports have consistently suggested rates of around 5%. The recent trial[43] from France reported a 3% intubation rate, almost identical to that in the 3CPO trial. It is difficult

to make direct comparisons because studies differ in the time at which mortality is recorded, but, if anything, survival has probably improved as intubation rates have fallen, suggesting better overall management.

One danger of NIV is that other aspects of medical therapy may be forgotten because the focus is on the application of NIV. Nitrates are key and the total dose delivered has been shown to be an important predictor of outcome.[46,47] Positive pressure is beneficial to the failing heart and has some similarities to the effects of nitrates (preload and afterload reduction); if medical management is suboptimal, ventilation will have a beneficial effect on the failing heart, which may be lost if these effects have already been achieved with medication.

Finally, the patients recruited may have been less unwell than those in other studies. There was no difference in survival between recruited and nonrecruited patients, and no interaction with disease severity making this unlikely. The physiologic disturbance in these patients put them at the sickest end of the spectrum of patients studied, and, indeed, in contrast to other studies, acidosis (mean pH: 7.22) and hypercapnia (mean partial pressure of arterial carbon dioxide [Pa_{CO_2}]: 7.6 kPa) were invariable.

Despite these negative findings, a reduction in dyspnea, which was very intense, was a striking feature in patients receiving ventilator support, and this alone is sufficient reason to utilize ventilation in CPE. There is a trade-off between the beneficial effects of this reduction in dyspnea against discomfort from the mask and other factors.

Hypoxemic Respiratory Failure. There are no RCTs of NIV outside the ICU in hypoxemic respiratory failure. An RCT in the ICU[12] showed that patients receiving NIV had significantly lower rates of serious complications, and those treated successfully with NIV had shorter ICU stays. Post hoc analysis of patients grouped according to the Simplified Acute Physiology Score (SAPS) showed that NIV was superior to conventional mechanical ventilation in patients with a SAPS less than 16. In patients with a SAPS equal to or greater than 16, outcome was similar irrespective of the type of ventilation. Another study,[48] in immunocompromised patients, introduced NIV at a much lower level of physiologic compromise than would be required for invasive ventilation, and the sequential strategy (predefined periods on and off NIV) suggests that these patients could manage periods of spontaneous breathing safely. Further data are needed but it is reasonable for selected patients to have a trial of NIV in an experienced noninvasive unit outside the ICU; rapid access to intubation and mechanical ventilation must be available.

Elective Ventilation for Chronic Ventilatory Failure

This subject is dealt with in more detail in Chapters 28 and 33. In summary, there is no prospective RCT evidence to support the chronic use of NIV in any patient group. Most practitioners, however, would consider it unethical not to offer NIV to patients with chest wall deformity and neuromuscular disease, and it is unlikely that there will ever be any RCTs of NIV in these conditions. Chronic NIV is not appropriate for most patients with COPD; RCTs are ongoing.

WHERE SHOULD NONINVASIVE VENTILATION BE PERFORMED?

Acute Noninvasive Ventilation: ICU or General Ward?

There have been no direct comparisons of outcome with NIV delivered in the ICU, in intermediate units, and in a general ward. It should be appreciated that while there is some overlap, the skills needed for NIV are different from those required for invasive ventilation. Familiarity with and confidence in NIV by all members of the multidisciplinary team is the most important factor. Nurses, physiotherapists, or respiratory therapists may be the primary caregiver; this will depend on local availability, enthusiasm, and expertise. The outcome from NIV is likely to be better on a general ward where the staff has a lot of experience of NIV than in an ICU with high nurse-to-patient, therapist-to-patient, and doctor-to-patient ratios, and a high level of monitoring, but little experience of NIV. The less intensive atmosphere of a noninvasive unit may not be as distressing for patients and their relatives. NIV may be quite time-consuming in the early stages, and patients may benefit from extra attention, more likely in an ICU compared with less-well-staffed areas. Staffing is usually less at night, but a study in an ICU revealed no difference between patients failing NIV during the day and the night[49]; because of the greater number of patients under the care of an individual nurse, this may not be true on a general ward and should be evaluated further.

Assuming that the skills to deliver NIV are equal in the various possible locations, there are a number of other factors to be considered. These include whether or not intubation is considered appropriate should NIV fail, the presence of other system failure, comorbidity, severity of the respiratory failure, and likelihood of success with NIV (Fig. 34-1). Patients who cannot sustain ventilation for more than a few minutes when acutely unwell require continuous observation. This level of support is more likely to be available in the ICU than in other ward environments.

Although there are no published data, anecdotally there may be a tendency to abandon NIV more readily in an ICU because intubation is easily available, and in some ways it is easier for staff to manage a paralyzed, sedated patient than one who is struggling with NIV. When intubation is not immediately an option, there is a need to keep going a little longer, and a number of patients who at first sight appear to be failing can be managed successfully with persistence. It certainly has been the experience of the author that problems have been solved between the time that the ICU staff has been contacted and its arrival in the ward to intubate and/or transfer the patient (10 to 15 minutes).

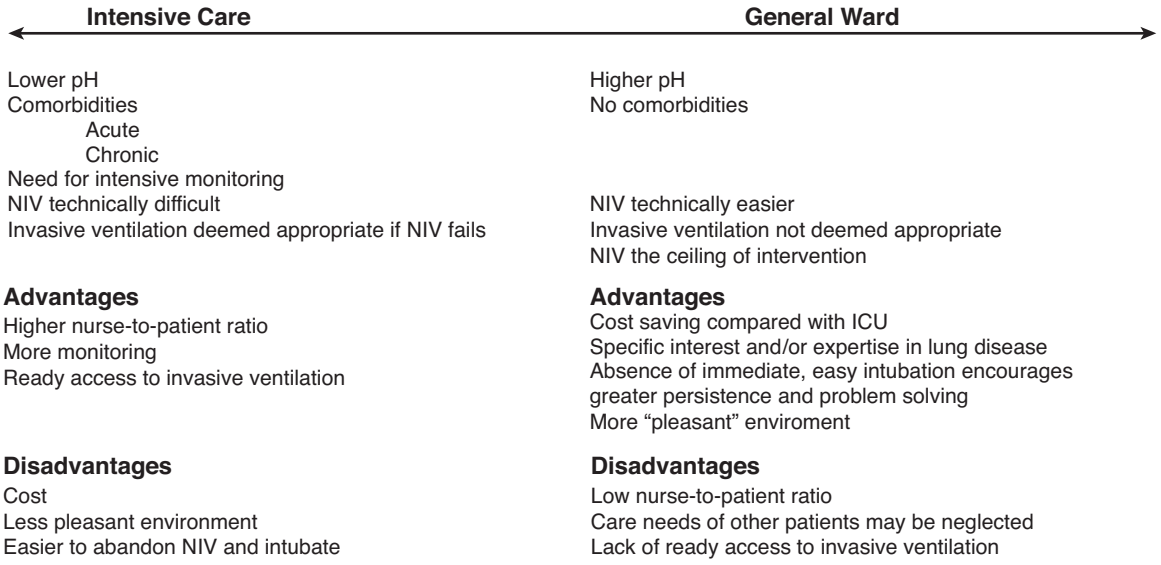

FIGURE 34-1 The spectrum of provision for an acute NIV service.

Another important difference between the ICU and the general ward is the complexity of monitoring and the types of ventilators available. Monitoring serves two roles: (a) safety and (b) optimization of ventilator settings. ICU ventilators differ from the portable devices designed primarily for home use but frequently used in general wards. The principal limitation to the use of home ventilators during acute respiratory failure is the lack of direct online monitoring of pressure, volume, and flow provided by these devices. The evaluation of patient–ventilator asynchrony is easier with visualization of flow and pressure waveforms.[50] This may be important, particularly during the initiation of ventilation, when it is important to assess patient–ventilator interaction, respiratory mechanics, and the expired tidal volume.[51] Further work is needed to establish which variables should be monitored to optimize NIV. It should be appreciated that high-technology monitoring is never a substitute for good clinical observation.[52] For safety, it is recommended that all patients receiving NIV for acute ventilatory failure should have continuous monitoring of oxygen saturation (SO_2) by pulse oximetry, regular assessments of arterial blood-gas tensions (because there is no accurate and reliable noninvasive measure of P_{CO_2} or, more importantly, of pH), and respiratory rate.[53,54] The SO_2 should be maintained at around 88% to 92%[55,56] to avoid the twin dangers of dangerous hypoxia and the risk of worsening hypercapnia secondary to altering the dead-space-to-tidal-volume ratio.[57] There is no reason why this level of monitoring cannot be provided in a general ward (Table 34-2).

If NIV is only to be provided in the ICU, the number of patients needing ICU care will increase, and this may not be necessary or appropriate. The study of Plant et al[22] showed that NIV is an option outside the ICU, but the outcome for patients with a pH of less than 7.30 was not as good as that seen for comparable patients in the studies performed in a higher-dependency setting. Also, for reasons of training, throughput, quality of service, and skill retention, NIV is best performed in a single location.[24] An intermediate unit with ready access to an ICU is probably the best compromise.[58] A study[3] of 756 consecutive patients admitted to twenty-six respiratory intermediate care units in Italy showed a better outcome than that expected on the basis of Acute Physiology and Chronic Health Evaluation (APACHE) II scores. The predicted inpatient mortality was 22.1%, whereas the actual mortality was 16%. All but forty-eight patients had chronic respiratory disease, mainly COPD ($n = 451$).

Patients with acute CPE should usually receive ventilator support where they are, because by the time arrangements have been made and transfer effected, most patients will have either improved or deteriorated to the point at which intubation is needed. Sufficient patients will attend the emergency room with CPE or develop it in the coronary care unit to make staff training in NIV in these areas worthwhile and to

TABLE 34-2: MONITORING DURING NONINVASIVE VENTILATION

Essential

- Regular clinical observation
- Continuous pulse oximetry
- Arterial blood gases after 1 to 4 hours of NIV and after 1 hour of any change in ventilator settings or fractional inspired oxygen concentration (FI_{O_2})
- Respiratory rate—continuous or intermittent

Desirable

- Electrocardiogram
- More detailed physiologic information such as leak, expired tidal volume, and measure of ventilator–patient asynchrony

ensure enough throughput to maintain skills. When patients develop CPE outside these areas (e.g., in a surgical ward), it is likely to be sufficiently infrequent that it is not worth training the staff, or if trained, staff will not have had sufficient opportunity to use and develop their skills. This is a situation in which the peripatetic NIV team or critical care outreach service may have a role. There may also be a role for CPAP delivered by helmet as it is easier to train staff in its use; it has been used successfully in the prehospital setting.[59] It is important that personnel are able to recognize and treat arrhythmias and myocardial ischemia.[60]

Elective Noninvasive Ventilation: General Ward or Chronic Care Facility?

The onset of established chronic ventilatory failure is usually insidious. Patients at risk are best seen and regularly reviewed in specialist centers so that the onset of significant nocturnal hypoventilation and the development of diurnal ventilatory failure can be anticipated. As a result, NIV usually should be instituted before the patient becomes critically ill. It is advisable to acclimatize patients to NIV at an early stage once the development of significant ventilatory failure becomes likely. In one study, 90% of patients without daytime hypercapnia but with a rise in transcutaneous CO_2 during sleep required NIV within 1 year.[61] Decompensation may occur with an intercurrent event, most commonly respiratory tract infection. NIV is much easier in the acute situation if the patient has experienced it previously when reasonably well. In such patients, if they are clinically stable, there is no need for assisted ventilation to "work" immediately; indeed, it does not matter if the patient is hardly able to use the ventilator at all initially.

There is little reason to admit these patients to the ICU, and it is questionable whether, with appropriate teams in place, the patient even needs admission to hospital. Similar outcomes were seen in an RCT of inpatient versus outpatient initiation of home ventilation in patients with neuromuscular disease and chest wall deformity. The mean (SD) inpatient stay was 3.8 (1.0) days, and the outpatient attendance sessions 1.2 (0.4). Health care professional contact time, including telephone calls, was: inpatient 177[99] minutes versus outpatient 188[60] minutes (p = NS). Two-month ventilator compliance was: inpatient 4.32 hours per night[7] versus outpatient 3.92[8] (p = NS) hours per night.[62]

Some patients, particularly those with severe neuromuscular disease, have complex nursing needs, and their home environment may be better adapted to their needs than a hospital ward. It is more pleasant for relatives and caregivers to stay in their own home. Particular issues for that patient concerning positioning of equipment, ensuring adequate access to electrical power, and so on can be addressed.[63]

If the patient is to be admitted to hospital, the choice may be between a chronic care facility and a general ward. As for acute NIV, staff expertise is the most important factor determining the best location (Table 34-3). Staffing and expertise being equal, advantages of the general ward include access to the ICU if things go wrong, and more ready access to other specialist teams because some of these patients have other complex needs, which the need to start NIV brings into focus. These advantages, however, are generalizations; depending on the nature of the chronic care facility, it may be better suited than a general ward for providing the care and support for the other needs of patients. Regardless of location, adequate control of nocturnal hypoventilation needs to be confirmed. For some patients, overnight oximetry may suffice; for others, particularly those receiving supplemental oxygen, monitoring of P_{CO_2} is necessary. Patients also will need intermittent arterial blood-gas analyses. Increasingly, it is possible to interrogate, including remotely, the home NIV ventilator, which can give important insights into why ventilation is poorly tolerated or supoptimal? Many days' data are recorded, important in a technique with which problems may be intermittent and subject to night-to-night variation. More detailed respiratory variable monitoring, including chest wall and abdominal motion, may provide important insights,[64] but is not of itself a reason for admission to hospital.

The Advantage of the General Ward

An acute and a chronic NIV service depends critically on local factors, particularly the skill levels of doctors, nurses, and therapists. The major advantage of the general ward is that it sits in the middle of the spectrum of locations for NIV provision and is likely to treat the greatest number of patients. Use of skills is a key factor in developing and retaining them. The skills learned looking after patients needing NIV acutely are equally relevant for patients being started electively on NIV. Familiarity with the nonrespiratory needs of patients with complex neuromuscular or musculoskeletal disorders, learned when patients are admitted electively to start NIV, are transferable to the care of such patients needing NIV acutely or for weaning. Continuity of care is also important. Some patients start home ventilation after an acute event, and the option of dealing with both aspects in the same place and with the same care team probably is advantageous to the patient and caregivers. If NIV is the ceiling of

TABLE 34-3: ELECTIVE VENTILATION FOR CHRONIC VENTILATORY FAILURE

There is likely to be great local variation. Factors that determine the best location

- Enthusiastic and trained staff
- Possibility of colocating with acute NIV unit
- Access to expertise in the management of nonrespiratory aspects of care
- Diagnostics, e.g., sleep laboratory
- Access to ICU

treatment, admission to an ICU is not necessary; if NIV is failing, the patient may be allowed to die in a less high-tech environment than that afforded by most ICUs.

There is an emerging role for NIV in the management of patients with end-stage COPD. It is well recognized that these patients receive suboptimal palliative care toward the end of life[65]; in part, this relates to the great difficulty in recognizing when the end is near. The boundary between life-sustaining therapy and palliation can move on a daily basis during an exacerbation as a patient's condition improves and then deteriorates again.[66] One of the biggest challenges facing doctors now and in the future is knowing when "enough is enough."[67] NIV provides a useful alternative to life-sustaining therapy, with limited palliative care, that is, invasive ventilation, or to treatment that may not be sufficient to sustain life, but does allow effective palliative care, that is, medical therapy alone. With NIV, patients retain a real say in their care, and, because assisted ventilation is not all or nothing, it is possible to move relatively easily between life sustaining and palliative care as the patient's situation changes.

SELECTION OF PATIENTS FOR NONINVASIVE VENTILATION IN A GENERAL WARD

Acute Respiratory Failure

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

The pH at the time NIV is initiated is the best single predictor of severity and the likelihood of success with the noninvasive approach.[68] Moreover, changes in pH and respiratory rate are easily measurable and useful in predicting the likelihood of a successful outcome from NIV.[9,17,69–73] Arterial blood gases should be checked at baseline and after 1 to 4 hours. Data from the largest study[74] showed that hydrogen ion concentration at enrollment (odds ratio 1.22 per nmol/L) and Pa_{CO_2} (odds ratio 1.14 per kPa) were associated with treatment failure. After 4 hours of therapy, improvement in acidosis (odds ratio 0.89 per nmol/L) and/or fall in respiratory rate (odds ratio 0.92 per breath per minute) were associated with success. If at least one of these two variables was improving, successful NIV was likely. pH, therefore, is useful in determining, first, who should receive NIV, second, in what location, and, finally, when the patient can move to a more or less intensive location. Generally speaking, the lower the pH, the greater is the risk to the patient of needing invasive ventilation if NIV is not offered or, if it is attempted, of failure. The more acidotic the patient, the greater is the need for that patient to be managed in an ICU because the risk of failure of NIV and the potential need for endotracheal intubation is higher.[75]

The same criteria can be extended to other patients with acute-on-chronic hypercapnic respiratory failure, for instance those with obesity. The pH criterion is less important as some of these patients will require chronic ventilator support, with either CPAP or NIV, if they already have symptoms of excessive daytime sleepiness or peripheral edema before admission. The patient should be reassessed post discharge because a significant proportion will be able to change their mode of ventilation or even need no ongoing ventilator support.[29] NIV certainly should not be delayed until acidosis occurs in patients with neuromuscular disease; by the time these patients become hypercapnic, respiratory reserve is very reduced and they are at high risk. NIV should be considered even if the patient is normocapnic if he or she is also tachypneic; these patients will tire out and the Pa_{CO_2} will start to rise. NIV will prevent this and also offload the respiratory muscles providing relief from dyspnea. Although it is less clear cut, the same principles apply to patients with chest wall deformity; chronic hypercapnia is an indication to start domiciliary NIV,[76] and there is therefore no reason not to start NIV if the patient is admitted to hospital with respiratory disease, even if not accompanied by acidosis. These patients do not require admission to an ICU.

HYPOXEMIC RESPIRATORY FAILURE

These patients are best managed in an ICU because the risks of failure are higher and because the major problem is inadequate oxygenation. Patients are more likely to need prompt invasive ventilation if they are deteriorating or have other organ failure; moreover, ventilators usually used on general wards are those designed primarily for home use, and a high FI_{O_2} cannot be delivered. One further consideration was highlighted by Delclaux et al[77] in a study on the use of noninvasive CPAP in patients with hypoxemic respiratory failure; there was a trend toward more cardiorespiratory arrests in the CPAP group. The increase was attributed to the improvement in oxygenation and other physiologic parameters while the patients were using CPAP, which led to a false sense of security; when patients take the mask off, even for a short period, SO_2 may fall rapidly, putting them at high risk. Any patient who desaturates within seconds of removing a mask should be monitored very carefully, usually in an ICU, and probably this should be considered an indication for intubation.

IMPLICATIONS FOR STAFFING AND TRAINING

Table 34-4 lists key training requirements.

NIV has been reported to be a time-consuming procedure.[78] As with any new technique, there is a learning curve, and the same authors subsequently published more encouraging results.[79] A number of ICU studies have shown that a significant amount of time is required to establish the patient on NIV, but this drops off substantially in subsequent days.[10,80,81] It is possible, therefore, that NIV may have a much greater impact on nursing workload outside the ICU, where nurses have responsibility for a larger number of patients. In the study of Plant et al,[22] NIV resulted in a modest increase

TABLE 34-4: KEY TRAINING REQUIREMENTS

Ethical issues relevant to the care of patients with incurable disease
Problem solving—the ability to recognize serious situations and act accordingly

in nursing workload, assessed using an end-of-bed log, in the first 8 hours of the admission, equivalent to 26 minutes, but no difference was identified thereafter. No data exist, however, on the effect NIV on the care of other patients on the ward, nor whether outcome would have been better had nurses spent more time with patients receiving NIV. Most of the centers that participated in the study had little or no previous experience of NIV and therefore required training in mask fitting and application of NIV. Formal training in the first 3 months of opening a ward by a research doctor and nurse was 7.6 hours (SD 3.6). Thereafter, each center received 0.9 hour per month (SD 0.82) to maintain skills. It should be appreciated that there was no need to make subtle adjustments to ventilator settings, which all was done according to protocol. Much more training would be needed if sophisticated ventilators are used. This underlines the fact, however, that NIV, in whatever location, is not just a question of purchasing the necessary equipment but also of staff training.

Although considerable input is likely when a unit commences to provide an NIV service, thereafter, as long as a critical mass remain, new staff will gain the necessary skills from their colleagues. Given that NIV in the more severely ill patient may require as much input as an invasively ventilated patient,[81] there usually should be one nurse responsible for no more than three or four patients, although this will depend on the other care needs of the patients. In the less severely affected patient, NIV can be successful with a lower level of staffing.[22]

ECONOMIC CONSIDERATIONS

Although the findings are not consistent, some of the larger studies show that NIV can shorten length of an ICU and/or hospital stay compared, for example, with medical therapy or invasive ventilation.[9,10,12,13,48,82] In no study has NIV been shown to lengthen hospital stay. Although not the primary aim of the studies, the finding of reduced length of stay creates or saves resources and thereby indicates a cost benefit from NIV.

In a North American cost-effectiveness analysis[83] in which NIV was delivered in the ICU, the authors concluded that NIV was more effective than standard treatment in reducing hospital mortality and also less expensive, with a cost saving of about $2500 per patient admission. Intensive care is also expensive care. Intermediate units provide an alternative to the classic ICU at reduced cost.[58] The daily costs of a ventilated patient may be reduced by two-thirds when NIV is performed in a specialized respiratory unit rather than in an ICU.[84] These costs can be reduced still further when NIV is performed on a general ward,[85] although effectiveness may not be as good as in higher-dependency settings. Carlucci et al[86] showed that over time practice changes. They found that after a few years, patients with more severe acidosis were ventilated successfully with NIV; more patients received NIV on general wards, with significant cost savings, compared with when they first started providing an acute NIV service.

THE FUTURE AND IMPORTANT UNKNOWNS

As the population ages, the pressure on ICU beds will increase and alternatives to intensive care will need to be developed further, even in health care systems that currently enjoy high levels of ICU provision. It is likely that, as has been seen in COPD, the management of more patients with NIV will take place outside of the ICU. The challenge will be to ensure that standards are maintained and that the real-world experience in the United Kingdom is avoided.[25] Technology will play a part, but staff training will remain key. The effect of provision of NIV upon the care of other patients on the general ward is an important consideration.

CONCLUSION

Staff training and experience are more important than location. Adequate numbers of staff, skilled in NIV, must be available throughout 24 hours. Because of the demands of looking after acutely ill patients, and to aid training and skill retention, acute NIV usually is best carried out in one single-sex location with one nurse responsible for three to four patients. Basic monitoring, at least pulse oximetry and facilities for arterial blood-gas analysis, should be available. Because the skills, both for NIV and for the other care needs of the patient population likely to need NIV, are transferable, there are significant advantages to locating both the acute and elective NIV service in the same place, but there must be ready access to invasive ventilation. The best location for both an acute and chronic NIV service will vary from institution to institution, and local expertise, enthusiasm, and hospital geography will be the major determinants of where the service should be located and how it is delivered.

EFFECTS OF MECHANICAL VENTILATION ON CONTROL OF BREATHING

Dimitris Georgopoulos

The main reasons for instituting mechanical ventilation are to decrease the work of breathing, support gas exchange, and buy time for other interventions to reverse the cause of respiratory failure.[1] Mechanical ventilation can be applied in patients who are making or not making respiratory efforts, whereby assisted or controlled modes of support are used, respectively.[1] In patients without respiratory efforts, the respiratory system represents a passive structure, and thus the ventilator is the only system that controls breathing. During assisted modes of ventilator support, the patient's system of control of breathing is under the influence of the ventilator pump.[2–4] In the latter instance, ventilatory output is the final expression of the interaction between the ventilator and the patient's system of control of breathing. Thus, physicians who deal with ventilated patients should know the effects of mechanical ventilation on control of breathing, as well as their interaction. Ignorance of these issues may prevent the ventilator from achieving its goals and also lead to significant patient harm.

PHYSIOLOGY

The respiratory control system consists of a motor arm, which executes the act of breathing, a control center located in the medulla, and a number of mechanisms that convey information to the control center.[5,6] Based on information, the control center activates spinal motor neurons that subserve the respiratory muscles (inspiratory and expiratory); the intensity and rate of activity vary substantially between breaths and between individuals. The activity of spinal motor neurons is conveyed, via peripheral nerves, to respiratory muscles, which contract and generate pressure (Pmus). According to equation of motion, *Pmus* at time *t* during a breath is dissipated in overcoming the resistance (*Rrs*) and elastance (*Ers*) of the respiratory system (inertia is assumed to be negligible) as follows:

$$\text{Pmus}(t) = Rrs \times \dot{V}(t) + Ers \times \Delta V(t) \quad (1)$$

where $\Delta V(t)$ is instantaneous volume relative to passive functional residual capacity and $\dot{V}(t)$ is instantaneous flow. Equation (1) determines the volume–time profile and, depending on the frequency of respiratory muscle activation, ventilation. Volume–time profile affects Pmus via neuromechanical feedback; inputs generated from other sources (cortical inputs) may modify the function of control center. Ventilation, gas-exchange properties of the lung, and cardiac function determine arterial blood gases, termed *arterial oxygen tension* (Pa_{O_2}) and *arterial carbon dioxide tension* (Pa_{CO_2}), which, in turn, affect the activity of control center via peripheral and central chemoreceptors (chemical feedback). This system can be influenced at any level by diseases or therapeutic interventions.

During mechanical ventilation, the pressure provided by the ventilator (Paw) is incorporated into the system.[3] Thus, the total pressure applied to respiratory system at

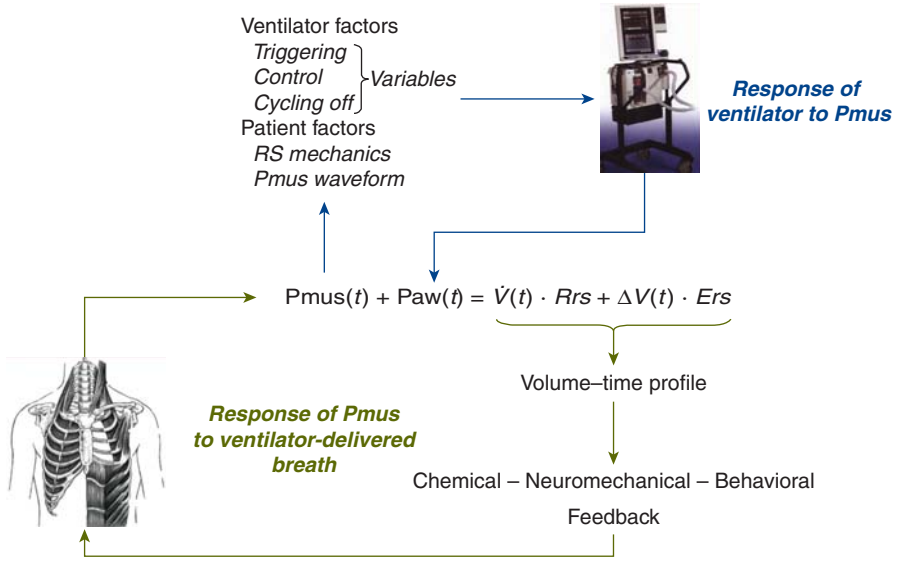

FIGURE 35-1 Schematic of variables that determine the volume–time profile during mechanical ventilation. Neuromechanical, chemical, and behavioral feedback systems are the main determinants of Pmus. The functional operation of the ventilator mode (triggering, control, and cycling-off variables) and patient-related factors (namely, respiratory system mechanics and the Pmus waveform) determine the response of the ventilator to Pmus. $\Delta V(t)$, instantaneous volume relative to passive functional residual capacity of respiratory system; *Ers,* elastance of the respiratory system; *Paw*(*t*), airway (ventilator) pressure; *Pmus*(*t*), instantaneous respiratory muscle pressure; *Rrs,* resistance of the respiratory system; *RS,* respiratory system; $\dot{V}(t)$, instantaneous flow.

time t [$P_{TOT}(t)$] is the sum of Pmus(t) and Paw(t). As a result, the equation of motion is modified as follows:

$$P_{TOT}(t) = \text{Pmus}(t) + \text{Paw}(t) = \dot{V}(t) \times Rrs + \Delta V(t) \times Ers \quad (2)$$

The relationships of Equation (2) determine the volume–time profile during mechanical ventilation, which via neuromechanical, chemical, and behavioral feedback systems affects the Pmus waveform (Fig. 35-1). The ventilator pressure, by changing flow and volume, may influence these feedback systems and thus alter either the patient's control of breathing itself or its expression. In addition, Pmus, depending on several factors, alters the Paw waveform (Fig. 35-1). Thus, during assisted mechanical ventilation (i.e., Pmus $\neq 0$), ventilatory output is not under the exclusive influence of patient's control of breathing; instead, it represents the final expression of an interaction between ventilator-delivered pressure and patient respiratory effort.

EFFECTS OF MECHANICAL VENTILATION ON FEEDBACK SYSTEMS

Chemical Feedback

Chemical feedback refers to the response of Pmus to Pa_{O_2}, Pa_{CO_2}, and pH.[5–7] In spontaneously breathing and mechanically ventilated patients, this system is an important determinant of respiratory motor output both during wakefulness and sleep.[7–11]

Mechanical ventilation can influence chemical feedback simply by altering the three variables Pa_{O_2}, Pa_{CO_2}, and pH. Hypoxemia, hypercapnia, or acidemia may be corrected by mechanical ventilation and thus modify activity of the medullary respiratory controller via peripheral and central chemoreceptors.[5,12] The effects of mechanical ventilation on gas-exchange properties of the lung are beyond the scope of this chapter and are discussed in Chapter 37. In this chapter, the fundamental elements of the response of respiratory motor output to chemical stimuli, their relationship to unstable breathing, and the operation of chemical feedback during mechanical ventilation are reviewed.

Response of Respiratory Motor Output to Chemical Stimuli

CARBON DIOXIDE STIMULUS

Carbon dioxide (CO_2) is a powerful stimulus of breathing.[5,12] This stimulus, expressed by Pa_{CO_2}, largely depends on the product of tidal volume (V_T) and breathing frequency (f) (i.e., minute ventilation) according to Equation (3):

$$Pa_{CO_2} = 0.863\ \dot{V}_{CO_2}/[V_T \times f(1 - V_D/V_T)] \quad (3)$$

where $\dot{V}_{CO_2}$ is CO_2 production, and V_D/V_T is the dead-space-to-tidal-volume ratio. Because minute ventilation is an adjustable variable in ventilated patients, understanding the relationship between respiratory motor output and CO_2 stimuli is of fundamental importance.

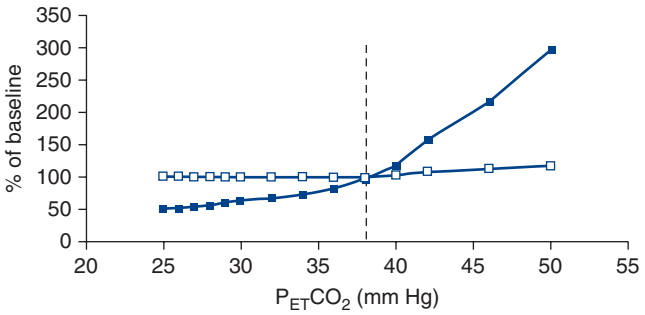

FIGURE 35-2 Schematic of the response of respiratory frequency (*open squares*) and pressure-time product of the inspiratory muscles per breath (an index of the intensity of patient effort, *closed squares*), both expressed as a percentage of values during spontaneous eupnea (baseline), to CO_2 challenge in conscious healthy subjects ventilated with a high level of ventilator assistance. $P_{ET}CO_2$ is end-tidal P_{CO_2}, and the *dotted vertical line* is $P_{ET}CO_2$ during spontaneous breathing (eupnea). Contrast the vigorous response of intensity of inspiratory effort to CO_2, even in the hypocapnic range, with the response of respiratory frequency, which remains at eucapnic level over a broad range of CO_2 stimuli. The response is based on data from references 7 and 13 to 16.

Several studies have examined the respiratory motor output to CO_2 in ventilated, conscious, healthy subjects.[7,13–16] Major findings include

1. Manipulation of Pa_{CO_2} over a wide range has no appreciable effect on respiratory rate. Despite hypocapnia, subjects continue to trigger the ventilator with a rate similar to that of eucapnia. Respiratory rate increases slightly when Pa_{CO_2} approaches values well above eucapnia (Fig. 35-2).
2. The intensity of respiratory effort (respiratory drive) increases progressively as a function of P_{CO_2}. This response is evident even in hypocapnic range. The response slope increases progressively with increasing CO_2 stimuli, reaching its maximum in the vicinity of eucapnic values (see Fig. 35-2).
3. There is no fundamental difference in the response to CO_2 between various ventilator modes.
4. Above eupnea, the slope of the response does not differ significantly with that observed during spontaneous breathing, suggesting that mechanical ventilation per se does not considerably modify the sensitivity of respiratory system to CO_2.

During sleep (or sedation), the response of respiratory motor output to CO_2 differs substantially from that during wakefulness, secondary to loss of the suprapontine neural input to the medullary respiratory controller.[10,17] In ventilated sleeping subjects, a decrease in Pa_{CO_2} by a few millimeters of mercury causes apnea.[10] Respiratory rhythm is not restored until Pa_{CO_2} has increased significantly above eupneic levels. The difference between eupneic Pa_{CO_2} and Pa_{CO_2} at apneic threshold, referred to as *CO_2 reserve*,[18] depends on several factors (see Response of Respiratory Motor Output to Chemical Stimuli—Chemical stimuli and unstable breathing). This reserve determines the propensity of an individual to develop breathing instability during sleep; propensity increases as CO_2 reserve decreases. Similar to wakefulness, the response of respiratory motor output to CO_2 is mediated mainly by the intensity of respiratory effort, whereas respiratory rate decreases abruptly to zero (apnea) when the CO_2 apneic threshold is reached.[19]

OTHER CHEMICAL STIMULI

The effects of mechanical ventilation on the response of respiratory motor output to stimuli other than CO_2 have not been studied adequately. In a steady state during wakefulness, the effects of oxygen (O_2) and pH on breathing pattern are similar qualitatively to that observed with CO_2: Changes in O_2 and pH mainly alter the intensity of patient effort, whereas respiratory rate is affected considerably less.[5,12] There is no reason to expect a different response pattern during mechanical ventilation. Indeed, this is the case regarding the hypoxic response in normal conscious subjects ventilated in assist-control mode during eucapnia.[20] Indirect data also revealed that during eucapnia, the sensitivity of respiratory motor output to hypoxia was not modified by mechanical ventilation.[20] During mild hypocapnia, however, the response was attenuated, whereas at moderate hypocapnia (end-tidal P_{CO_2} approximately 31 mm Hg) the response was negligible. The latter observations may be relevant clinically because ventilated patients do not always keep Pa_{CO_2} at eucapnic levels and can become hypocapnic.[16]

CHEMICAL STIMULI AND UNSTABLE BREATHING

The response pattern of respiratory motor output to CO_2 during sleep is relevant to the occurrence of periodic breathing in mechanically ventilated patients. Studies indicate that this breathing pattern might increase the morbidity and mortality of critically ill patients because it can cause sleep fragmentation and patient–ventilator dyssynchrony.[21–23] Sleep deprivation may cause serious cardiorespiratory,[24,25] neurologic,[26,27] immunologic, and metabolic consequences.[28–31]

The following is a brief review of the factors that can lead to unstable breathing. In a closed system governed mainly by chemical control (such as occurs during sleep or sedation), a transient change in ventilation at a given metabolic rate ($\Delta\dot{V}_{initial}$) will result in a transient change in alveolar gas tensions. This change is sensed by peripheral and central chemoreceptors, which, after a variable delay, exert a corrective ventilatory response ($\Delta\dot{V}_{corrective}$) that is in the opposite direction to the initial perturbation[32,33] (Fig. 35-3). The ratio of $\Delta\dot{V}_{corrective}$ to $\Delta\dot{V}_{initial}$ defines the loop gain of the system.[32] Loop gain is a dimensionless index that is the mathematical product of three types of gains: plant gain (the relationship between the change in gas tensions in mixed pulmonary capillary blood and $\Delta\dot{V}_{initial}$), feedback gain (the relationship between gas tensions at the chemoreceptor level and those at the mixed pulmonary capillary level), and controller gain (the relationship between $\Delta\dot{V}_{corrective}$ and the change in gas tensions at the chemoreceptor level) (Fig. 35-3). Loop gain has both a magnitude and a dynamic component.[32,33] In this

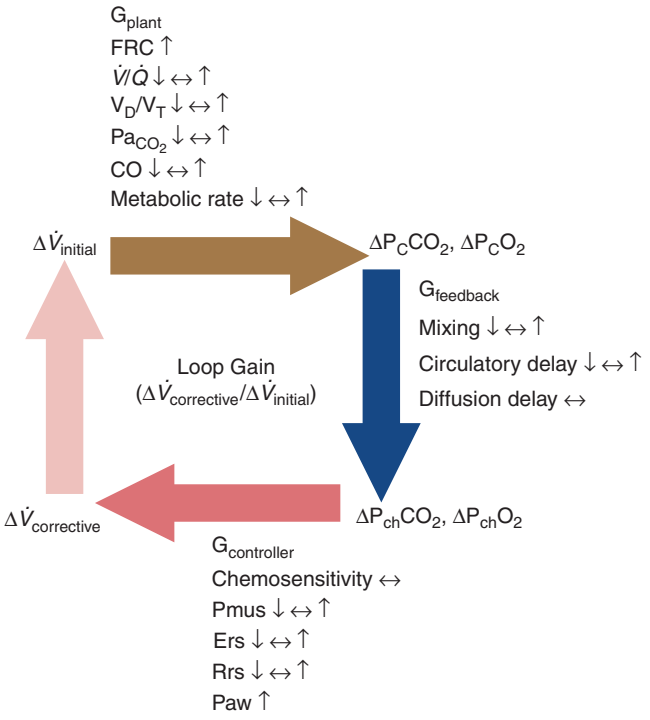

FIGURE 35-3 Schematic of the variables that determine the propensity of an individual to develop periodic breathing in a closed system dominated by chemical feedback. Loop gain is the product of three gains: plant, feedback, and controller. Instability occurs when $\Delta\dot{V}_{corrective}$ (the final response) is 180 degrees out of phase with $\Delta\dot{V}_{initial}$ (the transient initial perturbation) and $\Delta\dot{V}_{corrective}/\Delta\dot{V}_{initial}$ is greater than 1. Mechanical ventilation, by affecting almost all variables of the system (↑, increase; ↔, no change; ↓, decrease), may change both the magnitude and the dynamic component of loop gain and thus the propensity of an individual to develop periodic breathing. CO, cardiac output; ΔP_CCO_2 and ΔP_CO_2, the difference in partial pressures of CO_2 and O_2 in mixed pulmonary capillary blood, respectively; $\Delta P_{ch}CO_2$ and $\Delta P_{ch}O_2$, the difference in partial pressure of CO_2 and O_2 at chemoreceptors (peripheral and central), respectively; Ers and Rrs, elastance and resistance of respiratory system, respectively; FRC, functional residual capacity; *LG*, G_{plant}, $G_{feedback}$, and $G_{controller}$, loop, plant, feedback, and controller gains, respectively; Pa_{CO_2} alveolar partial pressure of CO_2; Paw, airway (ventilator) pressure; Pmus, pressure developed by respiratory muscles; $\dot{V}/\dot{Q}$, ventilation–perfusion ratio; V_D/V_T, dead-space fraction.

system, instability occurs when the corrective response is 180 degrees out of phase with initial disturbance (dynamic component) and loop gain is greater than 1 (magnitude component). This instability leads to fluctuation in chemical stimuli, namely, P_{CO_2}. If P_{CO_2} reaches the apneic threshold, apnea occurs.

Positive-pressure breathing exerts multiple effects on loop gain by influencing almost all the factors that determine plant, feedback, and controller gains. The effects are complex and at times opposing and variable (Table 35-1; see also Fig. 35-3). Nevertheless, the effect of mechanical ventilation on controller gain exerts the most powerful influence on the propensity to develop breathing instability.[8,19,21,23] The magnitude and direction of the change in controller gain depends on the ventilator mode, the level of assistance, the mechanics

TABLE 35-1: EFFECTS OF MECHANICAL VENTILATION ON GAIN FACTORS AND GAIN CHANGES

Gain Factors (Influence)	Ventilator Effect*	Gain Change
Lung volume (stabilizing)	↑	$\downarrow G_{plant}$
Cardiac output (destabilizing)	↓	$\uparrow G_{plant}$, $\uparrow G_{feedback}$
Thoracic blood volume (destabilizing)	↓	$\uparrow G_{feedback}$
Paw response to Pmus (destabilizing)	↑	$\uparrow G_{controller}$
Alveolar P_{CO_2} (stabilizing)	↓	$\downarrow G_{plant}$
Alveolar P_{O_2} (stabilizing)	↑	$\downarrow G_{plant}$, $\downarrow G_{controller}$
Respiratory elastance (destabilizing)	↓	$\uparrow G_{controller}$

Abbreviations: ↓, decrease; ↑, increase; Paw, airway pressure; Pmus, respiratory muscle pressure.

*Mechanical ventilation may also exert opposite effects on the various gain factors.

of the respiratory system, and the Pmus waveform (see the section Interactive Effects of Patient-Related Factors and Ventilator on Control of Breathing).[8,16,19,21] Disease states as well as medications (e.g., sedatives) also may interfere with the effects of mechanical ventilation on loop gain. For example, positive-pressure ventilation may increase or decrease cardiac output, causing corresponding changes in circulatory delay depending on cardiac function and intravascular volume (see Chapter 36).[34–37] It has been shown that nocturnal mechanical ventilation in patients with congestive heart failure decreases the frequency of Cheyne-Stokes breathing, presumably by causing an increase in cardiac output secondary to afterload reduction.[38–40] Sedatives at moderate doses, commonly used in ventilated patients, decrease considerably the loop gain, partly mitigating the effect of mechanical ventilation on controller gain and thus promote ventilatory stability.[41]

In addition to CO_2, O_2 and pH can play a key role in producing unstable breathing in ventilated patients during sleep (or sedation). It is well known that hypoxia, acting via peripheral chemoreceptor stimulation, decreases Pa_{CO_2}. The result reduces the plant gain (stabilizing influence); for a given change in alveolar ventilation, Pa_{CO_2} will change less when baseline Pa_{CO_2} is low than when it is high.[18] Hypoxia, however, increases the controller gain to a much greater extent[42] because the slope of ventilatory response to CO_2 below eupnea increases,[12] a highly destabilizing influence.[32,33] Similar principles apply if pH is considered as a chemical stimulus; acidemia decreases the plant gain (lowers Pa_{CO_2}) and increases, to a much lesser extent, the controller gain.[18,42] During mechanical ventilation, the propensity to unstable breathing in the face of changing O_2 and pH stimuli depends on a complex interaction between the effects of these stimuli and mechanical ventilation on plant, feedback, and controller gains (Fig. 35-4; see also Table 35-1).

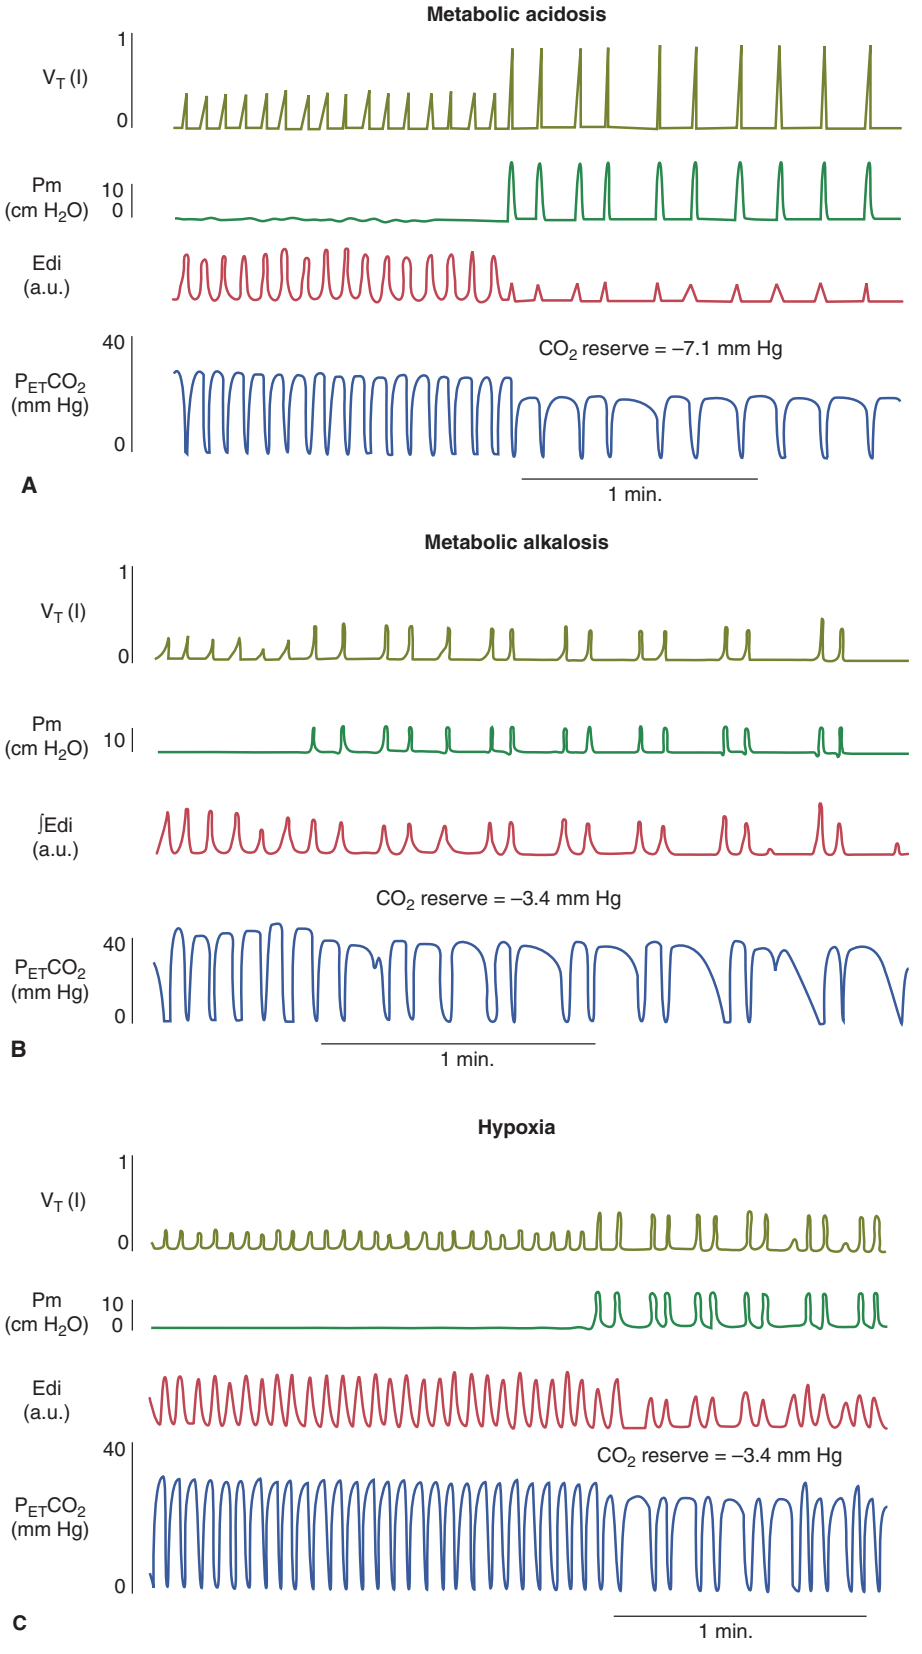

FIGURE 35-4 Tidal volume (V_T), airway pressure (*Pm*), integrated diaphragmatic electrical activity (*Edi*, arbitrary units), and partial pressure of end-tidal CO_2 ($P_{ET}CO_2$) in a tracheostomized dog during non–rapid eye movement sleep without and with pressure-support ventilation at a pressure level that caused periodic breathing. (**A**) At a background of 5 hours of metabolic acidosis (pH 7.34, HCO_3^- 16 mEq/L, Pa_{CO_2} 30 mm Hg). (**B**) At a background of 1 hour of metabolic alkalosis (pH 7.51, HCO_3^- 35 mEq/L, Pa_{CO_2} 44 mm Hg). (**C**) During hypoxia (Pa_{O_2} 47 mm Hg, Pa_{CO_2} 31 mm Hg). At a background of metabolic acidosis, CO_2 reserve was quite high; consequently, the pressure level that caused periodic breathing (20 cm H_2O) was significantly higher than the corresponding values (approximately 10 cm H_2O) during metabolic alkalosis or hypoxia. Hyperventilation during spontaneous breathing was similar during metabolic acidosis and hypoxia (similar stabilization influence via a decrease in plant gain secondary to low Pa_{CO_2}), indicating that the destabilizing influence of hypoxia was caused by an increase in controller gain (hypoxic increase in the slope of CO_2 below eupnoea). (Used, with permission, from Dempsey et al. *J Physiol.* 2004;560:1–11, based on data from Nakayama H, Smith CA, Rodman JR, et al. Effect of ventilatory drive on carbon dioxide sensitivity below eupnea during sleep. *Am J Respir Crit Care Med.* 2002;165:1251–1260.)

Operation of Chemical Feedback

The ventilator mode is a major determinant of driving pressure for flow and thus arterial blood gases. Before discussing the operation of chemical feedback, it is useful to review briefly the functional features of three main modes of assisted ventilation, namely, assist-control ventilation (ACV), pressure-support ventilation (PSV), and proportional-assist ventilation (PAV) (for detailed descriptions, see Chapters 6, 8, and 12). Figure 35-5 shows the response of the ventilator to respiratory effort in a representative subject ventilated with each mode in the presence and absence of CO_2 challenge.[16] With CO_2 challenge, Paw decreases with ACV, it remains constant with PSV, and it increases with PAV. Pressure-time product of inspiratory muscle pressure (PTP-$Pmus_I$) is an accurate index of the intensity of inspiratory effort.[43] With ACV, the ratio of V_T to PTP-$Pmus_I$ per breath (neuroventilatory coupling) decreases with increasing Pmus; the ratio is largely independent of inspiratory effort with PAV. With PSV, V_T/PTP-$Pmus_I$ per breath may change in either direction with increasing Pmus, depending on factors such as the level of pressure assist and cycling-off criterion, change in Pmus, and mechanics of the respiratory system. With PSV, in the absence of active termination of pressure delivery (with expiratory muscle contraction), the ventilator delivers a minimum V_T, which may be quite high, depending on the pressure level, mechanics of the respiratory system, and cycling-off criterion.[19]

Assume that in a ventilated patient Pa_{CO_2} drops because of an increase in the set level of assistance or decrease in metabolic rate and/or V_D/V_T ratio.[44] During wakefulness, patients will react to this drop by decreasing the intensity of their inspiratory effort, whereas the breathing frequency will remain relatively constant (see "Response of Respiratory Motor Output to Chemical Stimuli," above). The extent to which a patient is able to prevent respiratory alkalosis via operation of chemical feedback depends almost exclusively on the relationship between the intensity of patient inspiratory effort and the volume delivered by the ventilator (i.e., V_T/PTP-$Pmus_I$). Similarly, if Pa_{CO_2} increases (decrease in assistance level, increase in metabolic rate and/or V_D/V_T ratio), the patient will increase the intensity of inspiratory effort and, to much lesser extent, respiratory frequency. Thus, V_T/PTP-$Pmus_I$ per breath is critical for the effectiveness of chemical feedback to compensate for changes in chemical stimuli (Pa_{CO_2}). For given respiratory system mechanics, V_T/PTP-$Pmus_I$ is heavily dependent on the mode of support. Thus, the effectiveness of chemical feedback in compensating for changes in chemical stimuli should be mode-dependent. Modes of support that permit the intensity of patient inspiratory effort to be expressed on ventilator-delivered volume improve the effectiveness of chemical feedback in regulating Pa_{CO_2} and particularly in

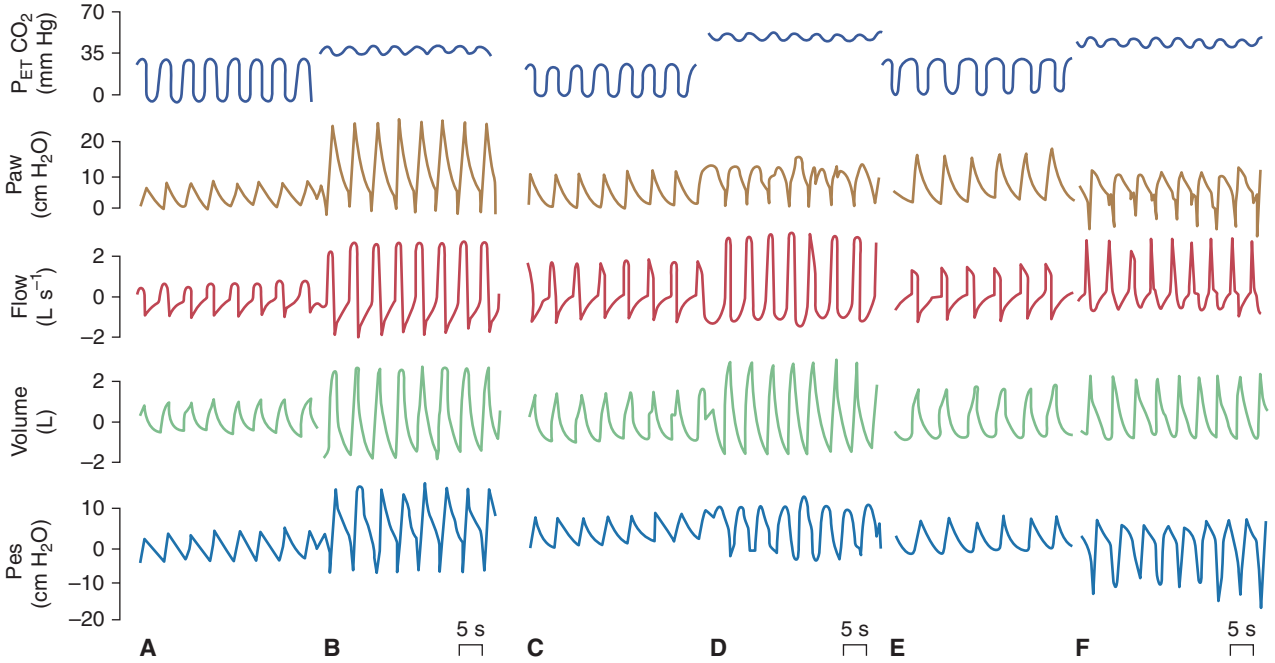

FIGURE 35-5 End-tidal carbon dioxide tension ($P_{ET}CO_2$), airway pressure (*Paw*), flow (inspiration up), volume (inspiration up), and esophageal (*Pes*) pressure in a representative subject during proportional-assist ventilation (**A**, **B**), pressure-support ventilation (**C**, **D**), and volume-control ventilation (**E**, **F**) in the absence (**A**, **C**, **E**) and presence (**B**, **D**, **F**) of CO_2 challenge. With CO_2 challenge, Paw decreases with assist-control ventilation (the ventilator antagonizes patient's effort); it remains constant with pressure-support ventilation (no relationship between patient effort and level of assist); and it increases with proportional-assist ventilation (positive relationship between effort and pressure assist). (Used, with permission from Mitrouska J, Xirouchaki N, Patakas D, et al. Effects of chemical feedback on respiratory motor and ventilatory output during different modes of assisted mechanical ventilation. *Eur Respir J.* 1999;13:873–882.)

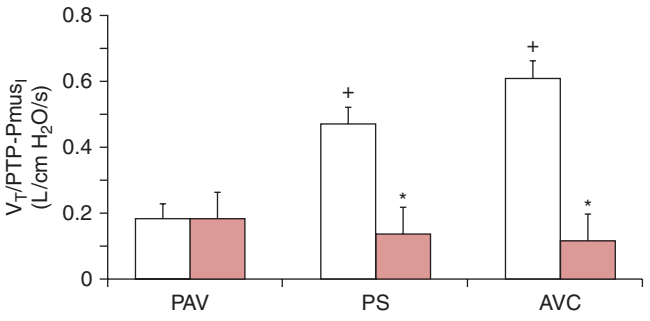

FIGURE 35-6 Ratio (mean ± SD) of tidal volume to pressure–time product of inspiratory muscles ($V_T/PTP\text{-}Pmus_I$) in normal, conscious subjects ventilated with three modes of assisted ventilation in the absence and presence of CO_2 challenge (inspired CO_2 concentration increased in small steps until intolerance developed). *Open* and *closed bars* represent zero and final (highest) concentration of inspired CO_2, respectively. *AVC,* assist-volume control; *PAV,* proportional-assist ventilation; *PS,* pressure-support ventilation. *Asterisk* indicates significant difference from the value without CO_2 challenge. *Plus* sign indicates significant difference from the corresponding value with PAV. With each mode, subjects were ventilated at the highest comfortable level of assistance (corresponding to 80% reduction of patient resistance and elastance with PAV, 10 cm H_2O of pressure support, and 1.2-L tidal volume with AVC). With CO_2 challenge, V_T/PTP-Pmus$_I$, decreased significantly when the subjects were ventilated with PS and AVC, but it remained relatively constant with PAV. Without CO_2 challenge, V_T/PTP-Pmus$_I$ was significantly higher with PS and AVC than with PAV. This response pattern caused severe respiratory alkalosis with PS and AVC ($P_{ET}CO_2$ decreased to approximately 22 mm Hg with both modes) but not with PAV ($P_{ET}CO_2$ approximately 30 mm Hg). Unlike with PS and PAV, subjects ventilated with AVC could not tolerate high values of $P_{ET}CO_2$ (final $P_{ET}CO_2$ was approximately 7, 11, and 13 mm Hg higher than baseline eupnea, respectively, with AVC, PS, and PAV). (Based on data from Mitrouska et al.[16])

preventing respiratory alkalosis. In normal conscious subjects receiving maximum assistance on the three main ventilator modes,[16] the ability of the subject to regulate Pa_{CO_2} depends on the operational principles of each mode, specifically in terms of V_T/PTP-Pmus$_I$ (Fig. 35-6). At all levels of CO_2 stimulation, preservation of neuroventilatory coupling increased progressively from ACV to PSV to PAV; the ability of subjects to regulate Pa_{CO_2} followed the same pattern.[16]

Neurally adjusted ventilatory assist (NAVA) is a new mode of support that, similar to PAV, uses patient effort to drive the ventilator.[45–47] The electrical activity of the diaphragm is obtained with a special designed esophageal catheter and serves as a signal to link inspiratory effort to ventilator pressure (see Chapter 13). Because neuroventilatory coupling is preserved, the principles described above also apply to NAVA.[46,47]

During sleep or sedation, the tendency to develop hypocapnia with ACV and PSV (see Chapter 57 for the effects of mechanical ventilation on sleep) may have serious consequences because a drop of a few millimeters of mercury in Pa_{CO_2} leads to apnea and periodic breathing.[8,19] Thus, excessive assistance with ACV and PSV promotes unstable breathing secondary to impaired neuroventilatory coupling; controller gain remains high in the face of low inspiratory effort (Fig. 35-7). Unstable breathing, however, during sleep secondary to mechanical ventilation may be prevented or attenuated with PAV and NAVA that does not guarantee a minimum V_T.[8,19,46,47] Modes that decrease the volume delivered by a ventilator in response to any reduction in the intensity of patient effort enhance breathing stability and may be associated with better sleep quality.[48] Nevertheless, if the assist setting during PAV or NAVA is such that controller gain increases considerably, and the inherent loop gain of the patient is relatively high, the patient will be at risk of developing unstable breathing.[23,33,41,49,50]

These principles may be altered by disease states and therapeutic interventions. Although little is known about the interaction between disease states and mechanical ventilation on control of breathing, two examples help in illustrating the point. First, in conscious patients with sleep apnea syndrome, a drop in Pa_{CO_2} because of brief (40 seconds) hypoxic hyperventilation resulted, contrary to healthy subjects, in significant hypoventilation and triggering of periodic breathing in some patients.[51] This hypoventilation was interpreted as evidence of a defect (or reduced effectiveness) of short-term poststimulus potentiation, a brainstem mechanism that promotes ventilatory stability.[51] In this situation, a level of assistance that causes a significant decrease in Pa_{CO_2} may promote unstable breathing in awake patients with sleep apnea syndrome, a situation closely resembling that observed during sleep. Second, studies in ventilated critically ill patients have shown that when awake patients are unable to increase V_T appropriately as a result of the mode used (i.e., PSV), they increase respiratory rate in response to a chemical challenge.[52] Behavioral feedback, however, may underlie this response pattern. In sedated patients with acute respiratory distress syndrome (in whom behavioral feedback is not an issue) receiving PSV, considerable variation in Pa_{CO_2} elicited a steady-state response limited to the intensity of breathing effort, a response pattern similar to that observed in normal subjects.[9,16]

Neuromechanical Feedback

INTRINSIC PROPERTIES OF RESPIRATORY MUSCLES

For a given neural output, Pmus decreases with increasing lung volume and flow, as dictated by the force-length and force-velocity relationships of inspiratory muscles, respectively.[53] Therefore, for a given level of muscle activation, Pmus should be smaller during mechanical ventilation than during spontaneous breathing if pressure provided by the ventilator results in greater flow and volume. It has been shown in healthy subjects ventilated with PSV that, compared with spontaneous breathing, the relationship between electrical activity (Edi) and pressure-time product of diaphragm (PTPdi) is shifted to the left; thus, at any given level of Edi, PTPdi is reduced.[54]

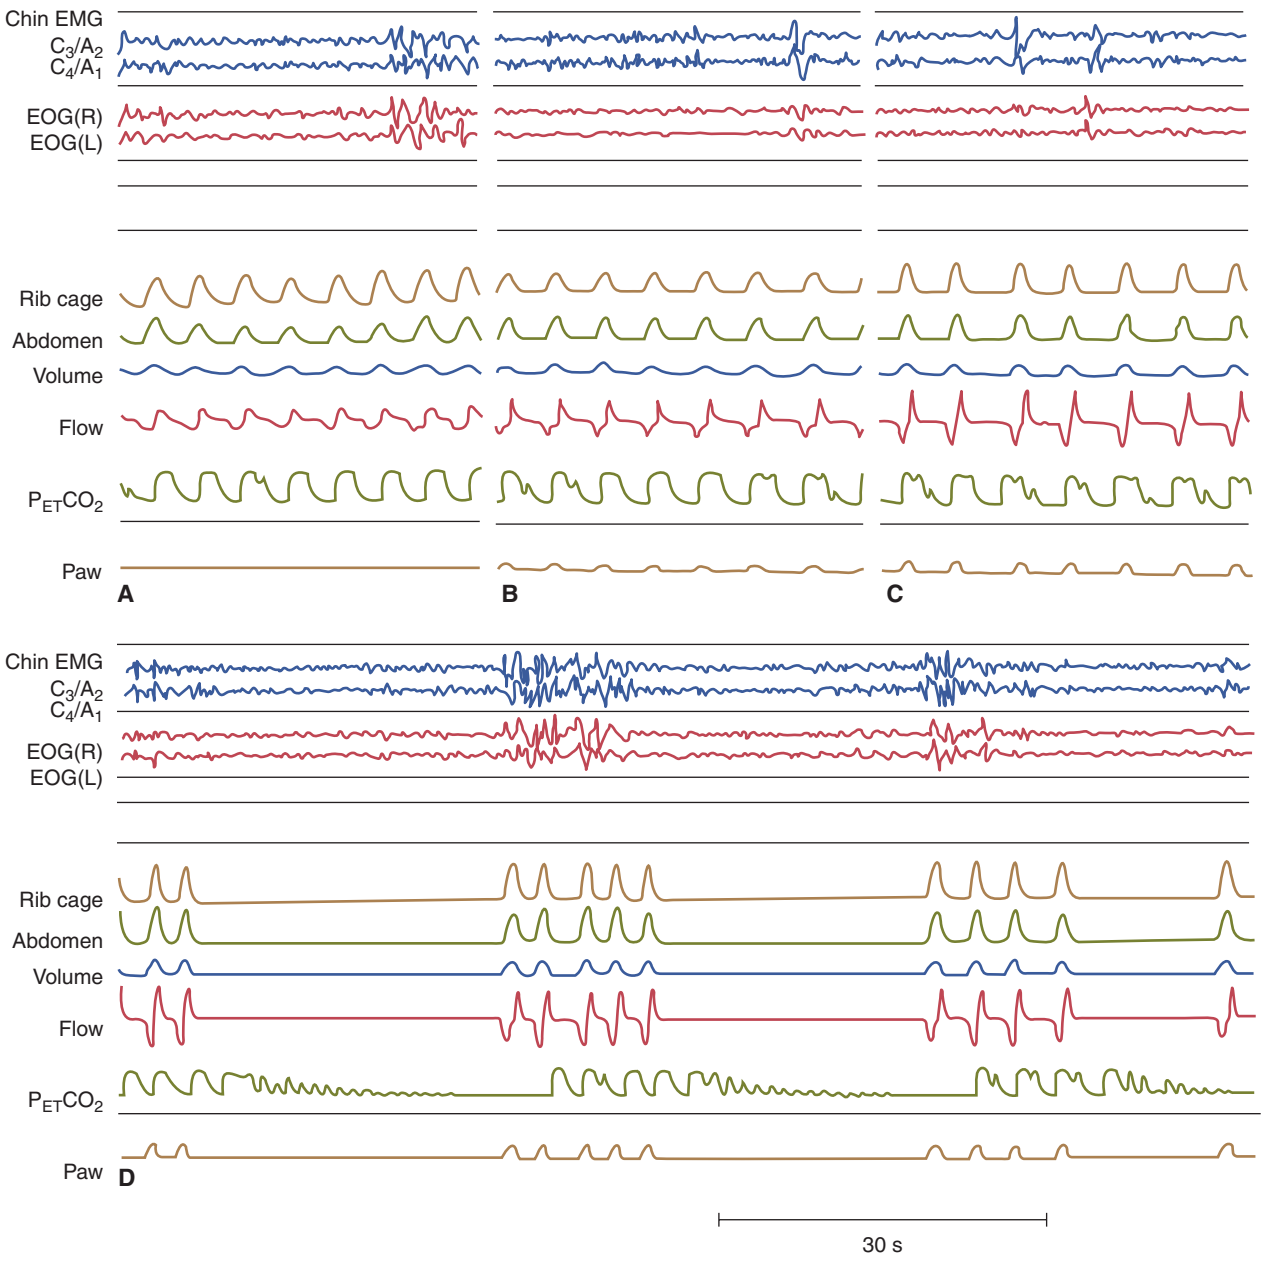

FIGURE 35-7 Polygraph tracings in a healthy subject during non-rapid eye movement sleep with and without pressure-support ventilation. (**A**) Spontaneous breathing with continuous positive airway pressure (CPAP). (**B**) to (**D**) Pressure support of 3, 6, and 8 cm H_2O, respectively. The influence and consequences of mechanical feedback during mechanical ventilation have not been studied satisfactorily. It is possible that this type of feedback is of clinical significance in patients with dynamic hyperinflation (high end-expiratory lung volume), high ventilatory requirements (requirements for high flow and volume), and/or impaired neuromuscular capacity.

REFLEX FEEDBACK

The characteristics of each breath are influenced by various reflexes that are related to lung volume or flow and mediated, after a latency of a few milliseconds, by receptors located in the respiratory tract, lung, and chest wall.[5,6] Mechanical ventilation may stimulate these receptors by changing flow and volume. In addition, changes in

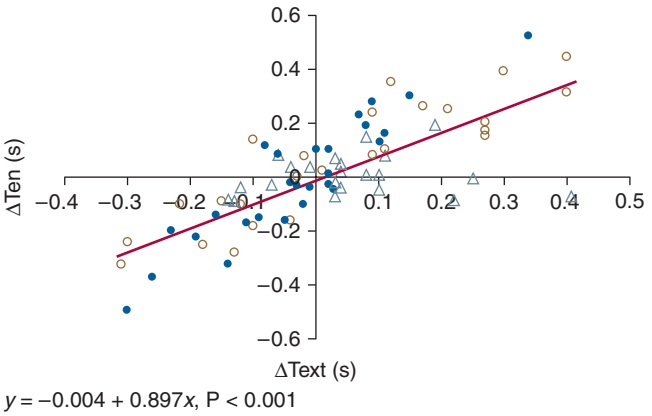

FIGURE 35-8 Relationship between the changes in the time that mechanical inspiration extended into neural expiration (Δ*Text,* expiratory asynchrony) and neural expiratory time (Δ*Ten*) in mechanically ventilated patients with acute respiratory distress syndrome. Closed circles, open circles, and open triangles represent ΔText induced by changes in volume (at constant flow), flow (at constant volume), and pressure support, respectively. Solid line, regression line. (Based on data from Kondili E, Prinianakis G, Anastasaki M, Georgopoulos D. Acute effects of ventilator settings on respiratory motor output in patients with acute lung injury. *Intensive Care Med.* 2001;27:1147–1157.)

ventilator settings, inevitably associated with changes in volume and flow, also may elicit acute Pmus responses mediated by reflex feedback. In sedated patients with acute respiratory distress syndrome, manipulation of ventilator settings altered immediately (within one breath) the neural respiratory timing, whereas respiratory drive remained constant.[9,55] Specifically, decreases in V_T and pressure support and increases in inspiratory flow caused an increase in respiratory frequency. Depending on the type of alteration, changes in respiratory frequency were mediated via alteration in neural inspiratory and expiratory time; increases in inspiratory flow caused increases in respiratory frequency mainly by decreasing neural inspiratory time; decreases in V_T and pressure support caused increases in respiratory frequency by decreasing neural expiratory time. This reflex response was similar, at least qualitatively, to that observed in healthy subjects during wakefulness and sleep.[56–60] There was a strong dependency of neural expiratory time on the time that mechanical inflation extended into neural expiration; neural expiratory time increased proportionally to the increase in the delay between the ventilator cycling off and the end of neural inspiratory time (Fig. 35-8).[9,55] This finding indicates that expiratory asynchrony may elicit a reflex timing response. A subsequent study in a general intensive care unit population confirmed the dependency of neural expiratory time on expiratory asynchrony.[61] The most likely explanation for the timing response is the Herring-Breuer reflex.

The final response may be unpredictable depending on the magnitude and type of lung volume change, the level of consciousness, and the relative strength of the reflexes involved. Nevertheless, reflex feedback should be taken into account when ventilator strategies are planned. A few examples may help in illustrating the importance of reflex feedback in patient–ventilator interaction. Assume that the patient is receiving pressure support that is being decreased during weaning. This results in lower V_T, which through reflex feedback decreases neural expiratory time, causing an increase in respiratory frequency.[9,55] This increase should not be interpreted as patient intolerance to the decrease in pressure support. Consider another patient with obstructive lung disease receiving ACV. V_T is decreased at a constant inspiratory flow so as to reduce the magnitude of dynamic hyperinflation (less volume is exhaled over a longer period). The lower V_T usually results in less delay in breath termination as compared with the end of neural inspiration, which through vagal feedback will decrease neural expiratory time, limiting the effectiveness of this strategy for reducing dynamic hyperinflation.[55] Assume in another patient receiving ACV that inspiratory flow is increased at a constant V_T, with the intent of reducing inflation time and providing more time for expiration so as to reduce dynamic hyperinflation. This step causes a reflex decrease in neural inspiratory time and an increase in respiratory frequency. Mechanical expiratory time may change in either direction depending mainly on the relation between neural and mechanical inspiratory time. In patients receiving ACV, expiratory time showed a variable response to changes in flow rate; some patients actually demonstrate a reduced expiratory time with a higher flow,[62] which cancels the desired reduction in dynamic hyperinflation.

There are neural reflexes that inhibit inspiratory muscle activity if lung distension exceeds a certain threshold, which is well below total lung capacity (Hering-Breuer reflex).[6,63,64] These reflexes protect the lung from overdistension, which is associated with lung injury.[65,66] Pressure-control or volume-control modes of assisted ventilation considerable interfere with the ability of these reflexes to regulate tidal volume.[16,67] With these modes, as a result of neuroventilatory uncoupling (high V_T/PTP-$Pmus_I$), overassistance may result in high tidal volume leading to regional or global lung overdistension. Conversely, recent evidence indicates that ventilator modes that permit reflex feedback to regulate the tidal volume and respiratory rate (viz., NAVA, PAV) may protect against or lessen ventilator-induced lung injury.

Brander et al[68] randomized anesthetized rabbits with early experimental acute lung injury into three ventilator strategies: NAVA (nonparalyzed), volume control with tidal volume of 6 mL/kg (paralyzed, protective strategy), and volume control with tidal volume of 5 mL/kg (paralyzed, injurious strategy). Animals randomized to NAVA selected an average tidal volume of 2.7 ± 0.9 mL/kg and respiratory rate up to three times higher than that in both controlled ventilation groups—a breathing-pattern response that can be explained by vagally controlled reflexes.[6,63,64] Compared to the 15 mL/kg group, animals ventilated with either NAVA or volume control at 6 mL/kg exhibited less ventilator-induced lung injury, as indicated by lung injury scores, lung wet-to-dry ratio, and lung and systemic biomarkers (Fig. 35-9). These

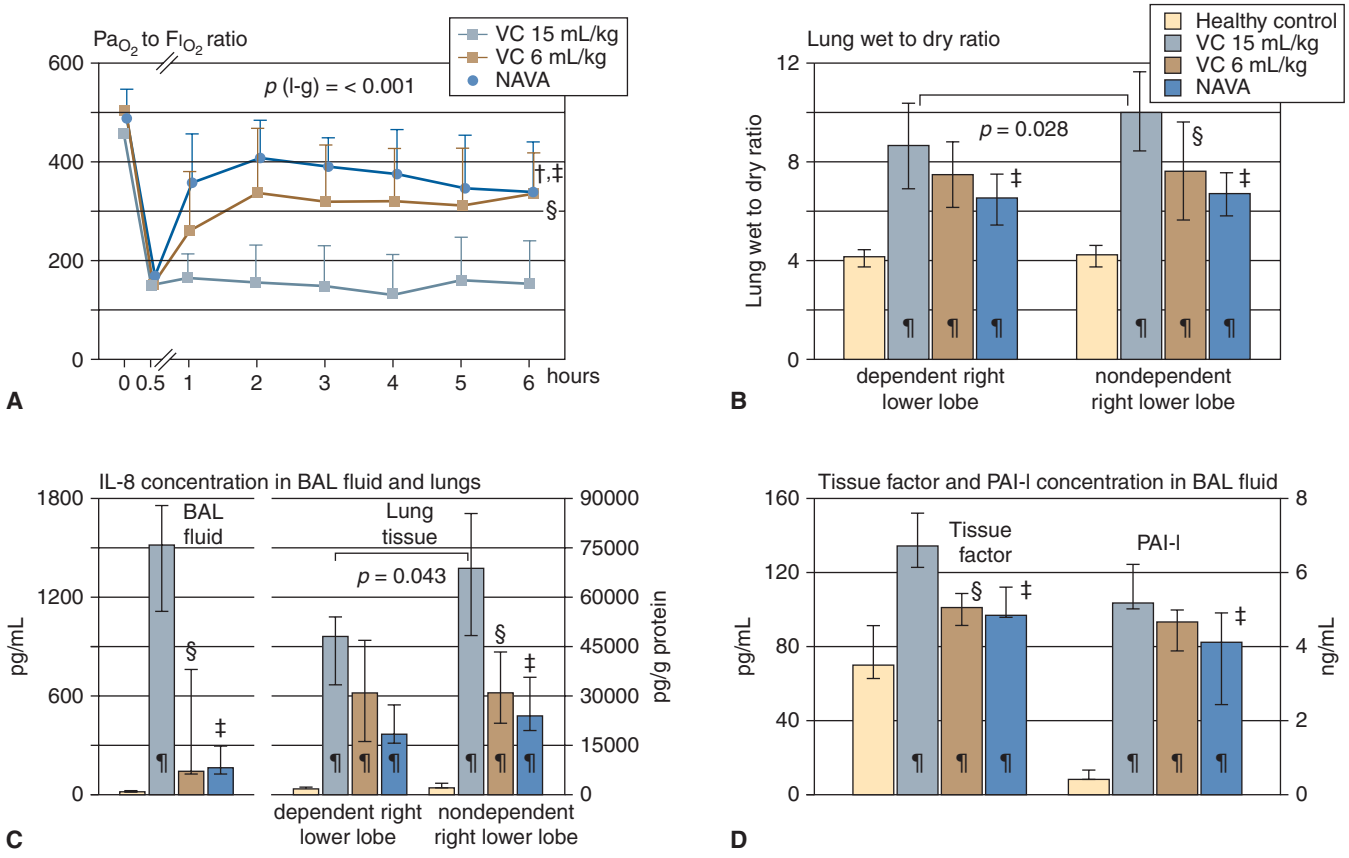

FIGURE 35-9 Parameters indicative of ventilator-induced lung injury (VILI) in rabbits with induced acute lung injury (ALI) and ventilated with three strategies: NAVA, volume control with tidal volume (V_T) of 6 mL/kg, and volume control with V_T of 15 mL/kg. (**A**) There were no differences in partial pressure of arterial oxygen to fractional inspired oxygen concentration ratio (Pa_{O_2}/FI_{O_2}) among groups before and 30 minutes after induction of ALI. The increase in Pa_{O_2}/FI_{O_2} shortly after switching to the assigned ventilation mode (i.e., after randomization into the treatment groups) was more pronounced with NAVA than with volume control (VC) 6-mL/kg ($p < 0.05$ post hoc analysis), although Pa_{O_2}/FI_{O_2} was not different between NAVA and VC 6-mL/kg at the end of the protocol. With VC 15-mL/kg, Pa_{O_2}/FI_{O_2} remained below 200. (**B**) The lung wet-to-dry ratio with NAVA and with VC 6-mL/kg was lower than with VC 15-mL/kg (albeit not significantly for the dependent lung in VC 6-mL/kg animals). (**C**) and (**D**) Interleukin 8 (IL-8), tissue factor, and plasminogen activator inhibitor type 1 (PAI-1) concentration in bronchoalveolar (BAL) fluid was higher in all study groups compared to healthy controls and was higher with VC 15-mL/kg than with the other two groups (except for PAI-1 in VC 6-mL/kg). Lung tissue IL-8 concentration was increased in all groups as compared to nonventilated controls and was highest in the nondependent lung regions with VC 15-mL/kg. In the VC 6-mL/kg and NAVA groups, lung tissue IL-8 concentration was lower compared to VC 15-mL/kg (albeit not significant for the dependent lung region). Groups are shown as mean ± standard deviation (SD) for *A* and *B*, or as median (quartiles) for *C* and *D*. *Symbols* represent group mean; *bars* indicate standard deviation. *e–g,* time–group interaction (two-way analysis of variance). Post hoc pairwise comparison procedure between groups: $^{\dagger}p$ <0.05 NAVA versus VC 6-mL/kg; $^{\ddagger}p$ <0.05 NAVA versus VC 15-mL/kg; $^{\S}p < 0.05$ VC 6-mL/kg versus VC 15-mL/kg. (Used, with permission, from Brander L, Sinderby C, Lecomte F, et al. Neurally adjusted ventilatory assist decreases ventilator-induced lung injury and non-pulmonary organ dysfunction in rabbits with acute lung injury. *Intensive Care Med.* 2009;35:1979–1989.)

results indicate that the use of NAVA, which allowed the animals to choose their own respiratory pattern, was at least as effective in preventing various manifestations of ventilator-induced lung injury as conventional, volume-controlled ventilation using a tidal volume of 6 mL/kg.

In a human study employing randomized design, Xirouchaki et al[69] ventilated 108 critically ill patients, most of whom had acute lung injury or acute respiratory distress syndrome, with PAV+ (PAV with automatic estimation of elastance and resistance of the respiratory system; see Chapter 12) Even with high assistance, tidal volume and end-inspiratory plateau pressure were comparable to these observed during protective controlled mechanical ventilation. Examination of individual end-inspiratory plateau pressures during PAV+ showed that out of a total of 744 measurements only on nine occasions (1.2%) and in five patients (4.6%) were plateau pressures above 30 cm H_2O (Fig. 35-10). Ninety-four percent of the end-inspiratory plateau pressures were below 26 cm H_2O, a value associated with lung protection.[70] Similar to the findings of Brander et al, these results can be explained by the operation of reflex feedback (vagally controlled reflexes).[6,63,64]

Is it possible to use this reflex feedback into a clinical scenario? Recent studies suggest that in patients with acute respiratory distress syndrome titration of tidal volume based on individual lung mechanics may be a better

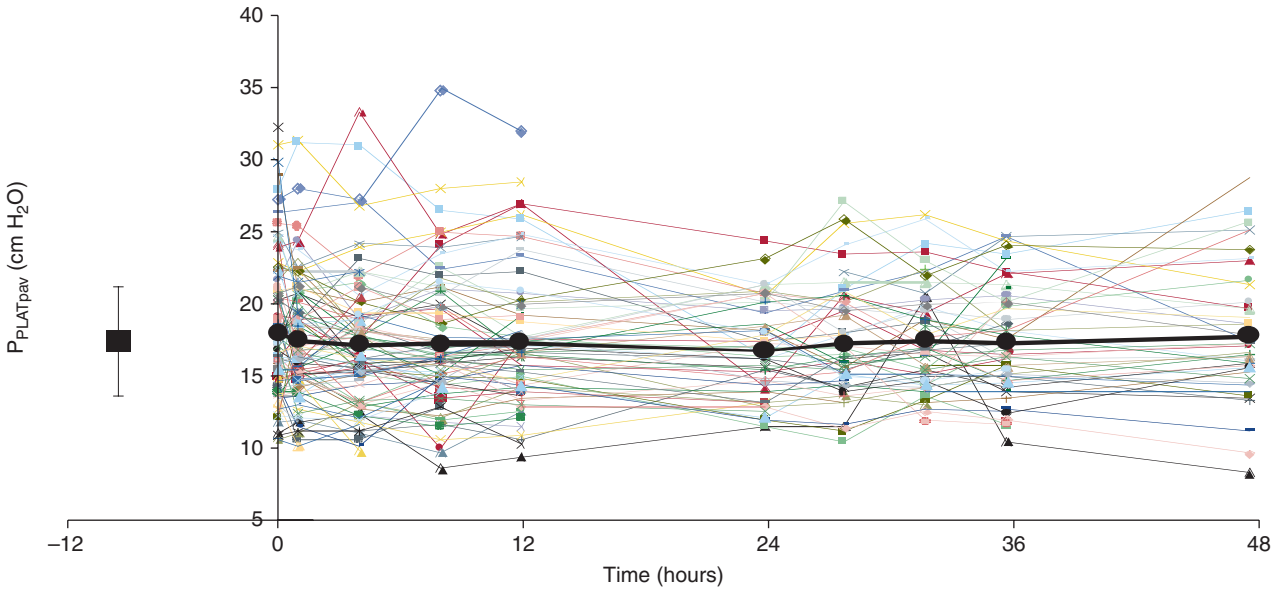

FIGURE 35-10 Individual values of quasi-static airway pressure obtained by 300 msec pause maneuver at the end of selected inspirations ($P_{PLATpav}$) as a function of time in 108 critically ill patients randomized (zero time) to proportional assist ventilation with load-adjustable gain factors (PAV+). PAV+ was continued for 48 hours unless the patients met predefined criteria, either for switching to controlled modes or for breathing without ventilator assistance. *Closed black circles* connected by solid thick line represent mean values. Each patient is denoted by a single color. For comparison the mean ± standard deviation (SD) values of static end-inspiratory airway pressure, obtained within 8 hours before randomization during controlled mechanical ventilation (CMV), is shown (*closed black square*). Notice that in the majority of the patients $P_{PLATpav}$ was below 26 cm H_2O. (Used, with permission, from Kondili et al. Patient–ventilator interaction. *Br J Anaesth.* 2003;91:106–119.)

strategy than using a fixed tidal volume (i.e., 6 mL/kg).[65,66,70–72] Obtaining lung mechanics, however, necessitates the use of cumbersome techniques not easily available at bedside. Theoretically, tidal volume selected by the patient should be based on individual lung mechanics, which serve as a guide for setting the ventilator.[73,74] Although studies support this hypothesis,[68,69] caution should be exercised in patients with strong signals of nonrespiratory origin (acidosis, brain dysfunction) that drive ventilation. Notwithstanding the limitations and feasibility of this approach, this hypothesis deserves further studies.

Neuromechanical Inhibition

Mechanical ventilation at relatively high tidal volume and ventilator frequency results in a non–chemically mediated decrease in respiratory motor output.[75–77] This decrease, referred to as *neuromechanical inhibition,* is manifested both in respiratory frequency and in amplitude of respiratory motor output. Neuromechanical inhibition lasts for several breaths after termination of mechanical ventilation, thus constituting a type of control system inertia and resetting of the spontaneous respiratory rhythm.[78] Although the mechanism underlying neuromechanical inhibition is not entirely clear, the Hering-Breuer reflex is the most plausible explanation. In addition, Sharshar et al[79] showed that mechanical ventilation reduces the excitability of cortical motor areas representing respiratory muscles. It is possible that mechanoreceptor feedback accounts for the depression of the motor-evoked potential of the diaphragm via vagal and other proprioceptive afferents to the respiratory center. The clinical relevance of neuromechanical inhibition is currently unknown. Available evidence suggests that its contribution to respiratory motor output in ventilated critically ill patients is rather minimal.[9,11,55]

ENTRAINMENT OF RESPIRATORY RHYTHM TO VENTILATOR RATE

Entrainment of respiratory rhythm to the ventilator rate implies a fixed, repetitive, temporal relationship between the onset of respiratory muscle contraction and the onset of a mechanical breath.[80–82] Human subjects exhibit one-to-one entrainment over a considerable range above and below the spontaneous breathing frequency.[83,84] Cortical influences (learning or adaptation response) and the Hering-Breuer reflex are postulated as the predominant mechanisms of entrainment. Theoretically, one-to-one entrainment should facilitate patient–ventilator synchrony, but studies of the entrainment response in critically ill patients are lacking.

Behavioral Feedback

The effects of behavioral feedback on control of breathing in ventilated patients are unpredictable, depending on several factors related to the individual patient and

surroundings. Alteration in ventilator settings, planned to achieve a particular goal, might be ineffective in awake patients because of behavioral feedback.[85,86] Inappropriate ventilator settings may cause breathing discomfort in awake patients. Consequent panic reactions further aggravate the unpleasant breathing sensation and create a vicious cycle. Behavioral feedback also may be altered considerably from time to time secondary to changes in the level of sedation, sleep–awake state, patient status, and environmental stimuli. The many factors involved in behavioral feedback complicate its study and the interpretation of its effects on the system that controls breathing in mechanically ventilated patients.

INTERACTIVE EFFECTS OF PATIENT-RELATED FACTORS AND VENTILATOR ON CONTROL OF BREATHING

Mechanics of Respiratory System

The mechanical properties of the respiratory system may influence the pressure delivered by the ventilator independent of patient effort and thus may modify the effects of mechanical ventilation on the various feedback loops. Excessive triggering delay and ineffective triggering are common in patients with obstructive lung disease and dynamic hyperinflation (Fig. 35-11). In the setting of airflow obstruction, mathematical models predict that PSV can be accompanied by marked variation in V_T and intrinsic positive end-expiratory pressure even when patient effort is constant.[87] This dynamic instability increases as the time constant of the respiratory system increases and produces patient–ventilator asynchrony of variable magnitude and type. The demonstration of increased arousals during PSV, but not during volume-cycled ventilation, may be caused in part by dynamic patient–ventilator asynchrony.[21]

Ineffective triggering has been observed with all modes of assisted ventilation. It is particularly common with tachypnea and when the level of assistance is relatively high and mechanical inflation extends well into neural expiration.[11,67,88,89] With PAV and NAVA, the likelihood of ineffective efforts is reduced significantly because mechanical inflation time is terminated close to the end of neural inspiration, and tidal volume in most cases remains relatively small.[46,47,67,69]

The phenomenon of ineffective efforts considerably influences the interpretation of ventilatory output in relation to the control of breathing during mechanical ventilation.[3,4] In the presence of ineffective efforts, ventilator frequency does not reflect the patient's spontaneous respiratory rate

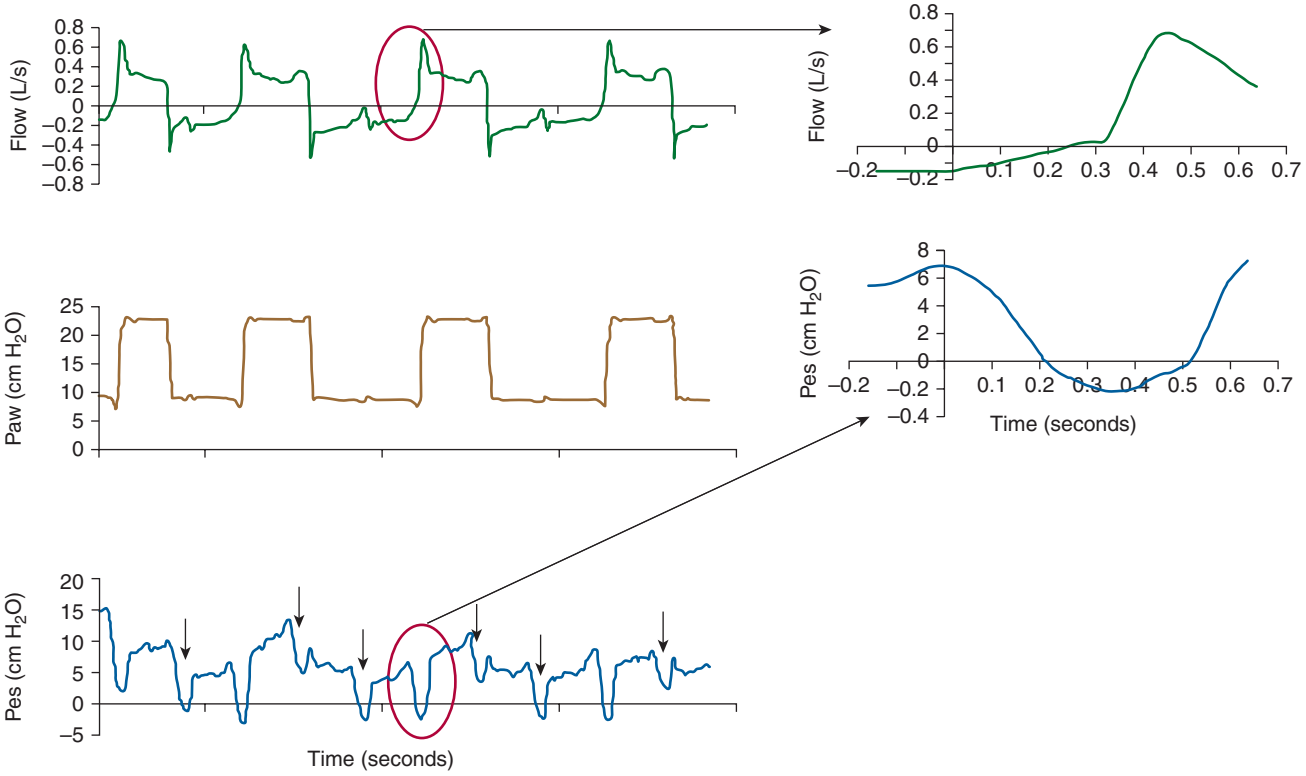

FIGURE 35-11 Airflow (inspiration up), airway pressure (*Paw*), and esophageal pressure (*Pes*) in a patient with obstructive lung disease ventilated with pressure support. Note the triggering delay with every mechanical breath (see the magnified tracing of flow and Pes) and the ineffective efforts (*arrows*). The ventilator rate was 12 breaths/min, whereas the patient's respiratory frequency was 35 breaths/min. Extrapolation from ventilator rate to the patient's system of control of breathing is misleading (Used, with permission, from Springer Science and Business Media: Brander, et al. *Intensive Care Med.* 2009;35:1979–1989.)

(see Fig. 35-11). Moreover, with ineffective efforts, significant alteration in a patient's respiratory effort occurs secondary to changes in feedback loop.

Characteristics of the Muscle Pressure Waveform

The characteristics of the Pmus waveform influence the ventilator-delivered volume in a complex manner, depending on several patient and ventilator factors. Extensive review of these factors is beyond the scope of this chapter, but some examples are provided.

The initial rate of increase in Pmus interacts with triggering of the ventilator.[11] A low rate of initial increase in Pmus occurs with a concave upward shape of Pmus or a low respiratory drive (such as with low Pa_{CO_2}, sedation, sleep, or a high level of assistance); this increases the time delay between the onset of patient inspiratory effort and ventilator triggering and promotes asynchrony. In the presence of dynamic hyperinflation, a prolonged triggering time, particularly when associated with a relatively short neural inspiratory time and low peak Pmus, may result in ineffective efforts. Alternatively, an increase in the intensity of inspiratory effort, such as occurs with an increase in metabolic rate, high Pa_{CO_2}, or decrease in the level of sedation or assistance, is manifested both in the rate of rise and in the peak of Pmus. The change may cause a decrease in the time delay, thus promoting patient–ventilator synchrony.[11] If, however, patient inspiratory effort is vigorous and longer than mechanical inflation time, the ventilator may be triggered more than once during the same inspiratory effort (Fig. 35-12).[3,90] It follows that changes in the characteristics of the Pmus waveform may influence the ventilator rate and ventilatory output despite no change in a patient's breathing frequency. Alterations in ventilatory output may secondarily modify patient effort through changes in feedback loops (see Fig. 35-1).

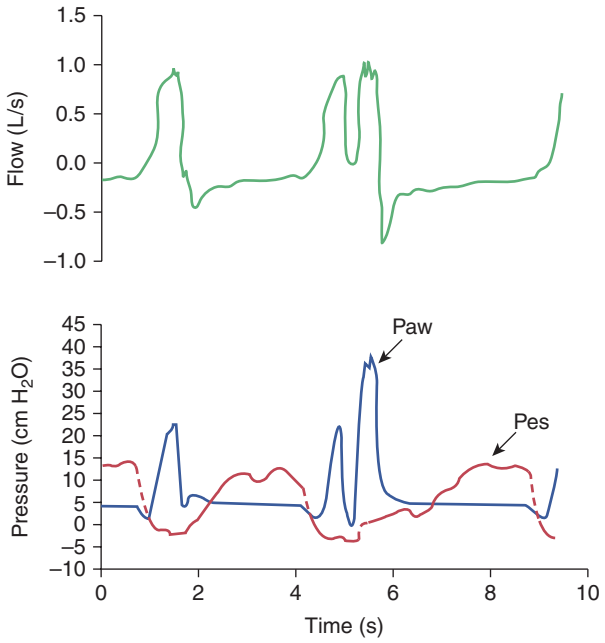

FIGURE 35-12 Flow, airway pressure (Paw), and esophageal pressure (Pes) in a patient recovering from acute lung injury and ventilated on assist volume control at constant inspiratory flow. In the second breath, tidal volume (volume was not shown) was decreased at constant inspiratory flow. As a result, there was premature termination of mechanical inspiration. Because the inspiratory muscles continued to contract, they developed sufficient pressure to overcome elastic recoil at end inspiration. As a result, Paw decreased below the triggering threshold, and the ventilator delivered a new mechanical breath. The ventilator was triggered three times by the two inspiratory efforts. Note the high Paw of the third mechanical breath secondary to high lung volume (the volume of the third breath was added to that of the second). Total breath duration of the second respiratory effort was considerably longer than that of the first effort owing to activation of Hering-Breuer reflex by the high volume. (Used, with permission, from Springer Science and Business Media: Xirouchaki, et al. Intensive Care Med. 2008;34:2026–2034.)

THE FUTURE

Over the past two decades, many studies have been performed in animals and human subjects with an aim of improving a patient's ability to control the ventilator. Various ventilator modes target either an improvement in the response of the ventilator to patient effort or tight coupling between the ventilator-delivered pressure and patient instantaneous ventilatory demands. Studies of these modes have yielded promising results. New methods of triggering have been shown to improve the response of the ventilator to patient effort.[45,91–93] Algorithms that automatically adjust the criterion for cycling off have been designed with a goal of reducing expiratory asynchrony.[94] Estimates of the inspiratory muscle pressure waveform may also be used to terminate pressure delivery, and these, theoretically, should improve patient–ventilator synchrony.[93] Mechanical[92] and electrical[46,95] activity of the diaphragm has been used to control the level and duration of inspiratory assistance. With PAV, methods of noninvasive automatic estimation of elastance and resistance of the respiratory system are now available (PAV+),[96,97] which enable controller gain to be maintained constant in the face of changes in the mechanical load of respiratory system[98] and result in fewer intervention in terms of ventilator settings compared to other modes.[99] Algorithms that use a signal generated from flow, volume, and airway pressure may be used to provide breath-by-breath quantitative information of inspiratory muscle pressure,[100] and this approach also may be used in the future to facilitate patient–ventilator synchrony. By achieving tight coupling between neural output and ventilator-delivered pressure, the ventilator is able to serve as a respiratory muscle with high capabilities and operate in harmony with the system that controls breathing. Nowadays, it seems feasible to shift from the physician who dictates the pattern of ventilation to the patient who chooses to breathe with a pattern that incorporates all the aspects of control of breathing. Because the control of ventilation is much more complex

than simply regulating blood gases, it is likely that the patient can do a better job than physicians can.

Negative-feedback methods, such as adaptive pressure-support servoventilation, have been designed recently with a goal of reducing periodic breathing through appropriate changes in the level of assistance and maintaining a target minute ventilation in the face of waxing and waning respiratory efforts.[82,101] Incorporation of this approach in assisted modes may decrease the propensity of high-risk individuals to develop periodic breathing. It is not known whether this mode could decrease morbidity in critically ill patients, although it should enhance sleep efficiency.[22,23]

CONCLUSION

Incorporating an auxiliary pressure into the system that controls breathing changes the volume–time profile of a breath. It also alters, via chemical, neuromechanical, and behavioral feedback, the pressure developed by the respiratory muscles. The latter, depending on ventilator and patient factors, may or may not modify the auxiliary pressure. The response of patient effort to a ventilator-delivered breath and the response of a ventilator to patient effort are the two essential components of control of breathing during mechanical ventilation. The physician dealing with a ventilated patient should be aware that both the basic features of control of breathing and its expression can be altered considerably by the process of mechanical ventilation.

EFFECT OF MECHANICAL VENTILATION ON HEART–LUNG INTERACTIONS

Hernando Gomez
Michael R. Pinsky

The heart and lungs are intimately coupled by their anatomical proximity within the thorax and, more importantly, by their responsibility to deliver the O_2 requirements of individual cells and organs while excreting the CO_2 by-product of metabolism. During critical illness, if these two organ systems fail, either alone or in combination, the end result is an inadequate O_2 delivery to the body with inevitable tissue ischemia, progressive organ dysfunction, and if untreated, death. Thus, restoration and maintenance of normalized cardiopulmonary function is an essential and primary goal in the management of critically ill patients. Heart failure can impair gas exchange by inducing pulmonary edema and limiting blood flow to the respiratory muscles. Ventilation can alter cardiovascular function by altering lung volume, and intrathoracic pressure (ITP), and by increasing metabolic demands. These processes are discussed from the perspective of the impact that ventilation has on the cardiovascular system.

CLINICAL RELEVANCE

The ventilatory apparatus and the cardiovascular system have profound effects on each other.[1,2] Acute hypoxia impairs cardiac contractility and vascular smooth muscle tone, promoting cardiovascular collapse. Hypercarbia causes vasodilation and increases pulmonary vascular resistance. Hyperinflation increases pulmonary vascular resistance, which impedes right-ventricular (RV) ejection and also compresses the heart inside the cardiac fossa in a fashion analogous to tamponade. Lung collapse also increases pulmonary vascular resistance, impeding RV ejection.[3] Acute RV failure, or *cor pulmonale,* is not only difficult to treat, but it can induce immediate cardiovascular collapse and death.

Ventilator technologies and numerous vasoactive drugs have been developed as means to improve oxygenation of arterial blood. These advances are the subjects of other chapters in this volume. The complex interactions, however,

between the heart, circulation, and lungs often leads to a paradoxical worsening of one organ system function while the function of the other is either maintained or even improved by the use of these technologies and drugs. To minimize these deleterious events, and in the hope of more efficiently and effectively treating critical ill patients with cardiorespiratory failure, a better knowledge and understanding of the integrated behavior of the cardiopulmonary system, during both health and critical illness is essential. Based on this perspective, the health care provider can more appropriately manage this complex and challenging group of patients.

Respiratory function alters cardiovascular function and cardiovascular function alters respiratory function. A useful way to consider the cardiovascular effects of ventilation is to group them by their impact on the determinants of cardiac performance. The determinants of cardiac function can be grouped into four interrelated processes: *heart rate, preload, contractility,* and *afterload.* Phasic changes in lung volume and ITP can simultaneously change all four of these hemodynamic determinants for both ventricles. Our current understanding of cardiovascular function also emphasizes both the independence and interdependence of RV and left-ventricular (LV) performance on each other and to external stresses. Complicating these matters further, the direction of interdependence, from right to left or left to right, can be similar or opposite in direction, depending on the baseline cardiovascular state. It is clear, therefore, that a comprehensive understanding of the specific cardiopulmonary interactions and their relative importance in defining a specific cardiovascular state is a nearly impossible goal to achieve in most patients. By understanding the components of this process, however, one can come to a better realization of its determinants, and, to a greater or lesser degree for any individual patient, predict the limits of these interactions and how the patient may respond to stresses imposed by either adding or removing artificial ventilatory support.

PHYSIOLOGY OF HEART–LUNG INTERACTIONS

Both spontaneous and positive-pressure ventilation increase lung volume above an end-expiratory baseline. Many of the hemodynamic effects of all forms of ventilation are similar despite differences in the mode of ventilation. ITP, however, decreases during spontaneous inspiration and increases during positive-pressure ventilation. Thus, the primary reasons for different hemodynamic responses seen during spontaneous and positive-pressure breathing are related to the changes in ITP and the energy necessary to produce those changes.

Effect of Lung Volume

Changing lung volume phasically alters autonomic tone and pulmonary vascular resistance. At very high lung volumes, the expanding lungs compress the heart in the cardiac fossa, limiting absolute cardiac volumes analogous to cardiac tamponade, except that with hyperinflation both pericardial pressure and ITP increase by a similar amount.

AUTONOMIC TONE
