
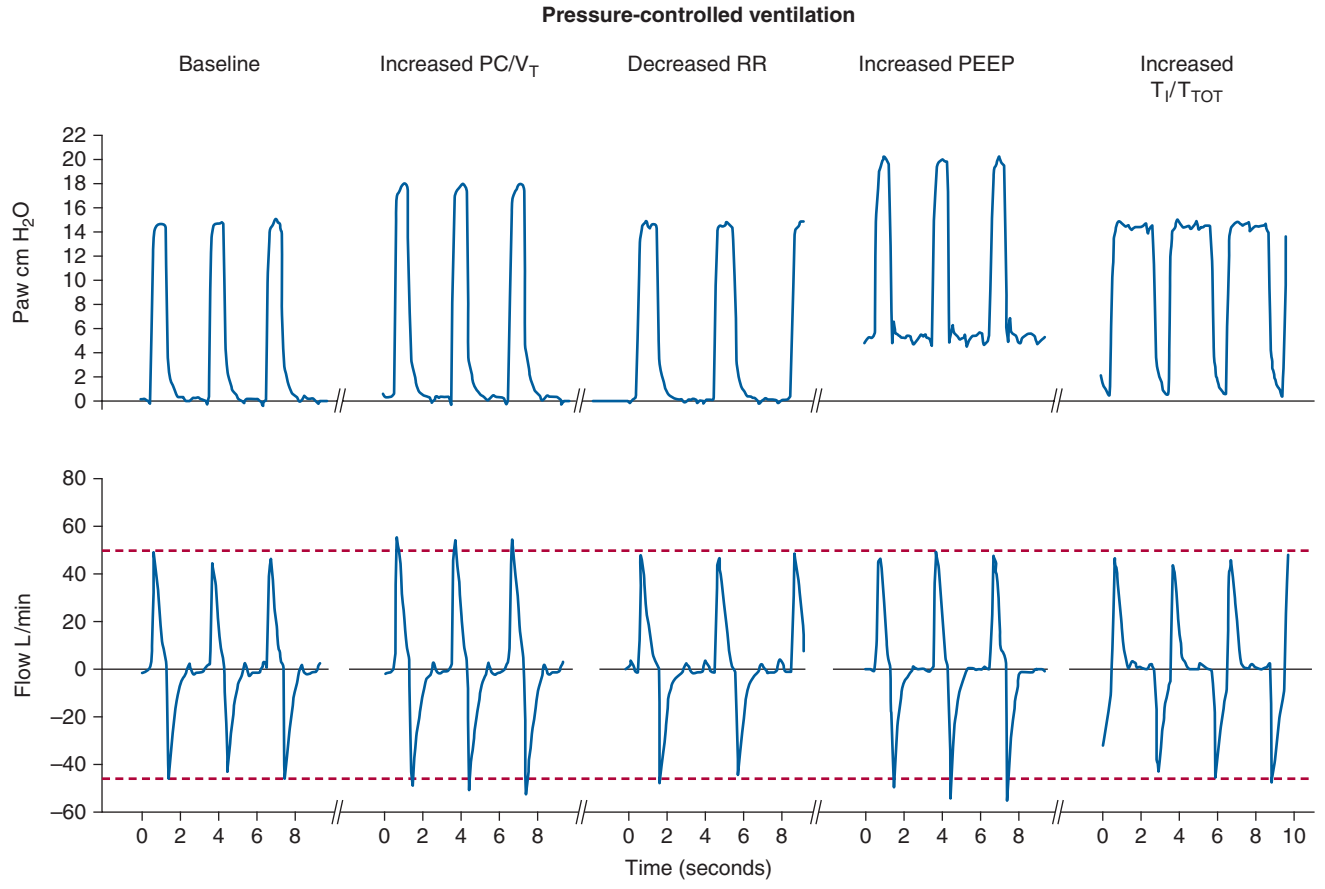

FIGURE 52-4 Pressure and flow waveforms during pressure-controlled ventilation in healthy pig (36 kg) obtained with a SERVO-i mechanical ventilator (Maquet, Wayne, NJ). The effects of pressure-limited modes of ventilation on airflow rates are more difficult to predict because inspiratory flow rate is partly related to the mechanical properties of the respiratory system. Inspiratory and expiratory flow rates generated through baseline ventilator settings (pressure control [*PC*] 14 cm H_2O, respiratory rate [*RR*] 20 breaths/min, duty cycle [T_I/T_{TOT}] 0.26) are compared to various adjustments of ventilator parameters. *Dotted red lines* indicate the highest inspiratory (47.2 L/min) and expiratory (−47.8 L/min) flow rates during baseline ventilation. Of note, only increases in pressure control from 14 to 17 cm H_2O produced an increase in inspiratory flow. Conversely, reducing respiratory rate to 15 breaths/min and increasing T_I/T_{TOT} to 0.75 decreased the inspiratory flow. Similarly to volume-controlled ventilation, changes in lung volume secondary to increased pressure control or positive end-expiratory pressure (*PEEP*; 5 cm H_2O) increased peak expiratory flow.

two-phase gas–liquid mechanism mainly depends on a balance between the airflow shear forces on the liquid layer and gravitational force. We have studied the effects of gravity in sheep,[39] positioned in a model of the semirecumbent position, and found that mucus, accumulated in the proximal trachea, moved in an abnormal backward direction toward and into the lungs (Fig. 52-5).

QUANTITATIVE ASSESSMENT OF SECRETION PRODUCTION AND REMOVAL

A quantitative assessment of mucus production and clearance in ventilated patients is essential to ascertain the benefits of novel therapeutic strategies; unfortunately, the methods for easy and reliable assessment at the bedside are still inadequate.

Mucus Production

The dynamics of mucin expression during mechanical ventilation are currently unknown and should be considered in future studies. Kirkham et al[4] first developed a Western blot analysis that allows quantitative measurement of different mucins from retrieved mucus. In clinical settings, mucus can be easily obtained during endotracheal suctioning and stored into a mucus trap. The volume of mucus should be quantified as soon as obtained so as to avoid quantification errors secondary to dehydration. Additionally, in daily clinical practice, it is also important to report qualitative characteristics of mucus, such as color and consistency, to promptly identify any acute or developing respiratory disease.[40]

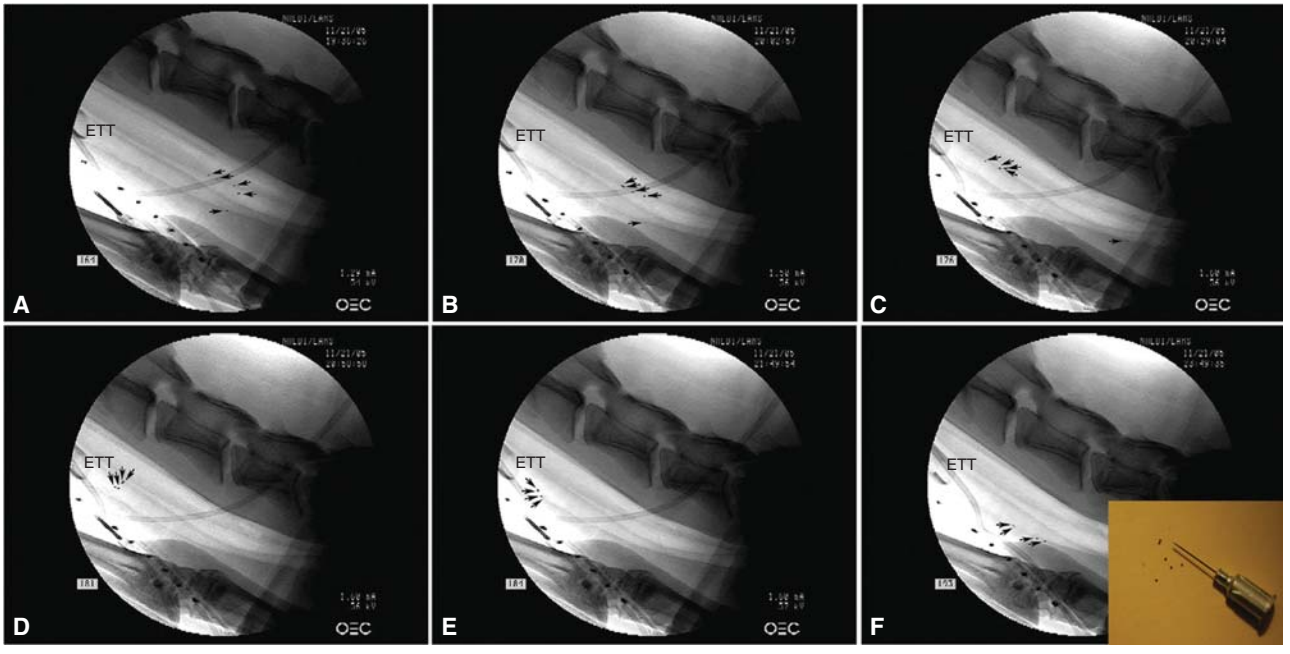

FIGURE 52-5 Tracheal mucus velocity studies in sheep after 12 hours of tracheal intubation and positioned with a tracheal orientation above horizontal. *Black/white arrows* indicate each tantalum disk, tracked to evaluate mucus transport. **A.** Following disk insufflation, five tantalum disks were deposited in the trachea; four disks were on the dorsal (nondependent) part of the trachea and one disk was on the ventral (dependent) part of the trachea (*black dots*). Fluoroscopic images taken (**B**) 24 minutes and (**C**) 59 minutes following insufflation show mucus transport toward the glottis on the nondependent part, while mucus on the dependent part of the trachea moves toward the lungs. **D** and **E.** After 80 minutes mucus almost reached the tip of the endotracheal tube, gravitated to the dependent part of the trachea, and (**F**) reversed flow back toward the lungs. The enclosed picture in F shows tantalum disks used for those experimental studies. Diameter, thickness, and weight of those disks are 0.60 mm, 0.10 mm, and 0.8 mg, respectively. (Adapted, with permission, from Li Bassi et al.[39])

Mucus Removal

The rate of mucus removal in vivo is assessed by measuring either (a) the velocity of traceable particles deposited within the trachea and/or bronchi or (b) the clearance rate of an inhaled radioactive tracer through a gamma camera. A brief description of the most common techniques are reported below and in Table 52-3, but it is important to note that most of these methods are difficult to apply in ventilated patients.

QUANTITATIVE ASSESSMENT VIA TRACEABLE PARTICLES

To measure the rate of mucus clearance, movement of a tracer needs to be followed over time and velocity appropriately computed. Normally, the tracer is deposited via the working channel of a bronchoscope. The anatomic location of the deposited tracer greatly influences the results, because an increased rate is reported from the peripheral toward the central airways.[28,29] In the cinebronchofiberscopic technique, as first described by Sackner et al,[27] ten to fifteen Teflon disks are insufflated into the trachea and their movement continuously monitored as they approach the bronchoscope. In clinical settings, movement of several other tracers has been evaluated through bronchoscopy. In the original studies of Keller et al[41] and in later reports,[42,43] 15 μL methylene blue dye was instilled into the airways of patients undergoing anesthesia, and movement of the front edge of the dye was then sequentially measured through the bronchoscope, and velocity calculated. Charcoal markers[44,45] have also been used. The main drawback of bronchoscopic techniques is the frequent invasive insertion of the bronchoscope, which may distort the results. The original technique was modified by Friedman et al,[46] who used fluoroscopic tracking of radiopaque disks of Teflon mixed with bismuth trioxide. In our laboratory, we use radiopaque disks made of tantalum.[39,47] Six to eight tantalum disks are insufflated into the trachea and their velocities averaged (see Fig. 52-5). Timed, serial, lateral fluoroscopic images are taken by means of a C-arm fluoroscopy system approximately every 5 minutes to compute tracheal mucus velocity through movement of the disks.

QUANTITATIVE ASSESSMENT VIA RADIOACTIVE TRACERS

Inhaled γ-emitting radioactive tracers have long been used to assess mucus clearance of the whole respiratory system; to quantify the rate of mucus transport, a radioactive bolus is typically deposited in the large airways (most commonly trachea) and its movement measured through external radioactivity counters. The technique was originally described by Yeates et al[26] and consisted of tracheal deposition of boluses

TABLE 52-3: TECHNIQUES FOR QUANTITATIVE ASSESSMENT OF MUCUS CLEARANCE

	Method of Assessment	Tracer	Technical Aspects	Settings	Comments
Traceable Particles	Cinebronchofiberscopy[27]	Teflon disks	Disk diameter: 0.67 mm Disk thickness: 0.13 mm Disk weight: 0.13 mg 10 to 15 disks are insufflated via bronchofiberscopy Velocity is computed via the relationship of the disk size to the distance from the distal lens of the bronchofiberscope	Clinical/laboratory	Deposition of particles and frequent assessment via bronchoscope may damage the airway epithelium altering mucus transport
	Bronchofiberscopy[41]	Methylene blue dye	15 µL of methylene blue dye are applied via an 18-gauge epidural catheter passed through the bronchoscope working channel The lens is positioned at the front edge of the dye and the distance from the endotracheal tube (ETT) exit measured. After a period of time, the bronchoscope is reintroduced, the leading edge of the spot relocated and the distance difference calculated to compute velocity	Clinical	Deposition of particles and frequent assessment via bronchoscope may damage the airway epithelium altering mucus transport
	Bronchofiberscopy[45]	Charcoal	5 to 15 µL of a suspension of carbon in saline The lens is positioned at the front edge of the dye and the distance from the ETT exit measured. After a period of time, the bronchoscope is reintroduced, the leading edge of the spot relocated and the distance difference calculated	Clinical	Deposition of particles and frequent assessment via bronchoscope may damage the airway epithelium altering mucus transport
	Fluoroscopy[46]	Teflon disks mixed with bismuth trioxide	Disk diameter: 0.64 mm Disk thickness: 0.08 mm Disk weight: 1.76 mg Timed serial lateral fluoroscopic images are taken through a C-arm fluoroscopy system to compute tracheal mucus velocity through movement of the disks A ruler with radiopaque markers is applied in close proximity of the animal's neck to help correct for magnification of fluoroscopic images	Clinical/laboratory	Fluoroscopic imaging avoids discomfort and potential bias associated with frequent bronchoscopy for assessment Potential risks linked to radiation exposure because of frequent assessments

	Fluoroscopy[47]	Tantalum Disk	Disk diameter: 0.60 mm Disk thickness: 0.10 mm Disk weight: 0.8 to 1 mg Timed serial lateral fluoroscopic images are taken through a C-arm fluoroscopy system to compute tracheal mucus velocity through movement of the disks A ruler with radiopaque markers is applied in close proximity of the animal's neck to help correct for magnification of fluoroscopic images	Laboratory	Fluoroscopic imaging avoids discomfort and potential bias associated with frequent bronchoscopy for assessment Potential risks linked to radiation exposure because of frequent assessments
Radioactive Tracers	Gamma camera[26]	Aerosolized human serum albumin microspheres with technetium-99 m	Albumin microspheres diameter: 0.5 µm Boli of radioactive microspheres are deposited on the large airways via breathing to near total lung capacity and at high airflow rate Studies may last up to 6 hours	Clinical/laboratory	The subject needs to drink water at frequent intervals to wash out any radioactivity in the esophagus Patient needs to be transferred to another department for gamma camera assessment
	Gamma camera[49]	10 to 80 µL bolus of albumin microspheres labeled with technetium-99 m	Microspheres albumin diameter: 5 to 40 µm The bolus is deposited on the tracheal mucosa through the working channel of the bronchoscope or a fine cannula	Clinical/laboratory	Patient needs to be transferred to another department for gamma camera assessment

of technetium 99m (^{99m}Tc) human serum albumin microspheres (0.5 μm) suspended in isotonic droplets, achieved by breathing close to total lung capacity and at high low rates. Movement rate of those radioactive boluses was then measured through timed-serial measurement of the radioactive activity for up to 6 hours. In later reports, the radioactive bolus was deposited inside the trachea through a catheter[48] or a bronchoscope.[49] Few reports have applied these methods in tracheally intubated patients,[50,51] mostly because the patient needs to be transferred for scintigraphic assessment, moreover, the analysis can be lengthy at times.

MUCUS DYSFUNCTIONS AND SOURCE OF SYMPTOMS IN DIFFERENT DISEASES

Patients with diseases associated with overproduction of mucus and impairment of its clearance, such as asthma, chronic obstructive pulmonary disease (COPD), and cystic fibrosis, often require mechanical ventilation. Although mechanical ventilation is lifesaving during acute worsening of those diseases, the delicate balance between mucus hypersecretion and clearance can rapidly deteriorate.

Invasive Mechanical Ventilation

Mucus retention is highly prevalent in mechanically ventilated patients because of several factors. First, following tracheal intubation, mucociliary velocity is approximately 80% slower than normal.[50] Sackner et al.[52] demonstrated that inflation of endotracheal tube cuff lowers mucociliary velocity by 52% after only 4 hours. Second, when mucus reaches the proximal trachea outward clearance is not possible because of the inflated cuff; therefore, mucus accrues, unless it is aspirated through suctioning or enters the endotracheal tube. Third, continuous leakage[53] of bacteria-laden oropharyngeal secretions sustains airways infection and hypersecretion of mucus. Finally, critically ill patients are often incapable of effectively clearing retained mucus secondary to immobilization, weak cough, and muscle weakness.

Asthma

Asthma is a chronic inflammatory disease characterized by increased and inappropriate release of inflammatory mediators following antigen exposure and consequent airway smooth-muscle constriction.[54] Patients with asthma present with varying degrees of cough, shortness of breath, chest tightness, and wheezing. The role of mucus in asthma is often underestimated by clinicians[55] because mucus is typically stationary within small and medium airways and clearance is severely impaired, ultimately resulting in the inability to centralize secretions. Many mucus plugs within constricted airways may be identified in patients who die of status asthmaticus.[56,57] Mucus in asthma is highly viscous because of an abnormal concentration of plasma proteins,[58,59] DNA, cells, and proteoglycans. The abnormal presence of plasma proteins arises mainly from increased plasma exudation.[60]

Chronic Obstructive Pulmonary Disease

COPD is highly prevalent worldwide[61] and is the fourth leading cause of death according to the World Health Organization. The characteristic features of COPD are chronic bronchitis with obstruction or full closure of small airways impacted by mucus, enlargement of air spaces, and destruction of lung parenchyma resulting in loss of lung elasticity and emphysema.[62,63] In patients with COPD, the increased mucus production is strongly associated with goblet cell metaplasia and mucus gland hypertrophy (see Fig. 52-1C and D). MUC5B is overexpressed, particularly the low-charge glycoform. Hence, the rheologic properties of mucus are altered resulting in deficient mucociliary clearance.[64–66] Mucus hypersecretion is associated with progressive impairment of respiratory function[67] and death.[68]

Cystic Fibrosis

Cystic fibrosis is caused by a defective cystic fibrosis transmembrane regulator gene,[69] which results in impaired intraluminal chloride release and increase sodium absorption.[70] The electrolytes homeostasis of the periciliary fluid is compromised, hence, the volume of the periciliary liquid layer is depleted and cilia movement is severely perturbed. Indeed, the pathologic hallmarks of the disease are viscous secretions, which adhere tenaciously to the airways and often obstruct the lumen. Although MUC5B is increased relative to MUC5AC,[71] the overall concentration of those mucins is reduced,[72] but they rapidly increase during disease exacerbations.[73]

ROLE IN CAUSING ATELECTASIS, PNEUMONIA, AND OTHER DISORDERS

When mucus is retained, several complications occur as a consequence of (a) progressive reduction of the airways lumen, impacted by mucus, and/or (b) overgrowth of pathogens entrapped within the retained mucus. Excessive accumulation of secretions within the respiratory system and artificial airways makes it difficult to exhale, resulting in intrinsic PEEP and increased work of breathing. Shah et al[74] found a significant reduction in the internal volume of the endotracheal tube, which was proportional to the duration of mechanical ventilation. Indeed clinicians, upon extubation, often acknowledge the vast presence of secretion within the endotracheal tube. The mucus-related increase in airflow

resistance and work of breathing[75] causes breathing discomfort and may retard ventilator weaning.[76]

Mucus retained in the peripheral airways can ultimately cause atelectasis and gas-exchange impairment. In intubated patients, mucus can be suctioned only in the larger airways; hence, mucus within the small airways may produce complete and irreversible closure, because the pressures necessary to reopen small airways are extremely high and difficult to achieve safely in a ventilated patient. Patients at particular risk of developing mucus-related atelectasis are those with asthma, COPD, cystic fibrosis, infants, children, and those undergoing surgery. In surgical patients, mucociliary clearance becomes impaired in the operative room,[77] through the use of anesthetics and tracheal intubation; moreover, inefficient cough, associated with the underlying diseases or the anatomical site of the surgical procedure, increase the risk.

Retained mucus is also associated with lung infections. Patients with underlying respiratory diseases experience periodic exacerbations caused by pulmonary infections. The microbicidal products contained in mucus exert a time-limited effectiveness; Cole et al[78] elegantly demonstrated that bacteria added to nasal mucus rapidly acquired resistance to the antimicrobial factors within 24 hours. Those findings suggest that the antimicrobial properties of mucus and clearance work synergistically, and retained mucus eventually become colonized.

AIRWAY SUCTIONING

In intubated or tracheostomized patients, endotracheal suctioning consists of aspirating secretions retained within the artificial airway, trachea, and main bronchi via a suction catheter. Suctioning is one of the most common daily procedures. It should be performed only by qualified personnel, namely, physicians, respiratory therapists, or nurses, with appropriate skills and training to recognize the need for suctioning, perform it appropriately, and promptly respond to any potential complication.

Indications and Technical Procedure

INDICATIONS

The primary indication for endotracheal suctioning is to maintain patency of the airways, but it is also commonly performed to obtain secretions for diagnostic purposes. Current guidelines recommend that suctioning should not be performed routinely[79] to minimize the risk of unnecessary complications.

Several parameters have been suggested to detect the need for suctioning (Fig. 52-6). Researchers have focused especially on the typical sawtooth pattern of airflow in patients with secretions (Fig. 52-7). Jubran and Tobin[80] first proposed that retained mucus could be detected via the flow-volume loop, and reported that a sawtooth pattern had a good sensitivity and specificity. Guglielmotti et al[81] subsequently confirmed that the best predictors of the need of suctioning were (a) respiratory sounds heard via a stethoscope over the trachea, and (b) the sawtooth pattern on a real-time flow-volume loop (sensitivity 0.82, specificity 0.70).

ENDOTRACHEAL SUCTIONING PROCEDURE

Endotracheal suctioning begins with inserting a suction catheter into the artificial airway. Because there is no obvious advantage with deep suctioning versus shallow suctioning, the tip of the catheter should be placed in close proximity to the tip of the endotracheal tube before applying vacuum. As the catheter is pulled back, intermittent suction should be applied and the catheter continuously rotated. Shallow suctioning is particularly advisable in infants to minimize complications.[82,83] The only goal of suctioning is aspiration of secretions; hence, application of negative pressure, when the catheter is not close to secretions, or when all the mucus has already been aspirated (i.e., prolonged suctioning), only increases the risk of complications with no improvement in efficacy. Suctioning should last no more than 15 seconds[79] after inserting a catheter into an artificial airway.

Selection of Suction Methods and Catheters

OPEN VERSUS CLOSED SUCTIONING

Endotracheal suctioning can be performed either by disconnecting the patient from the ventilator (open suctioning) or through use of a suction catheter that does not require ventilator disconnection (closed suctioning), which is located inside a plastic contamination shield and in-line with the ventilator circuit.[84,85] Closed suctioning is beneficial in patients who require high levels of PEEP and inspired fractional concentrations of oxygen (FI_{O_2}). Several studies in adults with acute lung injury and acute respiratory distress syndrome (ARDS) have confirmed that, unlike open suctioning, closed suctioning prevents reduction of lung volume and desaturation.[86–88] These studies suggest that closed suctioning is especially appropriate in patients with most severe lung failure (partial pressure of arterial oxygen [$Pa_{O_2}/FI_{O_2} \leq 200$), who are intolerant of even brief disconnections from the ventilator. In studies by Cereda et al[86] and Maggiore et al,[88] open suctioning caused almost 1.5 L volume loss, half of which was secondary to the ventilator disconnection.[88] Results of studies assessing open and closed suctioning in newborns with respiratory distress syndrome[89–92] are consistent with data from adults.

Closed suctioning is also been introduced to reduce environmental contamination,[93,94] exogenous colonization of the airways via suction catheters[95] and potentially ventilator-associated pneumonia. Three meta-analyses[–98] have compared closed and open suctioning and found no

POTENTIAL INDICATORS FOR ENDOTRACHEAL SUCTIONING:

1) Visible secretions within the artificial airway
2) Dyspnea or apparent increased work of breathing
3) Pathological sounds (i.e., rhonchi, coarse and gurgling) heard *via* a stethoscope over the trachea
4) Progressive pulse oxymetry desaturation not otherwise explained
5) Increased peak inspiratory pressure in volume-controlled MV or decreased V_T in pressure-controlled MV
6) Sawtooth pattern identified at the real-time flow-volume loop

PREPARATION PRIOR ENDOTRACHEAL SUCTIONING:

EQUIPMENT

1) Consider closed suctioning system (or swivel connector) in patients with severe respiratory disease requiring high level of PEEP and FI_{O_2}
2) Ratio of catheter OD/artificial airway ID should be ≤ 0.7 in adults and ≤ 0.5 in children
   Suction catheter diameter (Fr) = Artificial airway internal diameter*3/2
3) Choose catheters with nonparallel lateral suction holes. In selected cases, a curved tipped catheter may be helpful to suction mucus within bronchi difficult to access
4) Prepare suction tubing
5) The level of vacuum should always be adjusted to the lowest level of vacuum that efficiently removes secretions. In general, vacuum ≤ 150 mm Hg in adults and 80–100 mm Hg in infants.

PATIENT PREPARATION

1) In patient on MV, heart rate, pulse oximetry, arterial pressure, and in particular cases, intracranial pressure, should be monitored throughout the procedure
2) If patient is conscious, explain the procedure
3) The use of saline to hydrate inspissated secretions and centralize secretions through cough lacks of clear evidence. If secretions appear dehydrated, check if humidification of inspired gases is appropriate
4) Hyperoxygenate for 120 sec using in adults FI_{O_2} of 100% and a 10% increase from baseline in infants. Of note, several ventilators now provide a single operational control for suction support

OPERATOR PREPARATION

1) Wash hands
2) Wear disposable apron and protector visor, particularly during open suctioning
3) Wear sterile glove on the hand manipulating the catheter, and nonsterile glove on the other hand
4) During open suctioning, retrieve the catheter from the sleeve and hold it. In particular, avoid manipulation of the distal catheter tip
5) Connect the catheter to suction tubing.
6) During closed or quasi-closed suctioning, the ventilator should be allowed to trigger to provide gas in response to negative pressure

PROCEDURE:

1) Insert the catheter into the artificial airway and advance its distal tip up to the proximal trachea
2) Intermittent suction should be applied through occlusion of the catheter suction control port
3) Withdraw suction catheter continuously rotating it
4) The procedure should last 15 sec or less from catheter insertion
5) Check and appropriately treat any potential cardiovascular, pulmonary, and neurologic complication throughout the procedure

FOLLOW-UP:

1) Assess respiratory cardiovascular and neurologic parameters
2) Consider hyperoxygenation
2) Consider recruitment maneuver in selected patients with ARDS and ALI
3) Rinse suction tubing and, in case of closed suctioning system, suction catheter
4) Dispose of the suction catheter apron and gloves into the proper containers

FIGURE 52-6 Suggested operative protocol for endotracheal suctioning. *ARDS*, acute respiratory distress syndrome; *ALI*, acute lung injury; FI_{O_2}, inspiratory fraction of oxygen; *ID*, internal diameter; *MV*, mechanical ventilation; *OD*, outer diameter; *PEEP*, positive end-expiratory pressure; V_T, tidal volume.

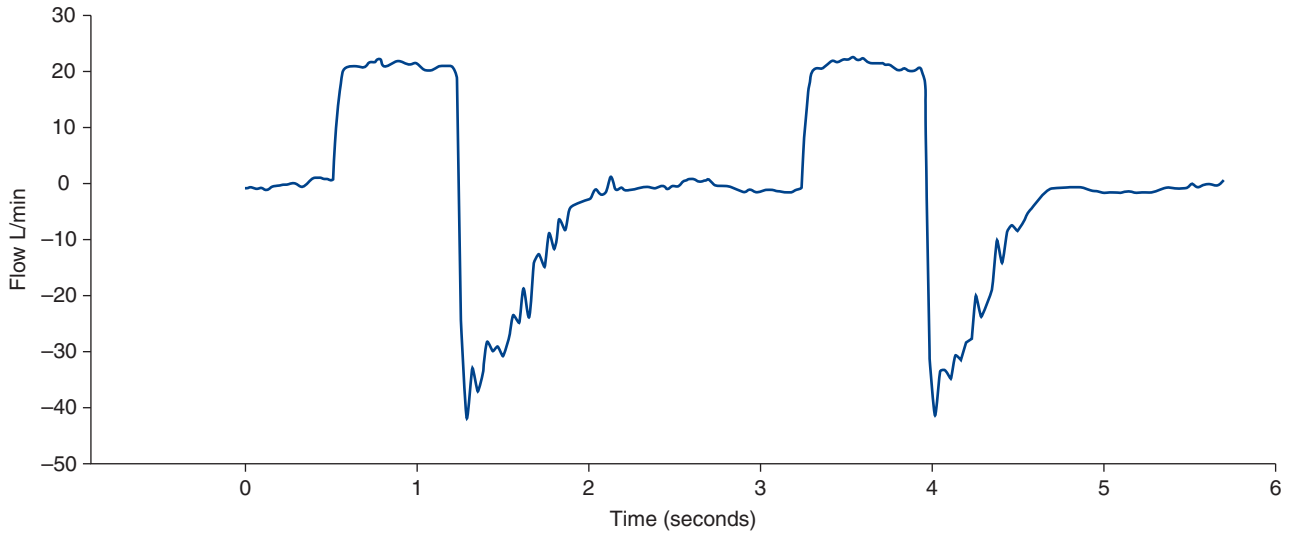

FIGURE 52-7 Flow waveform during volume-controlled mechanical ventilation. The typical expiratory sawtooth pattern used as an indicator for endotracheal suctioning can be recognized. Of note, the presence of water condensation within the circuit should be excluded before proceeding with suction.

benefits in preventing ventilator-associated pneumonia. Siempos et al[97] analyzed data from nine randomized trials, comprising of 1292 patients; data pooled from four showed a higher incidence of respiratory tract colonization using closed suctioning.

During closed suctioning it is important to note that triggered ventilator autocycling partially compensates for the loss of pressure, and investigators[99,100] have shown that the distal dispersion of secretions by ventilator airflow may reduce the effectiveness of closed versus open suctioning.

CATHETER CHARACTERISTICS

The main features that should be considered when choosing the most appropriate suction catheter are (a) the ratio between catheter outer diameter of the catheter and the internal diameter of the artificial airway; and (b) the size, number, and location of the suction holes. The outer diameter of the suction catheter greatly influences the loss of lung volume during the procedure. A larger catheter increases endotracheal tube resistance and facilitates loss of lung volume, because aspirated gas is not rapidly replaced by gas flowing through the endotracheal tube. These theories were clearly elucidated in early reports by Rosen et al[101,102] and confirmed in laboratory studies assessing pediatric[103,104] and adult[105] catheters. Evidence from those studies strongly suggests that the ratio of suction catheter outer diameter to artificial airway internal diameter should be 0.7 or less in adults and approximately 0.5 in children.

Several investigators have evaluated intrinsic characteristics of the suction catheter to identify factors associated with efficacy and safety.[106–109] Sackner et al[110] first demonstrated that invagination of the tracheal mucosa into the side holes frequently occurred with all the different catheter designs. In a more recent report, Shah et al[109] assessed six suction catheters (Fig. 52-8) with different designs and found that all performed equally with low viscosity mucus simulant; when viscosity resembled airway secretions, larger and nonparallel side holes were more efficient. In certain instances, a curved tipped catheter[111–113] may help when suctioning mucus within bronchi difficult to access with a straight catheter.

Additional Equipment

In ventilated patients, strict monitoring during endotracheal suctioning is strongly advised.[79] It is especially important to monitor heart rate, oxygen saturation, arterial pressure, and, in particular cases, intracranial pressure, throughout the procedure.

VACUUM ADJUSTABLE REGULATOR

The level of vacuum should always be adjusted before suctioning, so as to improve efficacy and minimize complications. Few studies have evaluated the efficacy and safety of suctioning at increasing vacuum levels. The latest guidelines[79] recommend a vacuum no higher than 150 mm Hg in adults and 80 to 100 mm Hg in neonates, although the lowest level of negative pressure that efficiently removes secretions should always be favored.

ADDITIONAL EQUIPMENT FOR STERILE SUCTIONING

Theoretically, during open suctioning there is a risk for environmental contamination from the patient and exogenous colonization of the patient. First and foremost, hand hygiene before and after the procedure is mandatory. Endotracheal suctioning is an invasive procedure and the use of sterile

Catheter	Side-Hole Diameter	Size	Whistle Design	Side-Hole Design
Cardinal Tri-Flo	3 mm	14 Fr		
Kendall Regu-vac	4 mm, 6.35 mm apart	14 Fr		
Kendall Sensi-vac	5 mm, 9.52 mm apart	14 Fr		
Medline Delee	4 mm, 9.52 mm apart	14 Fr		
Medline Whistle Tip	4 mm	14 Fr		
Portex suction tray	4 mm	14 Fr		

FIGURE 52-8 14 Fr suction catheters studied in vitro by Shah et al employing a mucus simulant with viscoelastic properties similar to human mucus. Nonparallel position and larger diameter of the suction holes were the major determinants of catheter's efficacy. (Used, with permission, from Shah et al.[109])

gloves is advisable, although there are no clinical studies specifically investigating the association between the use of unsterile gloves and respiratory infections. Blackwood et al[114] reported that gloves are important even during closed suctioning because of potential contamination of staff hands from the flush port.

SWIVEL CONNECTOR

A quasiclosed suctioning system, via a swivel adapter[115] positioned at the proximal tip of the endotracheal tube, is an alternative approach to minimize the loss of lung volume and desaturation during suctioning.[88,116] Investigators[87,88] found that suctioning through either a swivel adapter or a closed suctioning system similarly limited the decrease in lung volume as compared with open suctioning. Importantly, as during closed suctioning,[117] the ventilator should be allowed to autocycle to compensate for the loss of gas.

STERILE WATER

The use of 2 to 5 mL boluses of saline, instilled into the endotracheal tube before suctioning to induce cough and hydrate inspissated secretions remains controversial and lacks clear evidence. The first concern is that saline instillation, particularly in the semirecumbent position, may drip into the lungs and cause serious adverse effects, such as oxygen desaturation,[118,119] tachycardia,[119,120] dyspnea, and anxiety.[121] Second, several studies[122,123] have consistently demonstrated the presence of bacterial biofilm within the endotracheal tube, hence, instillation of saline may dislodge pathogens.[124] Caruso et al[125] published a report on 262 patients randomized to receive either isotonic saline instillation before suctioning or no treatment. The authors found a lower incidence of ventilator-associated pneumonia, and no significant differences in secondary outcomes. Because of limited evidence and the potential for adverse effects, routine saline instillation cannot be recommended; moreover, when mucus progressively becomes thicker, the humidifier's performance should be checked.

Complications of Endotracheal Suctioning and Preventive Measures

After discharge from an intensive care unit, patients remember endotracheal suctioning as one of the most unpleasant and painful procedures;[126–128] such memories may affect later quality of life.[129]

Once inside the trachea, the suction catheter frequently adheres to the tracheal mucosa, and may lead to the impairment of mucociliary transport[130] and severe mucosal injury.[110,131] Sackner et al[110] first addressed this problem by devising a novel suction catheter with a modified tip to prevent contact against the tracheal mucosa. In a later report[106] the new catheter was compared against standard catheters in dogs, and the investigators demonstrated that the risk of mucosal injury was specifically associated with deep suctioning rather than catheter design or vacuum level. Intermittent suctioning is recommended to prevent mucosal invagination into the suction holes.

Endotracheal suctioning is associated with several cardiovascular, pulmonary, and neurologic complications. Bradycardia and hypertension are the most frequent cardiovascular complications, mostly as a result of a vagal reflex and resulting in increases in parasympathetic and sympathetic activities.[132–135]

Hypoxemia during suctioning is extremely common, particularly in adults with severe lung disease[86,88] or infants.[92] As described above, closed or quasiclosed systems have been

used to prevent those complications. Hyperoxygenation before the procedure is also used to prevent hypoxia,[136,137] and several ventilators now provide a control for automatic preoxygenation and postoxygenation. A meta-analysis,[138] based on pooled data from fifteen studies in adults, demonstrated a 49% reduction of suction-related hypoxia when pre-hyperoxygenation and post-hyperoxygenation was applied. There is no clear evidence as to the level of FI_{O_2} that should be used to hyperoxigenate. In adults, FI_{O_2} of 100% is widely used. Hyperoxia, however, may be deleterious,[139] particularly in neonates; hence, in these instances, a 10% increase[79,140] from baseline is recommended. A recruitment maneuver applied after suctioning in selected patients with ARDS or acute lung injury is associated with more rapid return of baseline lung volume and reversal of hypoxia.[88,141,142] Finally, severe bronchoconstriction has been demonstrated during suctioning in animals[143,144] and humans.[145]

In patients with intracranial hypertension, an abrupt burst of coughing provoked by tracheal stimulation could increase the intracranial pressure; if there is not a concomitant increase in cerebral blood flow, brain ischemia may ultimately result.[146–148] Several drugs have been tested, mainly in adults, to blunt the responses to suctioning, including barbiturates,[149] narcotics,[150,151] anesthetic agents,[152–155] and neuromuscular blocking agents.[149,156,157] These drugs should be indicated on a case-by-case basis and the potential adverse hemodynamic effects of such agents[151,158] should be balanced against the perceived benefits.

Lastly, suctioning may increases endogenous and exogenous colonization of the lower airways. Manipulation of the suction catheter before insertion,[159] passage of the catheter within the colonized artificial airway,[160] and mucosal injury caused by negative pressure[110] are possible culprits involved in suctioning-related colonization of the airways. In ventilated newborns, transient bacteremia has been associated with endotracheal suctioning.[161] Finally, a number of studies found that closed suctioning catheters were easily colonized and associated with higher incidence of airways colonization;[161–165] nevertheless, the evidence is still controversial and, as described above, no increase in incidence of ventilator-associated pneumonia was found, even when the catheter was not changed daily.[166]

MANUAL VENTILATION TECHNIQUES

Exhaled Ventilation Techniques

In ventilated patients, who have excessive mucus production but are unable to produce an efficient cough, physiotherapists often apply manual and mechanical procedures with a goal of increasing expiratory flow and facilitating outward drainage of secretions[167] via annular two-phase gas–liquid flow.[36]

Manual hyperinflation to promote mucus clearance was originally described by Clement and Hubsch in 1968.[168] Manual hyperinflation is performed by disconnecting the patient from the ventilator and providing, via a resuscitator bag, a slow inspiration of a larger tidal volume, an inspiratory hold, and a quick release of circuitry pressure to assure a high expiratory flow rate. Extreme heterogeneity exists for the procedure and equipment.[169] A recent Dutch survey[170] substantiates this and relates how even the most important features of the procedure are frequently overlooked. Manual hyperinflation is commonly applied for mobilization of retained secretions, to recruit atelectatic lung regions, and to improve gas exchanges. During the procedure, the lack of respiratory monitoring and the potential to reach very high airway pressure[171] are of great concern. Significant hemodynamic fluctuations during the procedure have been reported.[172] The procedure should be performed by caregivers trained in the maneuver[173] and is usually contraindicated in patients with hemodynamic instability, undrained pneumothorax, intracranial hypertension, severe bronchospasm, and ARDS requiring a high level of PEEP or FI_{O_2}.[174] Among studies that specifically looked at mucus transport during manual hyperinflation, Jones et al[175] assessed transport of simulated mucus of three different viscosities and found that outward movement of mucus was consistently increased, particularly low viscosity artificial mucus. In eighteen intensive care unit patients positioned on their side, Hodgson et al[176] found increased retrieval of mucus following manual hyperinflation. One report[177] demonstrated even greater efficacy when the procedure was combined with the lateral Trendelenburg position.

It is commonly advocated that tidal volume be increased to 50% above baseline during manual hyperinflation, or an inspiratory pressure lower than 40 cm H_2O be achieved. Singer et al,[172] however, found that manual hyperinflation generated heterogeneous ranges of peak inspiratory pressure and tidal volume; therefore, inline manometers, spirometers, or both should be used both in research and clinical setting.

Three studies[178–180] compared the effects of manual hyperinflation against hyperinflation delivered by the ventilator; amounts of aspirated secretions were similar.[178,179]

Ventilatory Circuits for Manual Hyperinflation

The type of circuit used during manual hyperinflation strongly influences the resulting airflow rates, airway pressures, and mucus clearance. Circuits can be classified on the basis of the characteristics of the inflation bag, location of the fresh gas inlet, and expiratory valve.

FLOW-INFLATING BAG CIRCUITS

The most common rebreathing circuits used for manual hyperinflation are the Mapleson-A/Magill, Mapleson-C, and Mapleson-F (Fig. 52-9). The circuits consist of a highly compliant 2 L rubber or neoprene bag (with an open expiratory port in the Mapleson-F circuit) and an adjustable pressure-limiting valve (Magill and Mapleson-C circuits).

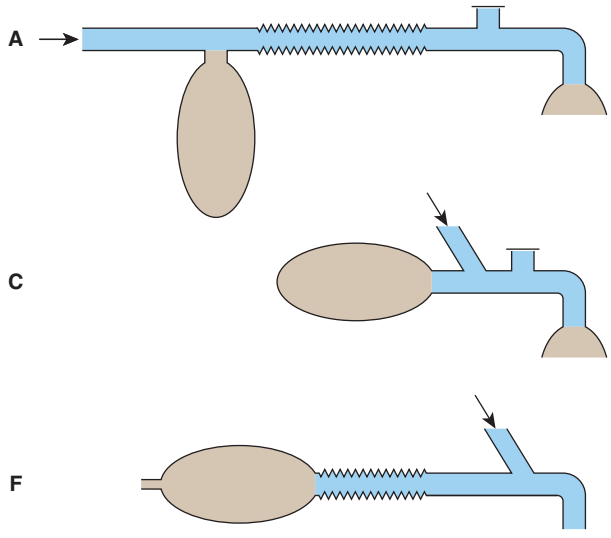

FIGURE 52-9 Most common semiclosed ventilatory circuits for manual hyperinflation delivered with a flow-inflating bag. The Mapleson A/Magill, Mapleson-C, and Mapleson-F are shown. Circuits differ in terms of location of fresh-gas inlet and presence of expiratory port (F) or valve (A and C). *Black arrows* indicate the fresh gas inlet.

The compliant bag allows the operator to better assess the patient's respiratory compliance during the procedure. The gas inlet is close to the patient in the Magill and Mapleson-C circuits and it is commonly connected to 100% oxygen at a flow rate of 15 L/min. During inspiration, an appropriate adjustment of the adjustable pressure limiting valve is required to inflate the bag and to provide ventilation at the necesary respiratory rate and volume. Differently, to ensure a rapid exhalation, the bag is fully and promptly released and the adjustable pressure limiting valve can be adjusted to the fully open position, and manually held closed during inspiration.

SELF-INFLATING BAG CIRCUITS

The self-inflating bag circuits comprise a silicone bag that is connected to the patient's artificial airway via a non–rebreathing valve assembly. At the other side of the bag are located the fresh-gas inlet and the oxygen-reservoir bag. Several studies in the recent decades have assessed performance of the Laerdal 1.6 L adult bag (Laerdal Medical Corp, New York, NY) and the Air Viva bag (now discontinued).

The ratio between the inspiratory and expiratory flow rates is the most important factor during manual hyperinflation. As expected, a longer inspiratory time is associated with a slower inspiratory flow rate.[181] In contrast, expiratory flow depends on (a) nonmodifiable factors, such as airways or endotracheal tube resistances and respiratory compliance, and (b) modifiable factors, that is, end-inspiratory lung volume and breathing circuits. In vitro studies[181,182] have compared performance of different breathing circuits for manual hyperinflation and have shown that the Mapleson-C and Mapleson-F circuits generate faster expiratory flow than do circuits with self-inflating bags. Moreover a clinical study by Hodgson et al[183] of patients receiving manual hyperinflation with a Laerdal and Mapleson-C circuit, found more secretions retrieved with the latter. In a more recent in vitro study,[184] the Mapleson-C circuit generated greater peak expiratory flows when compared to the Mapleson-A circuit, probably because of intrinsic characteristics of the exhalation valve.

ROLE OF PHARMACOLOGIC AGENTS

Numerous drugs commonly used in ventilated patients profoundly affect mucociliary clearance and increase mucus retention. Oxygen,[185] inhaled anesthetics,[42,43,186] and narcotics[187] have shown dose-dependent and time-dependent inhibitory effects on mucociliary clearance. Because mucus is composed mostly of water, administration of fluids and diuretics may affect hydration and rheologic properties of airway mucus.[188] Furosemide has a direct inhibitory effect on the $NaK(Cl)_2$ cotransporter located in the basolateral membrane of the airways epithelium and may influence the volume of the periciliary liquid layer. A study in mechanically ventilated patients[189] revealed some deleterious effects of furosemide on mucus transportability; further research is needed particularly because of conflicting laboratory results.[190,191]

Mucoactive Agents

Remarkably little data exist on the use of mucoactive agents in ventilated patients, and most of the knowledge in the field is provided by clinical trials assessing long-term effects of such agents in patients with underlying chronic respiratory diseases. Mucoactive drugs used in intensive care unit settings can be divided in mucolytics and mucoregulators.

Mucolytics alter viscoelastic properties of mucus by either dissociating the mucus polymers or the cellular residuals within mucus. *N*-acetylcysteine dissociates the disulfide bonds that generate the final mucin polymeric structure, hence, enhances fluidity of mucus to facilitate its clearance.[192] *N*-acetylcysteine can be administered intravenously, orally, and aerosolized, although it can cause airway irritation when inhaled.[193] Only one randomized, controlled study[194] has been conducted in ventilated patients. *N*-acetylcysteine had no significant benefit on viscosity of secretions or the risk of mucus plugs. Likewise, sodium 2-mercaptoethane sulphonate (MESNA) is a mucolytics agent[195] that reduces mucus disulfide bonds. The agent can be administered via a nebulizer[196] or instilled directly into the airways.[197] MESNA may induce severe bronchospasm and coadministration of a bronchodilator is advisable in intubated critically ill patients. Increased mucus concentration of highly polymerized DNA, caused by degenerated polymorphonuclear leukocytes, greatly alters the viscoelastic properties of mucus. The

resulting thick and tenacious mucus narrows the airways and may cause atelectasis. Recombinant human deoxyribonuclease hydrolyses DNA and has been largely used in patients with cystic fibrosis.[198] Scattered work has been published in ventilated pediatric patients, on the use of recombinant human deoxyribonuclease, inhaled or administered via bronchoscopy, to resolve established atelectasis secondary to mucus plugs.[199–205]

Mucoregulators affect mucus production and secretion. Among these drugs, anticholinergics, glucocorticoids, and β_2-adrenergic agonists are routinely prescribed in critical care, mainly to reduce bronchospasm and airway inflammation, often overlooking the important effects on airways secretions. Inhaled anticholinergics agents, such as atropine, ipratropium, and tiotropium, thwart mucus hypersecretion of submucosal glands. Glucocorticoids indirectly influence production of mucus by reducing airways inflammation. Similarly, macrolide antibiotics exert an immunomodulatory effect that can result in decreased mucus production. β_2-adrenergic agonists enhance mucociliary clearance.[206–209] The bronchodilator action may also favorably influence the peripheral interaction between airflow and retained mucus.

IMPORTANT UNKNOWNS

As already discussed, most of the quantitative techniques to assess mucus clearance were developed approximately 40 years ago, and currently they are applied in laboratory settings. Thus, surrogate end points have been used in research, that is, changes in oxygenation, pulmonary mechanics, and amount of aspirated secretions—all of which increase the odds for negative studies[210] and produce controversy in the field.

First and foremost, in daily clinical practice, indications for endotracheal suctioning remain uncertain. Studies have demonstrated that respiratory waveforms can predict the presence of retained secretions,[80,81] yet we do not know whether it is safe to allow mucus to accumulate in the proximal trachea until it is detected by such monitoring. The proximal trachea is often colonized by seepage of bacteria-laden oropharyngeal fluids; hence, mucus may provide a perfect media for exponential growth of pathogens that eventually flow[39] backward into the lungs driven by gravity. Second, several laboratory[36,37] and animal studies[38,39] suggest that the net movement of retained mucus is governed by gravity and tidal airflow forces. Those theories have been extrapolated to the pathogenesis of ARDS because mucus and noxious fluids, from an initially contained locus of infection, may propagate through the airways and ultimately cause ARDS.[211,212] Finally, although hypersecretion of mucus is universally found during prolonged ventilation, even in patients without underlying respiratory disease, the pathophysiologic basis of such hypersecretion is still unknown and there are no studies assessing the effects of mechanical ventilation on expression of mucins.

THE FUTURE

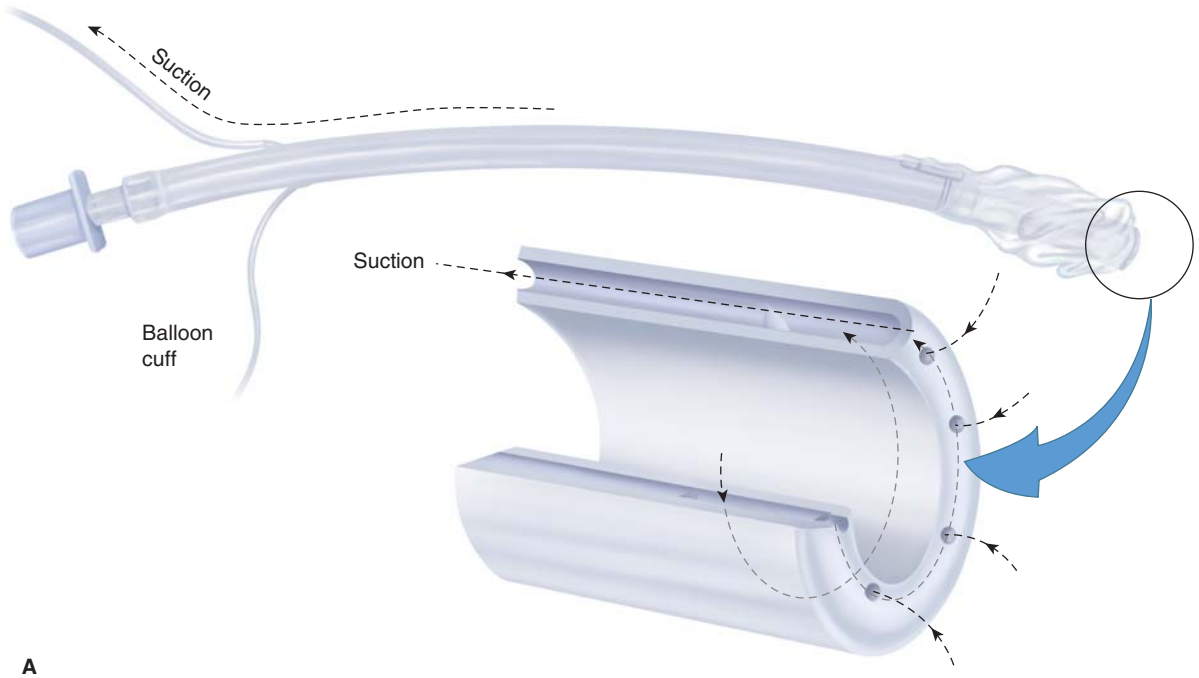
Several promising areas exist for future laboratory and clinical research. Development of new reliable techniques to quantitatively assess movement of airway secretions within the proximal and lower airways is the first priority. Graf et al[213] have employed sequential computed tomography to trace a radiopaque mucus simulant in preserved ex vivo porcine lungs. Although the technique was designed to track lung biofluids, the experimental approach provides an attractive option for future studies.

Given the adverse effects and the frequent use of endotracheal suctioning, efforts should be made to devise new strategies to clear mucus from the airways more efficiently and safely. Two prototypes have been described. The Mucus Slurper[214] (Fig. 52-10) consists of a novel endotracheal tube that provides intermittent and automatic suction at its tip. Using the Mucus Slurper, we were able to avoid endotracheal suctioning over 72 hours of mechanical ventilation, and we prevented any accumulation of mucus within the endotracheal tube and proximal trachea.[215] The Mucus Shaver[216] (Fig. 52-11) is an inflatable device that removes all accumulated mucus and biofilm within the endotracheal tube. Those prototypes, although currently not commercialized, offer novel insights into future designs and provide research directions to improve removal of secretions.

Another novel device that detects airway secretions through the analysis of airway sounds was recently described.[217] Although further experimental and clinical evaluation of the device is needed, analysis of airway sounds to detect retained secretions is intriguing and could be a valuable option to signal the need for suctioning.

SUMMARY AND CONCLUSION

The airway lining fluid, composed of mucus and periciliary fluid, overlies the airway epithelium and constitutes a first-line of defense. Mucus is continuously cleared from the airways by cilia and by a two-phase gas–liquid mechanism. Ventilated patients often retain secretions because of mucus hypersecretion and impaired clearance. The effects of gravitational force and ventilator settings on mucus transport are seldom considered, but may be major mechanisms of mucus retention in ventilated patients; these theories require comprehensive evaluation in future studies. Endotracheal suctioning is an essential procedure to remove accumulated mucus within large airways, but can cause discomfort and several complications. Further research is needed to identify the proper indications for suctioning and to improve the technology and safety of the procedure. Manual hyperinflation is based on the principles of mucus transport by means of a two-phase gas–liquid mechanism and, in selected patients, can be useful to centralize retained secretions. Unfortunately, most of the quantitative techniques used to assess mucus clearance are difficult to apply in ventilated patients, and



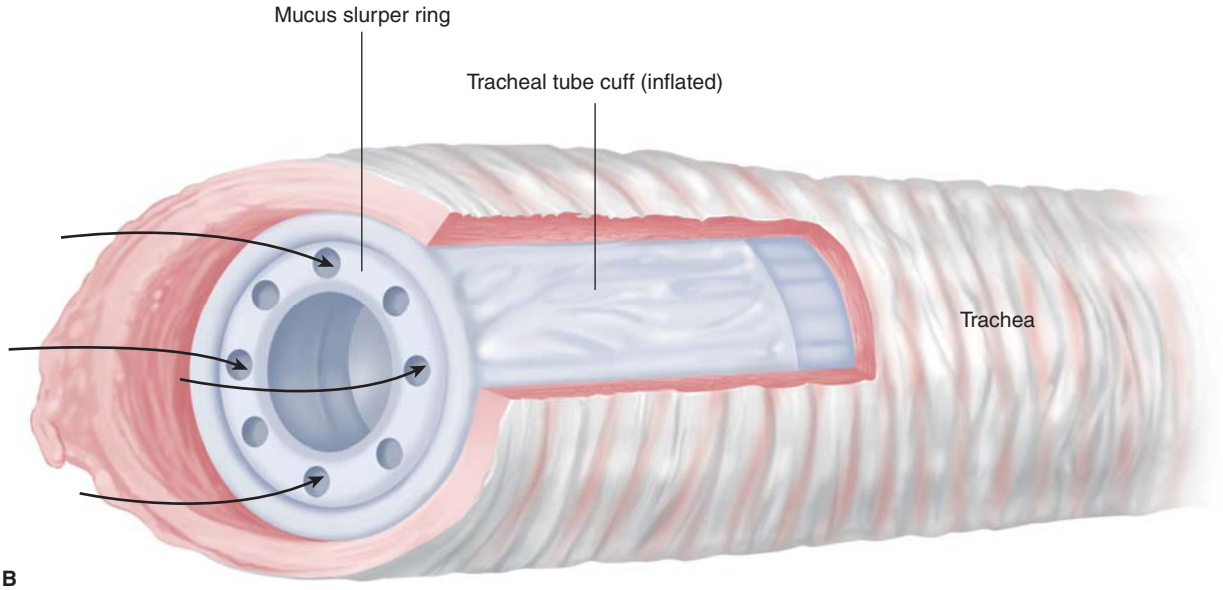


FIGURE 52-10 The Mucus Slurper. **A.** The Mucus Slurper is a modified Hi-Lo EVAC tracheal tube (Mallinckrodt Medical, Athlone, Ireland) in which the built-in evacuation lumen is extended beyond the cuff and connected to a vinyl hollow ring with eight holes. Suction at the distal tracheal tube tip is intermittent and automatic. **B.** The cuff of the Mucus Slurper is positioned at the very tip to reduce accumulation of mucus between the cuff and the tip of the Mucus Slurper. When the cuff is inflated, the eight suction holes has no contact with the tracheal mucosa. (Used, with permission, from Kolobow et al[214] and Li Bassi et al.[215])

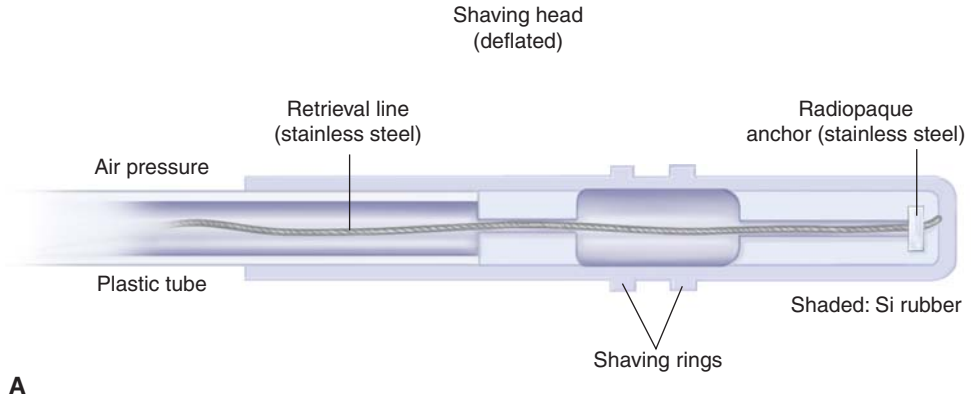

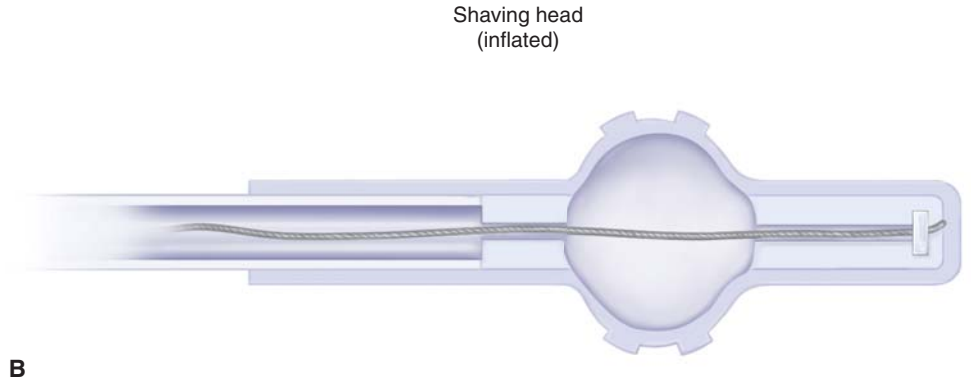

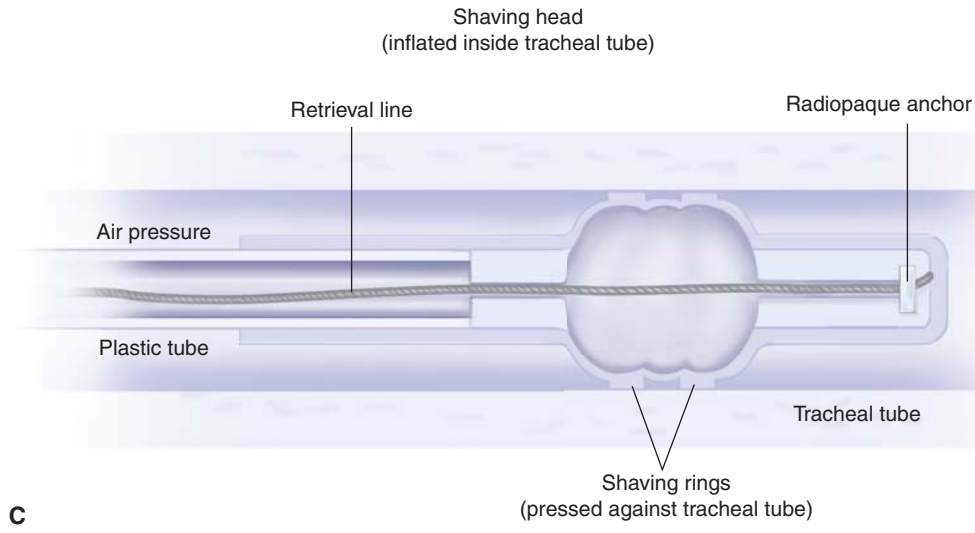

FIGURE 52-11 The Mucus Shaver. The Mucus Shaver is a 28-cm-long plastic tube with a 2-cm-long silicone inflatable balloon at its tip, with two or more 1.0-mm-wide, 0.5-mm-thick silicone rubber "shaving rings" (**A** and **B**). The device is inserted into the artificial airway up to its tip; then the balloon is inflated sufficiently to force the two shaving rings firmly against the internal wall (**C**). Finally, while inflated, the Mucus Shaver is gently retrieved to remove all accumulated mucus and biofilm. (Used, with permission, from Kolobow et al.[216])

consequently surrogate end points are commonly used to measure the response to interventions, increasing the potential for negative studies and hampering progress in the field.

ACKNOWLEDGMENTS

I am grateful to Nuria Cortadells and Laia Fernandez-Barat for their assistance and for electron microscopy pictures (Fig. 52-1) and to Professor Jose Ramirez for his stimulating comments and for microscopy pictures (Fig. 52-2). I also thank Dani Marti for his valuable help throughout this project and his advice on physiotherapy techniques. I especially thank Professor Antoni Torres and Dr. Theodor Kolobow for their invaluable suggestions on most of the topics discussed in this chapter.

53 FIGHTING THE VENTILATOR

Martin J. Tobin
Amal Jubran
Franco Laghi

A patient is connected to the ventilator. His eyes are closed and he appears calm. The ventilator is making soft rhythmic noises, and the patient's chest is expanding and receding in unison with the ventilator. A sweep of signals is gently traversing the monitor screen.

This peaceful scene erupts suddenly. The patient bolts upright. His eyelids retract. His nostrils flare. Sweat drips from his brow. His skin turns blue. His sternocleidomastoids contract vigorously. His rib spaces retract. One or more alarms sound loudly.

A patient fighting (or bucking) the ventilator is frightening not only to the patient but to staff. If the physician cannot find the source of the problem and fix it, the patient may die in minutes. The physician must immediately diagnose and manage the problem, and do both concurrently. The physician quickly scans the monitors for clues. Sometimes the problem is immediately spotted and solved, such as disconnected ventilator tubing.

If the cause is not immediately obvious, the physician's primary responsibility is to ensure adequate ventilation. This requirement takes precedence over diagnosis. After disconnecting the patient from the ventilator, the physician (or staff) starts to ventilate the patient manually with a self-inflating bag containing 100% oxygen. This step is both therapeutic and diagnostic (Fig. 53-1).[1,2] If the distress resolves, it indicates that the problem originated in the ventilator. If the distress continues, it indicates the problem is within the patient.

INITIAL ASSESSMENT

Where a physician begins the assessment varies with the particulars of the patient's presentation. The following sequence is not appropriate for all patients.

Because hypoxia can be rapidly lethal, the pulse oximeter reading is noted. Although several factors can give rise to erroneous readings, the displayed saturation generally bears a close relationship to the oxygen saturation on an arterial blood-gas test.[3]

If the high-airway-pressure alarm is sounding, the physician should, if possible, perform an end-inspiratory occlusion

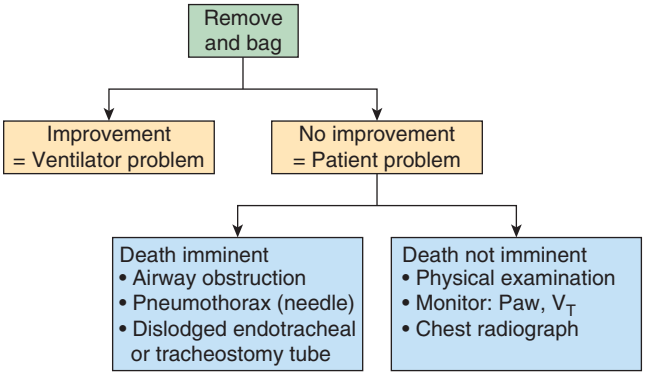

FIGURE 53-1 Removing the patient from the ventilator and providing manual ventilation with a bag (100% oxygen) is both therapeutic and diagnostic. Patient improvement indicates that the ventilator is the cause of the distress. Lack of improvement indicates that the problem is within the patient. If death appears imminent, the physician rapidly checks for airway obstruction (by passing a suction catheter), a dislodged endotracheal or tracheostomy tube, and a pneumothorax (if deemed likely, a small-gauge needle is inserted); depending on the clinical picture, other life-threading problems, such as aortic dissection, should be considered. If death is not imminent, the physician undertakes a more detailed physical examination and assessment of monitored variables. A chest radiograph may also be obtained. *Paw*, airway pressure; V_T, tidal volume.

maneuver to measure the plateau pressure (Fig. 53-2). An increase in peak airway pressure without a proportional increase in plateau pressure indicates narrowing of the airway.[4] Narrowing may arise from bronchoconstriction, an increase in secretions, a collection of fluid in the inspiratory limb of the ventilator circuit, kinking of the tubing, a foreign body, or herniation of the cuff of the endotracheal tube over its distal tip.

An increase in peak airway pressure accompanied by a proportional increase in plateau pressure indicates a decrease in thoracic compliance, which may arise within the lung or from extrinsic compression. A decrease in lung compliance may arise from pulmonary edema, early stages of the acute respiratory distress syndrome, dynamic hyperinflation associated with intrinsic positive end-expiratory pressure (PEEPi), and atelectasis. Extrinsic compression may be caused by rapid collection of pleural fluid (hemothorax, parapneumonic effusion, or transudative effusion) or a pneumothorax. If a tension pneumothorax is suspected and death appears imminent, the physician should insert a 14- to 16-gauge needle into the second intercostal space. If a gush of air is heard, a thoracostomy tube is inserted. Gastric distension, ileus, ascites, or extensive eschar formation can also cause a decrease in thoracic compliance.

A major obstruction of the airway will commonly cause oxygen desaturation and an increase in peak airway pressure. If obstruction is suspected, the clinician should pass a suction catheter through the airway to determine if the airway is patent and to remove secretions or other material that is causing a blockage.

The alarm may signal a low exhaled tidal volume (V_T). This can arise because of movement of the endotracheal tube into the hypopharynx or esophagus. It can also arise because of a disconnection in the ventilator circuit or a leak in the system. Many conditions can cause an increase in respiratory rate. Accordingly, a high rate is a very sensitive marker of an important change in a patient's condition. Because it is influenced by so many factors, it is not helpful in directing the clinician to the cause of the new change.

The patient's pattern of breathing may signal a marked increase in work of breathing. Important signs include tracheal tug (how much the larynx descends with each inspiration); palpable activity of the sternocleidomastoid muscles; recession in the suprasternal notch, supraclavicular space, and intercostal spaces; and paradoxical movement of the rib cage and abdomen (Fig. 53-3).

Auscultation of the chest may suggest a pneumothorax or movement of the endotracheal tube into the right main-stem bronchus. Cardiac auscultation may reveal the Hamman crunch, signaling the presence of pneumomediastinum. A new murmur may signal the development of a ventricular septal defect or other cardiac source of acute distress.

The pressure and flow tracings on the ventilator screen may provide clues to the sudden change in patient status. The contour of the airway pressure tracing may exhibit excessive scooping, indicating increased inspiratory effort; this pattern is seen when the delivered inspiratory flow no longer meets patient demand (Fig. 53-4).[5,6] The flow tracing

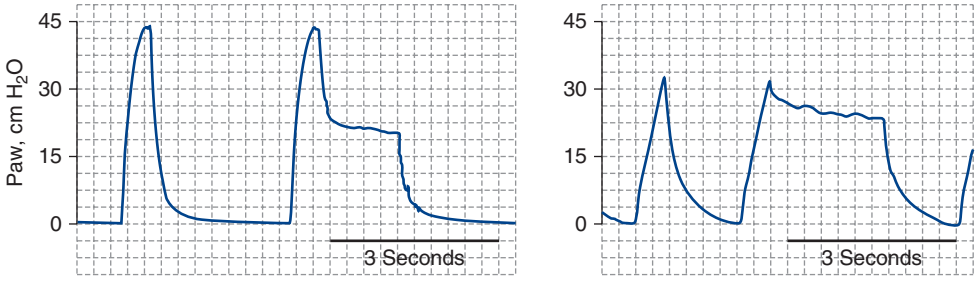

FIGURE 53-2 End-inspiratory occlusion maneuver during passive ventilation in two patients. In each patient, the second displayed breath was occluded for 2 seconds or less—a period that was not sufficient to achieve a complete plateau in either patient. *Left panel.* Airway pressure (*Paw*) drops by 24 cm H_2O during the end-inspiratory occlusion maneuver, indicating the presence of increased airflow resistance. *Right panel.* Paw drops by 5 cm H_2O during the end-inspiratory occlusion maneuver, indicating decreased respiratory compliance consequent to noncardiogenic pulmonary edema secondary to sepsis.

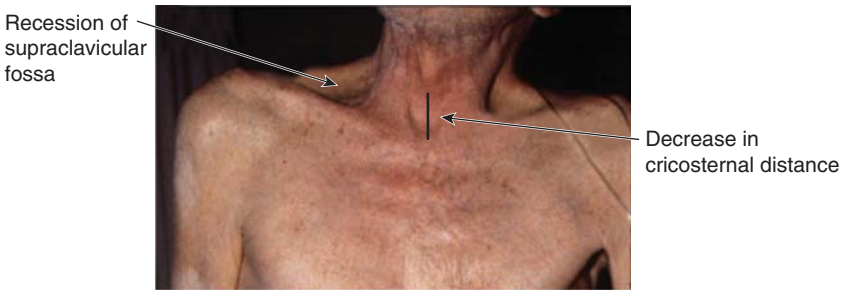

FIGURE 53-3 Examination of the neck in a patient with acute respiratory distress. Inspection reveals recession of the supraclavicular fossa, recession of the suprasternal notch, increased tracheal tug (not visible on the photograph), and prominent sternocleidomastoid muscles. Palpation confirms phasic activity of the sternocleidomastoid muscles, tracheal tug, and decreased cricosternal distance, indicative of hyperinflation.

may not return to the zero-flow line in the period immediately before the next inspiration, indicating PEEPi.[4] The flow tracing may exhibit a sawtooth pattern, indicating excessive secretions.[7]

A decrease in end-tidal carbon dioxide tension (P_{CO_2}) can be helpful. A sudden decrease in end-tidal P_{CO_2} may arise with pulmonary embolism or air embolism. Esophageal intubation also causes end-tidal P_{CO_2} to fall to zero. Unfortunately, end-tidal CO_2 readings do not reliably reflect arterial CO_2 tension (P_{CO_2}) in patients with underlying lung disease.

The blood pressure reading may signal a hypertensive crisis. The differential diagnosis of a fall in arterial pressure is wide, and influenced by clinical context. In a patient with a myocardial infarction, a fall in arterial pressure may signal the onset of cardiogenic shock. A pulmonary artery catheter can provide important clues. A new onset of large V (ventricular) waves in the pulmonary artery wedge tracing suggests the development of acute mitral regurgitation secondary to ruptured chordae tendineae cordis (Fig. 53-5).[8] The electrocardiogram (ECG) may reveal arrhythmias or ST-segment elevation. In contrast to the average patient, communication with an intubated patient is very difficult. A nonintubated patient who develops acute distress consequent to an acute myocardial infarction is able to relay the onset of crushing chest pain to staff. The presence of a tracheal tube prohibits speech. Nevertheless, clinicians can obtain a considerable amount of information about the nature of symptoms. Nurses are frequently more patient and skilled than physicians in achieving an ongoing dialogue with a patient.

The sequence of the above steps will vary with the clinical context. The approach is also incomplete. For example, sudden distress may have no cardiopulmonary cause. Instead, it may originate in a blocked Foley catheter leading to an overdistended bladder.

Based on the initial assessment, a physician diagnoses the most likely cause of a change in a patient's condition. Table 53-1 lists the most common causes of sudden respiratory distress in a ventilated patient.

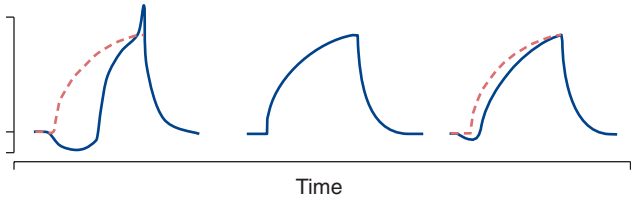

FIGURE 53-4 Airway pressure waveforms recorded in a patient shortly after the initiation of mechanical ventilation (*left*), in a patient making no respiratory effort (controlled mechanical ventilation, *middle*), and in a patient receiving an appropriate level of assist-control mechanical ventilation (*right*). The *dashed lines* on the left and right panels reproduce the tracing achieved by passive, controlled mechanical ventilation as occurs in a patient receiving neuromuscular blocking agents. The *left waveform* depicts a patient in respiratory distress who has excessive work of breathing; this can be inferred from the initial concavity, which results from vigorous inspiratory effort, and the spike at the end of ventilator assistance, which is the result of expiratory muscle recruitment. The *middle waveform* depicts a patient making no respiratory effort. The *right waveform* depicts a patient performing an appropriate amount of respiratory work: The small downward dip at the start of the breath indicates the small inspiratory effort required to trigger the ventilator, and the distance between the *solid line* (actual airway pressure) and *dashed line* (expected tracing during controlled ventilation, as in the middle panel) is proportional to the amount of work performed by the patient's inspiratory muscles while the ventilator is providing assistance. The patient in the right panel is performing much more respiratory work than the patient in the middle panel and much less work than the patient in the left panel. (Used, with permission, from Tobin et al.[6])

ARTIFICIAL AIRWAY PROBLEMS

Several different problems with artificial airways can produce acute respiratory distress in the ventilated patient.

Movement of the Endotracheal Tube

An endotracheal or tracheostomy tube that is initially properly positioned may subsequently move up or down in a patient's airway. Downward movement into a main-stem bronchus (endobronchial intubation) is estimated to occur in approximately 10% of ventilated patients.[9–11] It is usually caused by inadequate external fixation of the endotracheal tube, excessive neck movement, or both.[12]

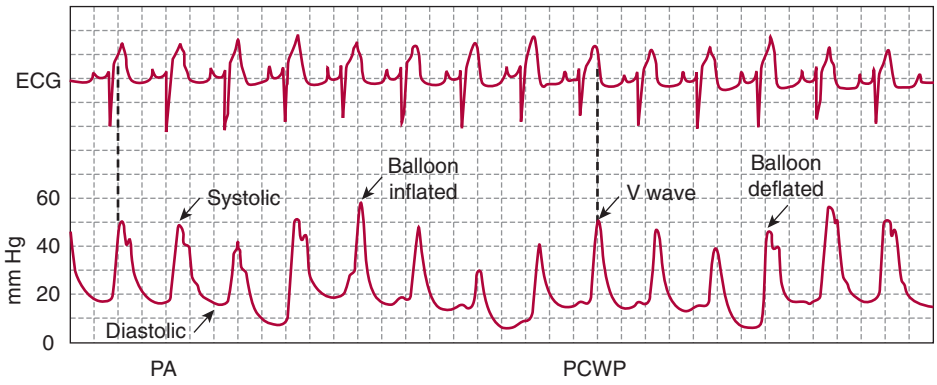

FIGURE 53-5 Simultaneous recordings of electrocardiogram (ECG, *top*) and pulmonary artery (*PA*) pressure (*bottom*) in a patient with acute mitral insufficiency. Following inflation of the balloon, giant *V* waves are seen in the pulmonary capillary wedge pressure (*PCWP*) tracing. Before balloon inflation and after balloon deflation, the PA tracing has a characteristic bifid appearance secondary to both a PA systolic wave and a V wave. Note that the V wave occurs later in the cardiac cycle than does the PA systolic wave, which is synchronous with the T wave on the electrocardiogram.

Main-stem intubation occurs more often on the right side, because the right main-stem bronchus forms a less-acute angle with the trachea than does the left main-stem bronchus[11] and because the bevel of most endotracheal tubes is directed rightward (Fig. 53-6). The lack of ventilation to the contralateral lung produces atelectasis, which, in turn, causes shunting of blood and hypoxemia. The delivery of a high volume to the intubated lung predisposes to the development of a pneumothorax.[4]

Clues to the development of endobronchial intubation include an increase in peak airway pressure accompanied by a proportional increase in plateau pressure, asymmetric expansion of each hemithorax, and a decrease in breath sounds over the contralateral lung. In a prospective study, however, Brunel et al[10] found that clinicians considered breath sounds equal over both lung fields in 60% of patients with an endobronchial intubation.

If endobronchial intubation is suspected, the endotracheal tube should be pulled back a few centimeters, the chest auscultated again, and the position of the tube confirmed by radiography. The problem can be prevented by securing the tip of the tube at least 3 to 4 cm above the carina, and obtaining a radiograph at the time of intubation.[12] In addition, centimeter markings on an endotracheal tube are helpful as a reference, although not completely reliable.[10] In general, an endotracheal tube should be secured at reference markings

TABLE 53-1: CAUSES OF SUDDEN RESPIRATORY DISTRESS IN A PATIENT RECEIVING MECHANICAL VENTILATION

Patient-related causes
- Artificial airway problems
  - Movement of the endotracheal tube
  - Cuff herniation external
  - Compression of the endotracheal tube by the cuff
  - Cuff leak
  - Endotracheal tube kinking
  - Foreign body
  - Tracheoesophageal fistula
  - Innominate artery rupture
  - Malpositioning of the nasogastric tube
  - Build-up of secretions
- Bronchospasm
- Pneumothorax
- Pulmonary edema
- Pulmonary embolism
- Acute hypoxemia
- Blood in the endotracheal tube
- Dynamic hyperinflation
- Abnormal respiratory drive
- Alteration in body posture
- Drug-induced problems
- Abdominal distension
- Agitation

Ventilator-related causes
- Ventilator malfunction
- External ventilator circuit
  - Leaks or disconnects
  - Condensate
  - Inline nebulizers
- Inadequate ventilator support
- Patient–ventilator dyssynchrony

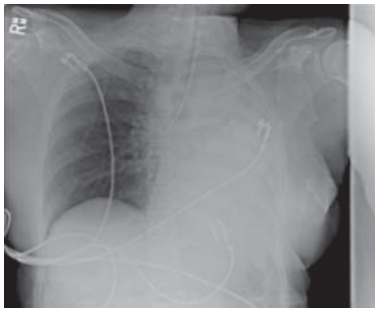

FIGURE 53-6 Right main-stem intubation. The endotracheal tube was inserted too far down, resulting in intubation of the right main-stem bronchus and atelectasis of the left lung with resultant mediastinal shift toward to the left.

of 23 cm in men and 21 cm in women.[10] On the chest radiograph, the tip of the endotracheal tube should be located at a level corresponding to the top of the aortic knob when the head is in a neutral position.[13]

An endotracheal tube may also migrate above the vocal cords, or get dislodged into the esophagus.[11] Esophageal intubation may arise as a result of attempts to blindly reposition an endotracheal tube. Malpositioning causes sudden distress accompanied by phonation, audible escape of air through the nose and mouth, absence of tube condensation, decrease in tidal volume (V_T), decrease (or increase) in peak airway pressure, and abdominal distension. Chest radiography can be misleading because the trachea overlays the esophagus, making it difficult to tell whether the tube is located in the esophagus or trachea. A reading of zero on an end-tidal CO_2 monitor helps in detecting esophageal intubation (Fig. 53-7). Upward movement of an endotracheal tube usually results from excessive neck movement and/or inadequate tube fixation. Conrardy et al[12] found that neck extension caused an endotracheal tube to move an average of 1.9 cm away from the carina, but movement was as much as 5.2 cm in some patients. This observation may explain why patients who are carefully restrained can still self-extubate.

Cuff Herniation

Herniation of the cuff of an endotracheal tube over its distal tip can cause complete airway obstruction.[11] This problem most commonly occurs after changes in position of the tube or changes in the posture of the head and neck. Clues to cuff herniation include an increase in peak airway pressure, resistance during manual ventilation, a decrease in V_T, difficulty in passing a suction catheter, and an abnormal musical sound during inspiration.[2] Deflation of the cuff produces immediate relief. In a stable patient with an unclear source of airway obstruction, the diagnosis may not be made without bronchoscopy.

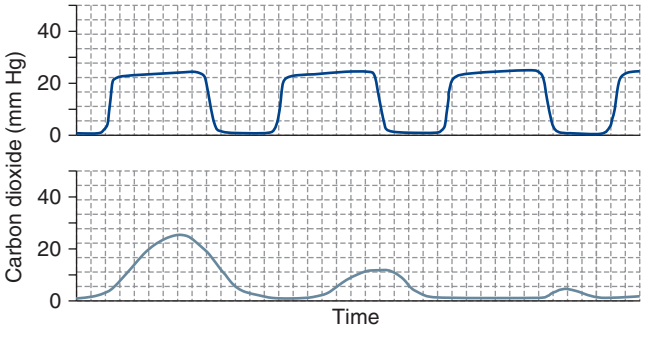

FIGURE 53-7 End-tidal CO_2 tracing and esophageal intubation. *Upper panel.* End-tidal CO_2 tracing in a patient in whom an endotracheal tube was inserted correctly in the trachea. During inhalation, end-tidal CO_2 is 0 mm Hg. During exhalation, the CO_2 tracing rises steeply, attains a near plateau, and then quickly returns to the baseline. The end tidal CO_2 in this patient, 25 mm Hg, is below the normal range of 35 to 45 mm Hg. *Lower panel.* End-tidal CO_2 tracing in a patient in whom an endotracheal tube was erroneously inserted in the esophagus. The expected shape of the CO_2 tracing has been replaced by small transient rises in the CO_2 tracing, which progressively decrease with each squeeze of the Ambu bag.

External Compression of the Endotracheal Tube by the Cuff

External compression of an endotracheal tube as a result of an inflated cuff is a rare cause of airway obstruction (Fig. 53-8).[14]

Cuff Leak

The failure of the cuff on an endotracheal tube to form a seal with the wall of the trachea leads to gas leakage, which may or may not be of clinical consequence.[11] A large leak may cause the ventilator alarms to sound, signaling a low peak airway pressure and low exhaled V_T, and cause alveolar hypoventilation. Other clues include ability to phonate, frothy secretions in the patient's mouth, hearing a gurgle over the trachea or larynx on auscultation, a discrepancy between expired and inspired V_T, and failure to maintain a set level of PEEP.[11]

The most common cause of cuff leak is malposition of the endotracheal tube. Consequently, the development of a cuff leak should cause the physician to reevaluate tube position.

The cuff may be deflated not only because of a leak in the cuff itself, but also because of a leak in the pilot balloon or in the external valve assembly.[13] A clamp placed on the cuff inflation tubing proximal to the valve and pilot balloon can temporarily correct this problem (without having to immediately replace the endotracheal tube).

Complete rupture of a cuff can lead to aspiration of saliva, vomit, or food; the entire endotracheal tube needs to be replaced.

Endotracheal Tube Kinking

The endotracheal tube can become kinked as a result of changes in the position of the head and neck.[10] Some authors have recommended immersing an endotracheal tube in warm saline as a means of decreasing the incidence of mucosal trauma and epistaxis following nasal intubation,[15] but this practice has been reported to give rise to subsequent kinking.[16] Kinking may also occur if the tube softens through being warmed by heated humidified gas,[13] or when the patient bites the tube. Figure 53-9 shows an instance of endotracheal-tube kinking that was attributed to earlier movement of the tube from one angle of the mouth to the other.[17] We speculate that this shift in position of the tube might have led to a force acting in a direction perpendicular to the torque of the natural curve of an endotracheal tube, and thus induced kinking. Kinking leads to an increase in peak airway pressure and difficulty in passing a suction

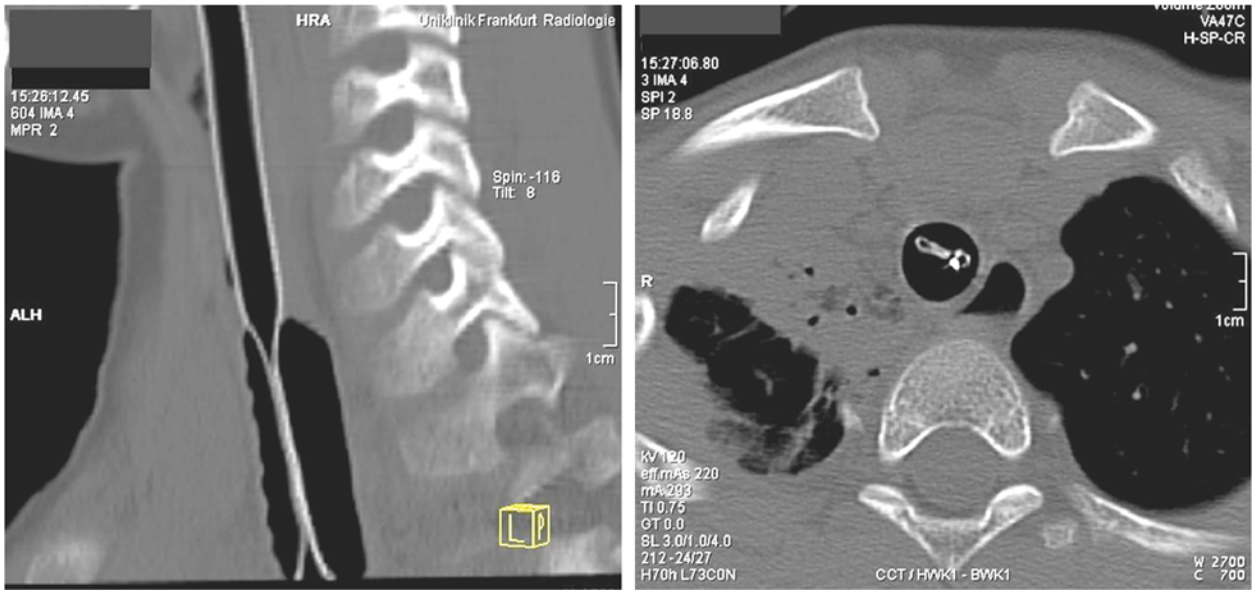

FIGURE 53-8 External compression of endotracheal tube. Computed tomography images of the sagittal plane of the cervical spine and trachea (*left panel*) and transversal plane at the level of the first thoracic vertebra (*right panel*) in an 8-year-old boy who required endotracheal intubation as a result of multiple injuries received in a traffic accident. The inflated cuff produced critical obstruction of the endotracheal tube. The *white dot* on the scan in the right panel indicates the obstructed lumen of the tracheal tube. (Used, with permission, from Hofstetter et al.[14])

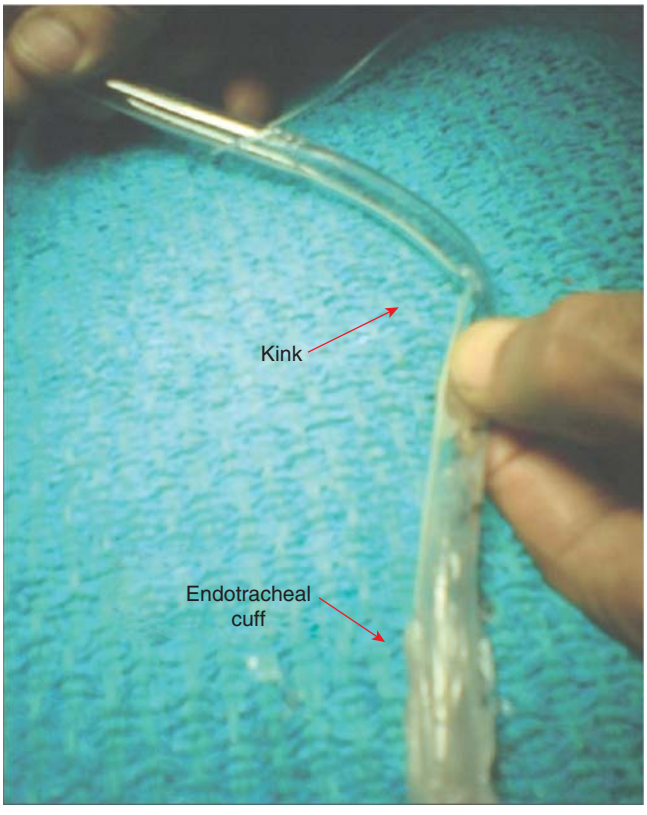

FIGURE 53-9 A kink found approximately 10 cm above the cuff of an endotracheal tube in a direction opposite to the natural curvature of the tube (toward the convex side) that resulted approximately an hour after the tube had been moved from the right angle of mouth and fixed on the left angle. (Used, with permission, from Hariharan et al.[17])

catheter. When this occurs, the endotracheal tube should be withdrawn and replaced.

Foreign Body

The endotracheal tube can become occluded with a variety of foreign bodies, including dried lubricant,[18] surgical tape,[18] a broken stylet sheath,[19] plastic debris retained from the time of manufacturing the Murphy eye in the tube,[20] and nasal turbinates avulsed during nasotracheal intubation.[21]

Tracheoesophageal Fistula

Tracheoesophageal fistula is a rare complication that is primarily caused by ischemia of the tracheal wall secondary to pressure from an overinflated cuff or by movement of a tracheal tube or its tip.[22] Patients with this complication typically have had both a tracheal tube and a nasogastric tube in place for a long time.[11,23]

Clues to the presence of a tracheoesophageal fistula include the inability to deliver a preset V_T despite a functional cuff, gastric distension, audible leak of air through the mouth, copious airway secretions, the suctioning of gastric contents from the lower respiratory tract, and clinical deterioration and coughing on deflation of the cuff.[13] Diagnosis needs to be verified by bronchoscopy with direct visualization of the esophagus or by cine-esophagography or cine-tracheography.[13] Most experts believe that closure of the fistula demands operative repair; opinions vary as to optimal timing.[13]

Innominate Artery Rupture

Erosion of the innominate artery has been reported to occur in 0.4% to 4.5% of tracheostomies.[24] Most ruptures occur at some point during the first three weeks after a tracheotomy,[24] with peak incidence 7 to 14 days after the procedure.[25] The underside of the tracheal tube, the tracheal cuff, or the tip of the tube erode through the anterolateral tracheal wall, at the point where the innominate artery crosses the trachea. Risk factors include excessive movement of the tube, excessive movement of the neck, overinflation of the cuff, or radiotherapy. Several authors emphasize that making a tracheotomy incision below the third tracheal ring increases the risk of fistula formation, but the complication can occur even when the incision is placed between the second and third tracheal rings, as recommended.[25]

Any peristomal bleeding or hemoptysis in a patient with a recent tracheotomy should lead to detailed assessment to ascertain the underlying cause. Bleeding within 48 hours is usually associated with local factors such as traumatic puncture of anterior jugular or inferior thyroid veins, mucosal abrasion from a suction catheter, or systemic coagulopathy. Bleeding occurring 3 days to 6 weeks after a tracheotomy should be judged to be the result of innominate artery rupture until proven otherwise.[25] The clinical presentation may be quite dramatic, with blood gushing from the tracheal tube. It may be heralded by pulsation of the tracheal cannula or a "sentinel bleed," which is reported to occur in more than 50% of patients.[25]

Adequate oxygenation is the mainstay of immediate management with simultaneous identification and termination of bleeding.[25] The tracheostomy cuff should be overinflated in an attempt to achieve tamponade, and the cuffed tube advanced so that the balloon lies distal to the tracheostomy stoma. An attempt should be made to digitally compress the artery by inserting an index finger into the stoma and compress the artery against the posterior surface of the manubrium.[24] If this is successful, a blood transfusion should be administered while the patient is being transported to the operating room for sternotomy and ligation of the vessel. Time should not be wasted in performing imaging studies. Mortality is extremely high: greater than 85% in a review of the world literature.[24]

OTHER PROBLEMS

Malposition of the Nasogastric Tube

A stiff nasogastric tube can easily bypass the cuff of an endotracheal tube and enter the airway. If the nasogastric tube is connected to suction, the continuous negative pressure will create a constant flow of gas out of the airways.[26] Consequently, the low V_T alarm will sound. The negative pressure can also cause triggering of the ventilator. In particular, ventilator triggering in a patient who is receiving a paralytic agent suggests that a nasogastric tube is misplaced in the airway. Other complications of nasogastric tubes include passage of the tube through the tracheobronchial tree into the pleural space, causing the formation of a bronchopleural fistula; infusion of nutritional solutions through the misplaced nasogastric tube can cause an empyema. A nasogastric tube can also cause esophageal perforation leading to pneumomediastinum, pneumothorax, and tracheoesophageal fistula.

Secretions

Airway secretions can cause problems by being too copious or too dry. Excessive secretions can lead to mucus plugging and atelectasis. To avoid this problem, careful bronchial toilet and frequent suctioning are necessary in patients with copious secretions. If atelectasis occurs and fails to resolve with conservative measures, bronchoscopy should be undertaken.

A helpful clue to the presence of excessive secretions is the presence of a sawtooth pattern on the flow tracing.[7] In a study of fifty intubated patients, Jubran and Tobin[7] found that the presence of a sawtooth pattern was approximately six to eight times more likely in patients who had secretions than in patients without secretions. Conversely, a smooth flow-volume curve was about one-quarter as likely to be found in patients with secretions as in patients without secretions. Clinical examination had much higher false-positive and false-negative rates (42% and 43%, respectively) than the flow-volume curves (12% and 14%, respectively). The usefulness of a sawtooth pattern for detecting secretions was confirmed by Guglielminotti et al[27] in a study of sixty-two patients who were receiving pressure-support or assist-control ventilation.

A tracheal tube bypasses the upper airway, which normally heats and humidifies inspired gas. Consequently, secretions may become excessively dry and encrusted. Inspissated secretions can cause significant blockage of the tracheal tube over a relatively short period.[23] Clues to this problem include an increase in peak airway pressure without an associated increase in plateau pressure, and difficulty in passing a suction catheter. Obstruction appears to be a greater problem when heat and moisture exchangers are employed, as opposed to hot water humidifiers (see Chapter 51).

When secretions dry and accumulate, they can cause complete obstruction or ball-valve obstruction of the endotracheal tube. When this occurs at the distal tip of the tube, positive pressure during inspiration will cause the mass to move away from the tip, permitting the flow of gas. During expiration, expiratory pressure will push the mass of dried secretions into the distal port producing occlusion and cessation of airflow. The ball-valve obstruction causes pulmonary hyperinflation and may produce a tension pneumothorax.[28]

Bronchospasm

Bronchoconstriction is a common cause of sudden respiratory distress. Clues to its development include an increase in peak airway pressure with little or no change in plateau pressure. Clinical manifestations include wheezes, pulsus paradoxus, and evidence of increased work of breathing (recession of the suprasternal space, supraclavicular fossae, and intercostal spaces; heightened activity of the accessory muscles; tracheal tug; and paradoxic motion of the rib cage and abdomen). Management includes bronchodilator therapy.

Pneumothorax

Sudden respiratory distress in a ventilator-supported patient should always arouse suspicion of a pneumothorax, because 60% to 90% of such pneumothoraces are reported to be under tension (Fig. 53-10).[29] Chapter 44 provides a full discussion of barotrauma and its pathogenesis.

A pneumothorax is typically associated with an increase in peak airway pressure and a proportional increase in plateau pressure. Other manifestations include hyperresonance, tracheal deviation to the contralateral side, decreased breath sounds, and cardiovascular collapse. If a pneumothorax is suspected and death is imminent, a 14- to 16-gauge needle should be inserted into a second intercostal space. If a gush of air is heard, a thoracostomy tube is inserted. If the patient is stable, however, a chest radiograph should first be performed to verify the diagnosis before inserting a chest tube.

FIGURE 53-10 Development of a large left pneumothorax in a mechanically ventilated patient. Portable anteroposterior chest radiograph showing large (tensionlike) pneumothorax with significant displacement of heart and mediastinum to the opposite side. Vascular congestion of the right lung also noted.

Pulmonary Edema

Pulmonary edema can cause sudden distress associated with an increase in plateau pressure and a smaller increase in the gradient between the peak and plateau pressures. When present, pink, frothy secretions and an increase in pulmonary artery wedge pressure are particularly helpful.

Pulmonary Embolism

Acute pulmonary embolism is an uncommon cause of sudden respiratory distress in a ventilated patient. Typical manifestations include dyspnea, tachypnea, chest pain, fever, hemoptysis, pleural rub, and features of deep vein thrombosis. An important clue, when it occurs, is sudden hypoxemia with no change in peak airway pressure—a unique combination. The risks associated with transporting a critically ill patient alter the approach to diagnosis. Bedside duplex ultrasonography of the leg veins is a reasonable initial test.[30] Although ventilation–perfusion scans are difficult to perform in a ventilated patient, they have reasonable diagnostic reliability.[31] Helical computed tomographic scanning is worthwhile, although doubts have been raised about its accuracy in this setting.[32]

Acute Hypoxemia

Some ventilated patients present with acute hypoxemia, which may or may not be accompanied by acute distress. The differential diagnosis for new onset of hypoxemia can be considered in terms of ventilator-related problems, progression of the underlying disease, onset of a new medical problem, effects of interventions and procedures, and medications.[33] Table 53-2 lists the causes of worsening oxygenation in the ventilated patient.

Blood from the Endotracheal Tube

The return of bright red blood from a tracheal tube is alarming.[34] It is most commonly caused by trauma from a suction catheter, especially in patients with inflamed airways. Trauma secondary to the cuff also causes bleeding: The most dramatic form is innominate artery fistula. Airway bleeding may arise with infection, such as necrotizing pneumonia or tracheobronchitis. Pulmonary hemorrhage may be part of the underlying disease, such as Goodpasture syndrome, Wegener granulomatosis, neoplasm, or disseminated intravascular coagulation. Blood mixed with pink, frothy secretions suggests pulmonary edema. Pulmonary embolism accounts for a small proportion of patients with hemoptysis.

Pulmonary artery rupture can arise as a complication of pulmonary artery catheterization.[35] Rupture usually results from inflating the balloon when the catheter is too far distal. Risk factors include advancing the catheter with the balloon deflated, failure to observe the pulmonary artery

TABLE 53-2: CAUSES OF WORSENING OXYGENATION IN THE VENTILATED PATIENT

Ventilator-related problems
- Airway malfunction
- External circuit malfunction
- Ventilator malfunction
- Inappropriate ventilator settings

Progression of an underlying disease process
- Acute respiratory distress syndrome
- Cardiogenic pulmonary edema
- Pneumonia
- Sepsis
- Acute exacerbation of asthma or chronic obstructive pulmonary disease

Onset of a new problem
- Pneumothorax
- Atelectasis
- Aspiration (gastric or oropharyngeal)
- Ventilator-associated pneumonia
- Sepsis
- Pulmonary thromboembolism
- Fluid overload
- Bronchospasm
- Retained secretions
- Shock
- Seizure

Effects of interventions and procedures
- Endotracheal suctioning
- Changes in body position
- Chest physiotherapy
- Bronchoscopy
- Thoracentesis
- Peritoneal dialysis
- Hemodialysis

Medications
- Bronchodilators
- Vasodilators
- β–blockers

pressure while the balloon is being inflated (inflation should cease immediately when a wedged tracing is obtained), hand flushing of the catheter while it is wedged, and pulmonary hypertension. If pulmonary artery rupture is suspected, the patient should be placed in a lateral decubitus position with the affected lung down, a double-lumen endotracheal tube inserted (to protect the contralateral lung), and arrangements made for surgical intervention.

Dynamic Hyperinflation

Ventilator-supported patients commonly display tachypnea and an increased time constant (secondary to increased respiratory resistance and/or low pulmonary compliance), which predisposes to the development of dynamic hyperinflation.[36] This hyperinflation is associated with the presence of a positive recoil pressure at the end of expiration, termed *intrinsic PEEP (PEEPi)* or *auto-PEEP*.[37,38]

Hyperinflation may cause significant patient discomfort for at least two reasons. One, it decreases the efficiency of force generation by the respiratory muscles. Two, it increases work of breathing because inspiration occurs at the upper, less compliant portion of the pressure–volume curve of the lung, where inwardly directed elastic recoil of the chest wall poses an additional elastic load.[39,40] To initiate inspiratory gas flow, a patient has to generate a negative pressure equal in magnitude to the opposing elastic recoil pressure (level of PEEPi) (Fig. 53-11). Likewise, if a patient with PEEPi is triggering a ventilator, the patient has to generate a negative-pressure equal in magnitude to the level of PEEPi in addition to the set minimum circuit pressure drop before a ventilator-assisted breath is initiated. This is one factor that accounts for the common occurrence of failure to trigger despite obvious respiratory effort (Fig. 53-12).[41,42]

Therapeutic measures to decrease PEEPi include bronchodilator agents, employment of a large-bore endotracheal tube; decreasing the minute ventilation by controlling fever or pain; and minimizing the ratio of inspiratory time to expiratory time by increasing inspiratory flow rate, or using non-distensible tubing in the ventilator circuit.

Addition of external PEEP can also decrease work secondary to the inspiratory threshold load effect of PEEPi.[38,43] To initiate inspiratory flow, alveolar pressure must be decreased below ambient pressure. During normal spontaneous breathing, this is accomplished by only a small decrease in pleural pressure. For alveolar pressure to fall below ambient pressure in the presence of hyperinflation, however, a much greater decrease in pleural pressure is required. If ambient pressure is elevated by the application of external PEEP, inspiration is more easily accomplished because alveolar pressure needs to be decreased only below the level of external PEEP (rather than below zero). This may seem paradoxical: External PEEP, which is commonly used to induce hyperinflation in patients with microatelectasis, is being used to decrease the work of breathing induced by hyperinflation.

This paradox can be understood by considering the analogy of a waterfall over a dam.[40] The height of the waterfall represents the critical closing pressure of airways in patients with PEEPi and chronic obstructive pulmonary disease (COPD) (Fig. 53-13). Thus, elevating downstream pressure, as with external PEEP, has no influence on either expiratory airflow or the pressure upstream (PEEPi) from the site of critical closure (Fig. 53-13, *upper panel*). This situation exists until downstream pressure is elevated to a value equal to the critical closing pressure (Fig. 53-13, *middle panel*). Once downstream pressure is elevated above the critical closing pressure (the height of the waterfall), however, the pressure upstream increases immediately, and hyperinflation is exacerbated (Fig. 53-13, *lower panel*).

The counteracting effect of external PEEP operates only in the setting of airflow limitation. In the absence of airflow limitation, or when PEEPi results from expiratory muscle activity, the addition of external PEEP is a hindrance and adds to work of expiration. It is important to keep in mind that while external PEEP can help decrease inspiratory work,

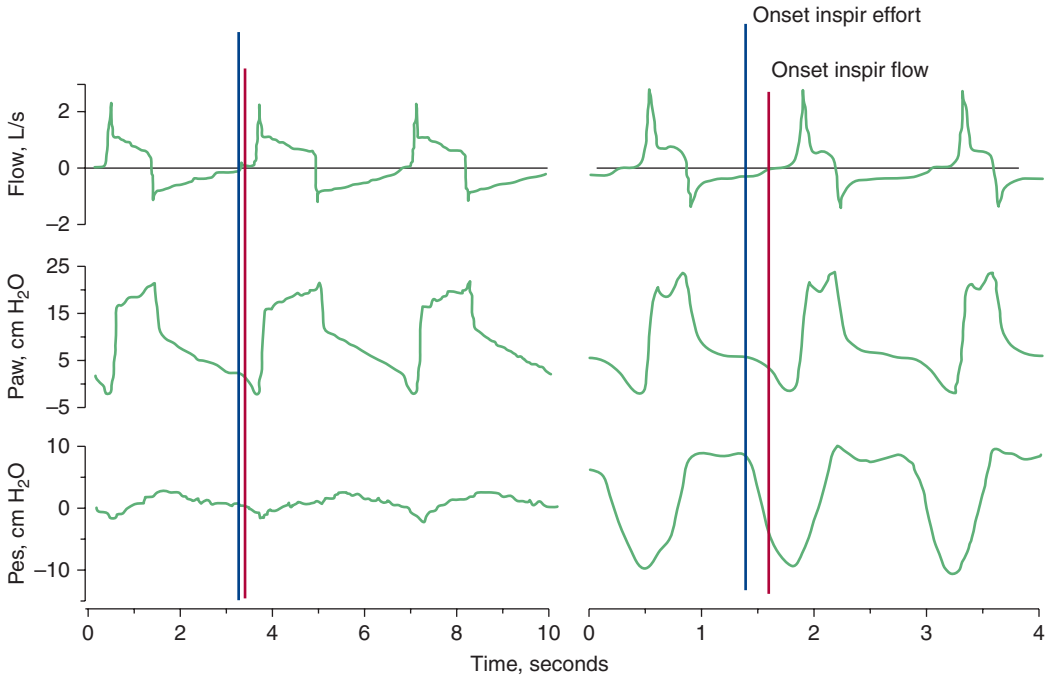

FIGURE 53-11 Differing degrees of intrinsic positive end-expiratory pressure (PEEPi) in patients with chronic obstructive pulmonary disease. Tracings are flow, airway pressure (*Paw*), and esophageal pressure (*Pes*) in two patients with chronic obstructive pulmonary disease receiving assisted ventilation with pressure support set at 20 cm H_2O (no external PEEP is applied). The patient on the left had a myocardial infarction complicated by congestive heart failure, and the patient on the right had sepsis. PEEPi, estimated as the difference in esophageal pressure between the onset of inspiratory (*Inspir*) effort (*vertical blue line*) and the onset of inspiratory flow (*vertical red line*), was 0.5 cm H_2O in the patient on the left and 10.6 cm H_2O in the patient on the right. This method of estimating PEEPi is based on the assumption that the change in esophageal pressure reflects the inspiratory muscle pressure required to counterbalance the end-expiratory elastic recoil of the respiratory system.

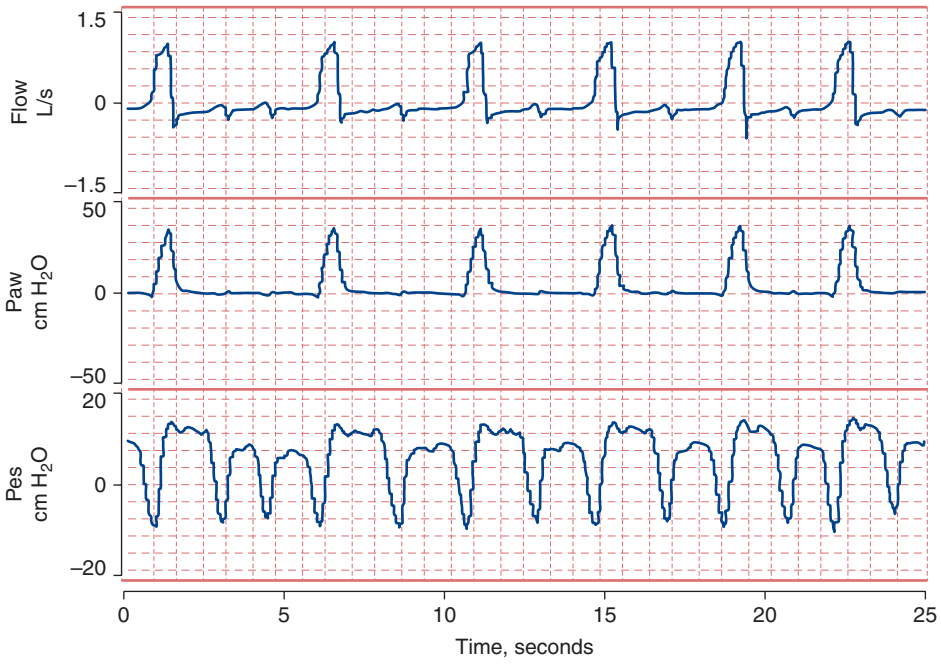

FIGURE 53-12 Failure to trigger the ventilator. Flow, airway pressure (*Paw*), and esophageal pressure (*Pes*), in a patient with chronic obstructive pulmonary disease who is receiving assist-control ventilation at the following settings: tidal volume 600 mL, inspiratory flow 60 L/min, trigger sensitivity –2 cm H_2O, and positive end-expiratory pressure 0 cm H_2O. The patient's intrinsic respiratory rate is 28 breaths/min, whereas the number of breaths delivered by the ventilator is 16 breaths/min. That is, 43% of the patient's inspiratory efforts fail to trigger ventilator assistance. Contractions of the inspiratory muscles during the failed triggering attempts cause a temporary deceleration of expiratory flow and much less obvious decreases in airway pressure. The temporary decelerations in expiratory flow are followed by temporary accelerations of expiratory flow that coincide with the termination of the unsuccessful inspiratory effort.

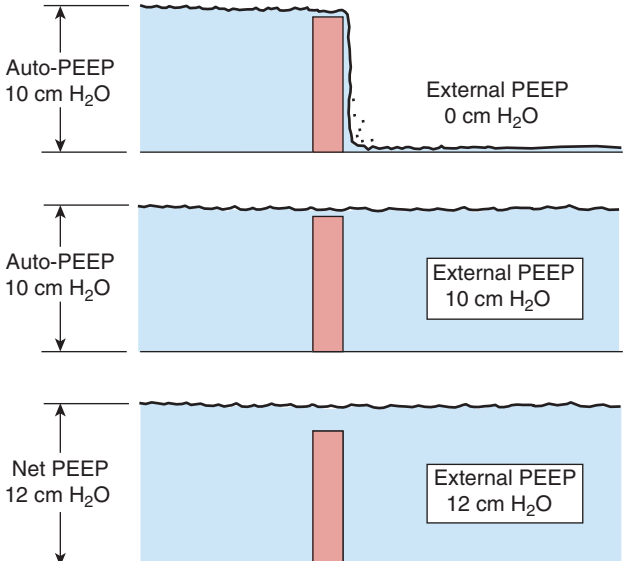

FIGURE 53-13 The analogy of a waterfall over a dam (indicated by the *solid block*) is used to explain the effect of external PEEP (downstream pressure) on PEEPi (upstream pressure) during expiration. Elevation of downstream pressure with external PEEP has no influence on either expiratory flow or upstream pressure (PEEPi) until it is equal to the critical closing pressure. When downstream pressure exceeds the critical closing pressure, the pressure upstream increases and hyperinflation is exacerbated. (Used, with permission, from Tobin and Lodato.[40])

it does nothing to relieve the accompanying hyperinflation, which has other detrimental effects.[39] Another caveat is the heterogenous distribution of lung units in patients with airflow limitation, each with its own critical closing pressure.[44] Given the regional inhomogeneities among lung units, the average level of PEEPi must exceed the lowest regional alveolar pressure. Thus, external PEEP equal to PEEPi could cause hyperinflation in the faster-emptying lung units.[45–47] To minimize this risk, it is prudent to limit the level of external PEEP to approximately 70% of the level of PEEPi.

The importance of PEEPi as a cause of electromechanical dissociation during cardiopulmonary resuscitation is now well recognized.[48,49] Rosengarten et al[48] reported a dramatic example. A young woman with acute severe asthma was intubated 25 minutes after initial presentation. Ventilation was commenced with a V_T of 8 to 10 mL/kg and a respiratory rate of 10 to 14 breaths/min. Oxygen saturation increased momentarily. Five minutes after intubation, blood pressure could not be recorded. External cardiac massage was instituted, but the patient remained in electromechanical dissociation. Twenty-five minutes after intubation, the situation was considered irretrievable. All resuscitation was stopped. Three minutes later, the patient returned to sinus rhythm, and the pulses became palpable. Ventilation was recommenced at 15 breaths/min. Within 15 seconds, the pulse disappeared. Ventilation was reduced to 6 to 8 breaths/min, and the pulse returned. Ventilation was transiently increased on three more occasions, and blood pressure disappeared each time. Seventy-five minutes after commencing resuscitation, the patient's blood pressure was 165/80 mm Hg. The patient suffered initial ischemic brain damage, but eventually made a close to complete recovery. In retrospect, it is clear that this patient suffered repeated episodes of circulatory arrest as a result of unrecognized ventilator-induced hyperinflation.

If faced with persistent hypotension in a patient with airflow limitation who is undergoing cardiopulmonary resuscitation, elevated PEEPi should be suspected. In such instances, the patient should be subjected to an apnea trial (after first ventilating the patient with 100% oxygen).[13] Ventilation is stopped for 1 minute, and blood pressure measured. If blood pressure improves, ventilation is resumed, but aiming to achieve a lower minute ventilation.

Inadequate Respiratory Motor Output

Decreased respiratory neuromuscular output may cause sudden deterioration in a patient's respiratory status. Decreased respiratory motor output, however, is not typically accompanied by respiratory distress. Respiratory motor output may be decreased as a result of acute neurologic disorders, heavy sedation, or neuromuscular blocking agents.[50] A normal, or even elevated, motor output may be insufficient to maintain alveolar ventilation if ventilatory demands or the mechanical load suddenly increase.

Elevated Respiratory Motor Output

Excessive respiratory motor output may cause severe respiratory alkalosis, which, in turn, may cause arrhythmias, hypotension, cerebral vasoconstriction, and seizures.[51,52] Ventilation can be stimulated by many physiologic, psychologic, and pathologic factors.[50] Extreme anxiety and panic cause dyspnea, fear, tachycardia, and palpitations, and when a patient misinterprets the basis of these symptoms, hyperventilation commonly develops.[53,54] A patient's likelihood of hyperventilating in response to stress probably depends on biologic vulnerability, personality, and cognitive variables.[54]

Several respiratory and nonrespiratory organic disorders stimulate breathing. The best known example is asthma, and even mild or moderate airway obstruction may be accompanied by a fall in partial pressure of arterial carbon dioxide (Pa_{CO_2}) to below 25 mm Hg.[55] The mechanism of the hyperventilation is uncertain: It is probably related to hyperinflation[56] and stimulation of vagal afferents,[57] and it is not reversed by bronchodilation.[58] The reduction in Pa_{CO_2} is quantitatively consistent with hypoxic stimulation of the peripheral chemoreceptors, although supplemental oxygen does not restore ventilation to normal.[59] Respiratory stimulation also occurs in patients with COPD,[60] pulmonary fibrosis,[60,61] pneumonia,[62] pulmonary embolism,[63] pulmonary hypertension,[60,64] and heart failure.[65] In asthma, the most profound hyperventilation occurs with relatively mild disease,[55,66] and the same may apply with the other causes of respiratory stimulation. Pain stimulates breathing,[67] whereas hyperventilation increases the pain threshold.[68] Hyperventilation can be severe with certain drug overdoses,

such as aspirin,[69] and it is a striking feature of sepsis[70] and major organ system failure,[71] although it does not occur in thyrotoxicosis. Acute diabetic ketoacidosis stimulates the peripheral chemoreceptors to produce deep rapid breathing and hypocapnia.[72]

Plum et al[73] coined the term *central neurogenic hyperventilation* to describe nine patients with tachypnea, of metronomic regularity, which persisted for hours or days at a time. Plum et al[74] subsequently revised their opinion, and attributed the heightened ventilation to stimulation of afferent peripheral reflexes arising in the lung and chest wall. It has not been possible to reproduce central neurogenic hyperventilation in animals. In their own clinical practice, Plum et al[74] are convinced of having seen only three patients with the condition, although brain histology was obtained in none of these cases. A few patients have been reported who displayed profound respiratory alkalosis, persisting during sleep or after administration of morphine, with normal oxygenation, normal chest radiography, and who had histologic evidence of pathology in the pons or some other area of the brain.[75–80] The rarity of this disorder is supported by the data of North et al.[81] Of 227 patients admitted to a neurosurgical unit, fifty-seven had a respiratory rate greater than 25 breaths/min and nine of these had a Pa_{CO_2} less than 30 mm Hg. In all but one patient, however, the tachypnea and hypocapnia could be explained by hypoxemia associated with a pulmonary abnormality or metabolic acidosis. While hyperventilation in critically ill patients with an acute neurologic disorder is rarely neurogenic in nature, it nevertheless carries a poor prognosis.[81–84]

Body Posture

An alteration in body posture can cause a fall in partial pressure of arterial oxygen (Pa_{O_2}) of as much as 30%,[33,85] especially in patients with unilateral lung disease. The hypoxemia is secondary to the effect of gravity on blood flow, as blood is shunted through the diseased dependent lung.

Drug-Induced Deterioration

Hypoxemia may result from worsening of ventilation–perfusion relationships secondary to bronchodilators or vasodilators (e.g., nitroglycerin or nitroprusside). Administration of intravenous lipid compounds can also produce hypoxemia.[33] Aminoglycoside antibiotics can provoke or aggravate neuromuscular blockade and produce respiratory embarrassment.[86] High levels of theophylline may produce agitation and/or seizures.

Abdominal Distension

Abdominal distension can cause elevation of the diaphragm, basilar atelectasis, and deterioration in ventilation–perfusion relationships. Abdominal distension may result from gastric distension, ascites, peritoneal dialysis, or bowel perforation. Gastric distension may result from a prolonged or difficult attempt at intubation; elevation of mouth pressure above the lower esophageal sphincter pressure during the delivery of manual ventilation; or tracheal pressure exceeding the cuff pressure and lower esophageal sphincter pressure and the mouth remaining closed during mechanical ventilation.[87,88] Massive distension, "meteorism," can produce gastric rupture. Insertion of a small-bore nasogastric tube helps prevent or alleviate this complication.

Massive colonic distension without small intestinal dilation or distal obstruction (Ogilvie syndrome) has been described in patients receiving mechanical ventilation (Fig. 53-14).[89,90] The mechanism is not known, but exaggerated aerophagia may be an important factor. Perforation of an overdistended cecum is often the first evidence of this complication. Accordingly, abdominal radiographs should be obtained in patients with abdominal distension, and cecostomy should be considered when the cecal diameter exceeds 9 cm. Massive colonic distension with or without massive ascites can also complicate *Clostridium difficile* colitis.[91]

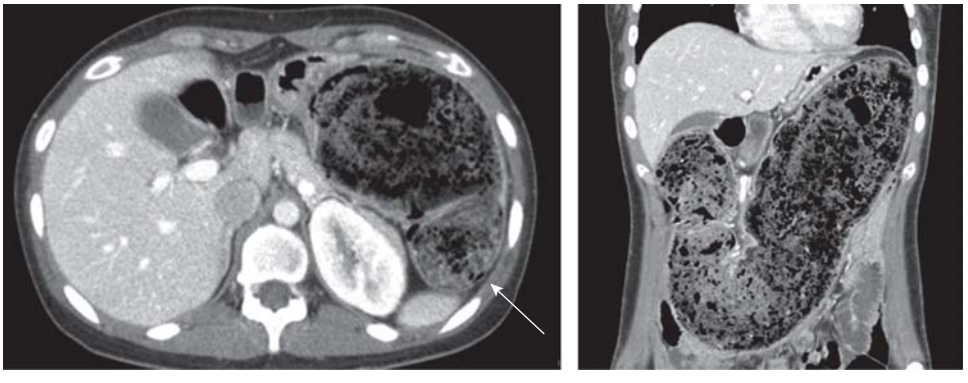

FIGURE 53-14 Ogilvie syndrome in a 31-year-old woman. Axial (*left panel*) and coronal (*right panel*) contrast-enhanced computed tomography images demonstrate a markedly distended transverse colon with large amount of fecal material. The *arrow* in the left panel points at the transitional zone (splenic flexure) that is devoid of any obstructive lesions. (Used, with permission, from Choi et al.[89])

Agitation

Ventilated patients develop agitation as a result of four major factors: pain, anxiety, delirium, and dyspnea. Innumerable factors can cause pain in a critically ill patient, ranging from simple factors such as poorly applied adhesive tape to the pain of a major surgical procedure. Feelings of anxiety, insecurity, fear, and panic are very common in ventilator-dependent patients,[92,93] including a fear of impending death. Untreated pain and anxiety can lead to insomnia and delirium. These problems are aggravated by the discomfort of dyspnea, which may result from injudicious ventilator settings (see *Patient–Ventilator Dyssynchrony* below). It is important to follow a systematic approach when evaluating a patient for the source of pain or anxiety, because simple problems, such as an overdistended bladder, may be overlooked while a search is conducted for a more esoteric source of distress.

VENTILATOR MALFUNCTION

Resolution of a patient's distress with the onset of bagging indicates that the problem lies within the ventilator or its external circuit (see Fig. 53-1). Malfunction of the ventilator may arise from tubing connected to a wrong outlet; a poor fit of connections; uncoupling of connections; defective material; obstruction of the circuit secondary to kinks, intraluminal fluids, or a malfunctioning valve; or malfunction of microprocessor controls. If malfunction is suspected, the ventilator should be replaced while each component is checked against the schematic circuit diagram. When a patient's delivered V_T is adequate and distress is relieved by manual ventilation, a fault in the setting of the fractional inspired oxygen concentration should be suspected. This problem can be verified by obtaining an independent direct measurement of inspired oxygen concentration.

External Ventilator Circuit

The ventilator circuit primarily consists of the tubing and connectors that form inspiratory and exhalation limbs; the humidifier; the exhalation valve assembly and flow measuring devices; adaptors placed within the circuit for monitoring or delivering medications; and inline filters.[13] Problems within this circuit that can cause patient distress include leaks, disconnects, accumulation of condensate, and inline nebulizers.

LEAKS OR DISCONNECTS

A leak may arise in parts of the circuit assembly that screw together. Leaks or uncoupling of connections will cause sounding of the low pressure and low V_T alarms. The Y-connection to the tracheal tube is the most common site of a disconnection. Other locations of disconnections and leaks include the humidifier system, an incompetent exhalation valve assembly, disconnection of the proximal line that connects the pressure tap at the Y-piece to the ventilator manometer, or small ruptures in the tubing.

In patients ventilated with pressure support, a leak at any location in the circuit, including at the cuff of the endotracheal tube, predisposes to a unique problem.[94] During pressure support, the ventilator strives to maintain a preset level of pressure throughout inspiration. A leak, however, will tend to cause the airway pressure to fall. To prevent the fall in airway pressure, the ventilator increases inspiratory flow. The algorithm employed by many ventilators for terminating the time of lung inflation is a fall in inspiratory flow to an absolute value of 5 L/min (or a fall in flow of 75% from the peak value). The increase in flow being delivered by the ventilator means that inspiratory flow never falls to the threshold required for termination of inflation. This phenomenon results in the unremitting application of positive pressure, which is relieved by correcting the leak.

CONDENSATE

Gas supplied to the inspiratory limb is typically warmed to 32°C (89.6°F) to 34°C (93.2°F) and fully saturated with water vapor. The gas cools as it passes through the inspiratory tubing, causing condensate to form. The condensate accumulates in a U-loop of the circuit. If enough condensate accumulates, movement of the water can cause the ventilator to trigger. During assist-control ventilation, excessive triggering can lead to barotrauma or hemodynamic compromise. During pressure-support or pressure-controlled ventilation, the resistance caused by the condensate may cause a decrease in achieved V_T for a set airway pressure.

INLINE NEBULIZERS

The insertion of a continuous-flow nebulizer between the patient and the pressure sensor within the ventilator can lead to hypoventilation during pressure support or intermittent mandatory ventilation (IMV).[95] When a patient's mean inspiratory flow rate is less than the flow of gas used to power the nebulizer (6 to 10 L/min), airway pressure will not fall sufficiently to trigger the ventilator. Moreover, the continuous flow from the nebulizer creates a bias flow, which the ventilator interprets as forming part of the patient's minute ventilation. Consequently, the low minute volume alarm will not sound.

Patient–Ventilator Dyssynchrony

Patient–ventilator dyssynchrony can lead to considerable patient distress, and it also impedes the effectiveness of the ventilator in decreasing respiratory work. For the most effective unloading of the inspiratory muscles, the ventilator should cycle in synchrony with the patient's central respiratory rhythm. For perfect synchronization, the period

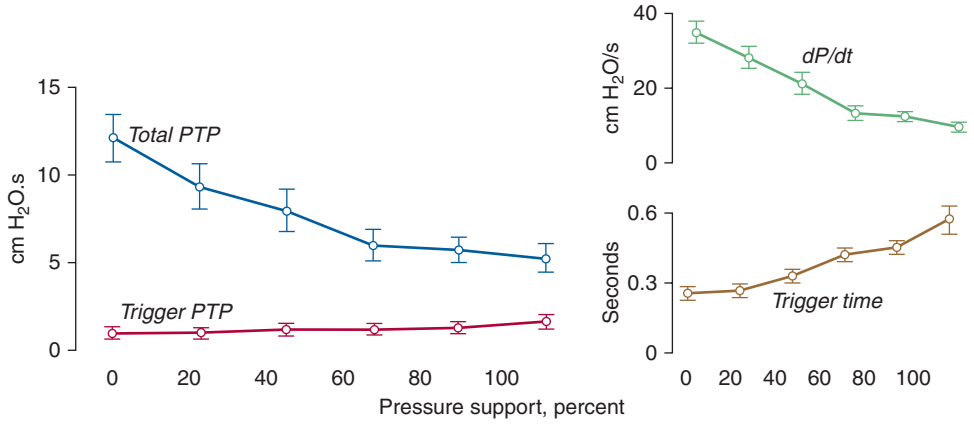

FIGURE 53-15 Graded increases in pressure support produced a decrease in total pressure-time product (*PTP*) per breath (*blue symbols*), although PTP during the trigger phase (*red symbols*) did not change (*left panel*). The constancy of PTP during triggering probably resulted from different factors becoming operational at different levels of assistance (*right panel*). At low levels of pressure support, respiratory motor output (dP/dt *green symbols*) and intrinsic positive end-expiratory pressure (PEEPi) were high but triggering time was short (*brown symbols*), resulting in a large change in pleural pressure over a brief interval. At high levels of pressure support, dP/dt and PEEPi were low but triggering time was long, resulting in a smaller change in pleural pressure over a longer time. (Based on data from Leung et al.[91])

of mechanical inflation must match the period of neural inspiratory time (the duration of inspiratory effort), and the period of mechanical inactivity must match the neural expiratory time.[96,97] The interplay between the ventilator and the respiratory neuromuscular apparatus is complex, and problems can arise at several points in the respiratory cycle: the onset of ventilator triggering, the remainder of inspiration after triggering, the switch from inspiration to expiration, and the end of expiration.[42]

TRIGGERING OF THE VENTILATOR

Patients reach the set sensitivity by activating their inspiratory muscles. For a given set sensitivity, the delay between onset of patient inspiratory effort and onset of ventilator assistance is a function of a patient's respiratory motor output. When a patient's respiratory drive is low, assistance may not begin until well into the patient's inspiratory time, thereby causing the ventilator to cycle almost completely out of phase with the patient's respiratory cycle. When the threshold to open the demand valve is reached and the ventilator starts to provide positive-pressure assistance, the inspiratory neurons do not simply switch off, and a patient may expend considerable inspiratory effort throughout the machine-cycled inflation.[98] The level of patient effort during this post-trigger phase is closely related to a patient's respiratory motor output at the point of triggering.[99] As such, measures that decrease respiratory drive may enhance respiratory muscle rest during mechanical ventilation.

If respiratory motor output at the point of triggering is important, one might expect that effort during the time of triggering would determine patient effort during the remainder of inspiration.[100] To investigate this issue, Leung et al[99] applied graded levels of pressure support in eleven critically ill patients. They achieved a fourfold reduction in overall patient effort. Yet patient effort during the time of triggering did not change. The constancy of effort during the trigger phase was probably secondary to different factors becoming operational as the level of ventilator assistance was varied (Fig. 53-15). Thus, increases in the level of ventilator assistance do not substantially decrease patient effort during the time of triggering.

INEFFECTIVE TRIGGERING

At high levels of mechanical assistance, up to one-third of a patient's inspiratory efforts may fail to trigger the machine (see Fig. 53-12).[99,101,102] The number of ineffective triggering attempts increases in direct proportion to the level of ventilator assistance.[99] Surprisingly, unsuccessful triggering is not the result of poor inspiratory effort. In a study of factors contributing to ineffective triggering, a decrease in the magnitude of inspiratory effort at a given level of assistance was not the cause; indeed, effort was 38% higher during nontriggering attempts than during the triggering phase of attempts that successfully opened the ventilator valve.[99] Significant differences, however, were noted in the characteristics of the breaths before the triggering and nontriggering attempts. Breaths before nontriggering attempts had a higher V_T than did the breaths before triggering attempts, 486 ± 19 and 444 ± 16 mL, respectively, and a shorter expiratory time, 1.02 ± 0.04 and 1.24 ± 0.03 seconds, respectively. An abbreviated expiratory time does not allow the lung to return to its relaxation volume, leading to an increase in elastic recoil pressure. Indeed, PEEPi was higher at the onset of nontriggering attempts than at the onset of triggering attempts: 4.22 ± 0.26 versus 3.25 ± 0.23 cm H_2O. Thus, nontriggering results from premature inspiratory efforts that are not sufficient to overcome the increased elastic recoil associated with dynamic hyperinflation.[99]

When triggering fails as a result of dynamic hyperinflation, the nontriggering on that breath allows the lungs to more completely empty in preparation for the next breath. Occasionally, two or three failed triggering attempts take place before triggering becomes successful. Because there is no lung inflation during a failed triggering attempt, mechanical exhalation continues for a longer time and end-expiratory volume continues to fall until triggering becomes successful. This pattern may occur repeatedly such that it resembles the Wenckebach pattern of atrioventricular block on an ECG.[103]

In addition to an increase in elastic recoil pressure,[99] an elevated PEEPi can also result from an increase in expiratory muscle activity. Parthasarathy et al[97] investigated the relative contributions of these two factors to ineffective triggering in healthy subjects receiving pressure support and in whom they induced airflow limitation with a Starling resistor. Nontriggering was linked to the fraction of PEEPi caused by elastic recoil but not to the fraction caused by expiratory effort. This observation suggests that external PEEP might be clinically useful in reducing ineffective triggering.

Although the magnitude of expiratory effort does not appear to influence the success of triggering attempts, the time that expiratory efforts commence in relation to the cycling of the ventilator is an important factor. Parthasarathy et al[97] quantified the relationship between the onset of expiratory muscle activity, measured with a wire electrode in the subject's transversus abdominis, and the termination of mechanical inflation by the ventilator. At pressure support of 20 cm H_2O, mechanical inflation was found to continue for a longer time into neural expiration in the breaths preceding nontriggering attempts. Continuation of mechanical inflation into neural expiration counters expiratory flow, and also decreases the time available for unopposed exhalation. Consequently, elastic recoil increases. In turn, a greater inspiratory effort will be needed to achieve effective triggering. In this way, the time that a patient commences an expiratory effort (in relation to cycling-off of mechanical inflation) partly determines the success of the ensuing inspiratory effort in triggering the ventilator.

DOUBLE TRIGGERING

Some patients exhibit two mechanical inflations within a single neural inspiration, a phenomenon known as *double triggering* (Fig. 53-16). With assist-control ventilation, double triggering is likely when the set mechanical inspiratory time is substantially less than a patient's neural inspiratory time. In this situation, mechanical inflation terminates while the patient is still making an inspiratory effort. After a brief period, the ventilator may trigger again, resulting in a second inflation within the same neural inspiration and, thus, greater alveolar distension than with the delivery of a single tidal volume.[103]

With pressure-support ventilation, double triggering is likely when the time constant is short (low resistance, high elastance) and patient neural inspiratory time is relatively long (a slow, spontaneous respiratory rate).[104] Following the loss of ventilator pressure after a first triggering attempt, volume decreases because the pressure exerted by the inspiratory muscles (Pmus) alone is not sufficient to sustain elastic recoil. During this phase, the persistence of neural inhalation will cause a progressive increase in Pmus, while elastic recoil continues to decrease. If the patient's neural inspiratory time is sufficiently long, a point is reached where Pmus will exceed elastic recoil and flow will become inspiratory and double triggering will occur.[105]

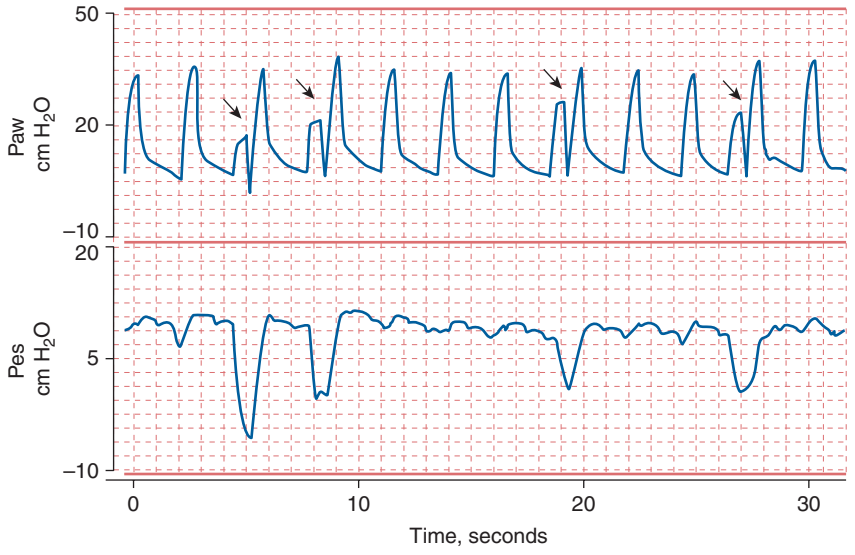

FIGURE 53-16 Four incidents of double triggering, each indicated by an *arrowhead*. Airway pressure (*Paw*) and esophageal pressure (*Pes*) in a patient with COPD and pneumonia who was receiving assist-control ventilation at the following settings: tidal volume 600 mL, inspiratory flow 60 L/min, trigger sensitivity −2 cm H_2O, and positive end-expiratory pressure 5 cm H_2O. The duration of neural inhalation of the double-triggered breaths, roughly equivalent to the width of the associated swings in esophageal pressure, was substantially longer than the neural inhalation of the normally triggered breaths.

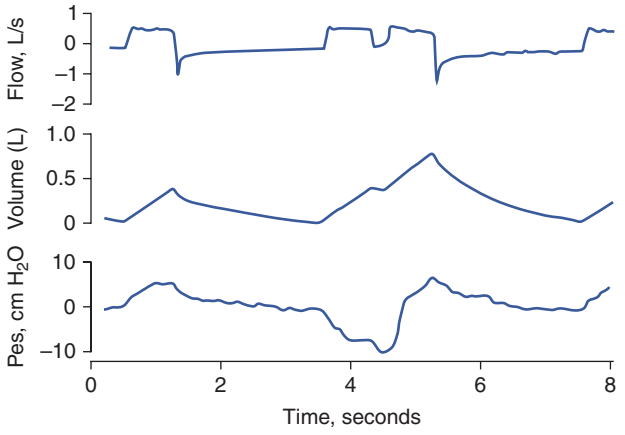

FIGURE 53-17 Volume stacking caused by double triggering. Flow (*top panel*), volume (*middle panel*), and esophageal pressure (*Pes*; *lower panel*) in a patient with COPD receiving assist-control ventilation. During first breath, esophageal pressure remains positive indicating that the patient did not trigger the inflation. During the second breath, esophageal pressure becomes negative indicating active inspiratory effort, which lasts more than 1 second; the duration of mechanical inflation is 0.6 second. The longer duration of neural inspiration as compared with mechanical inflation causes the ventilator to deliver a second breath before there is time for exhalation. As a result, end-inspiratory lung volume increases (breath stacking) with a consequent increase in elastic recoil. The increase in elastic recoil is responsible for the higher peak expiratory flow on the second breath as compared with the first breath.

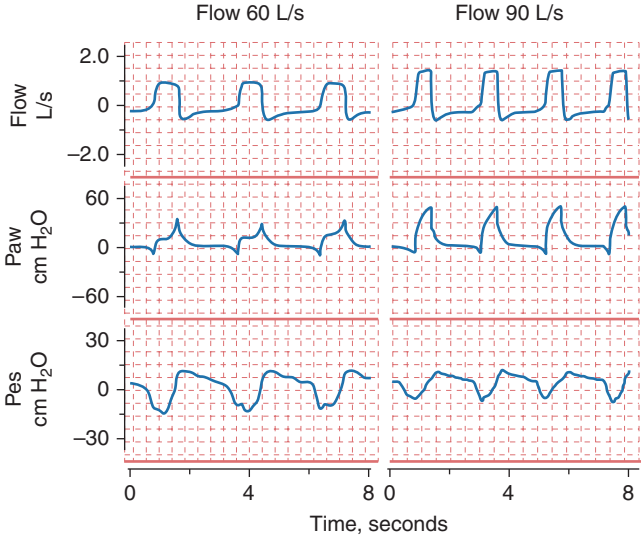

FIGURE 53-18 Influence of ventilator flow setting on patient effort. Flow (inspiration directed upward), airway pressure (*Paw*), and esophageal pressure (*Pes*) in a patient with respiratory failure who is receiving assist-control ventilation; inspiratory flow is set at 60 L/min in the *left panel* and at 90 L/min in the *right panel*. At an inspiratory flow of 60 L/min (*left panel*), the pronounced negative deflection in airway pressure (patient effort to trigger the ventilator) together with subsequent extensive scalloping signifies that the inspiratory flow delivered by the ventilator is insufficient to meet the high demand. At an inspiratory flow of 90 L/min (*right panel*), the small negative deflection in airway pressure together with the subsequent smooth convex contour signifies that the delivered flow satisfies the patient's respiratory drive. Accordingly, the flow of 90 L/min achieved greater unloading of the respiratory muscles, as signaled by the shorter duration of inspiratory effort and the smaller swings in esophageal pressure.

Randomized clinical trials have revealed that use of a high tidal volume (12 mL/kg) is associated with an increased mortality in patients with the acute respiratory distress syndrome.[106] Consequently, it has become standard practice to lower the delivered tidal volume in order to minimize alveolar overdistension; for example, to keep the inspiratory pressure during a pause at the end of inspiration (plateau pressure) to 32 cm H_2O or lower.[106] A low tidal volume is typically accompanied by a short mechanical inspiratory time and thus these patients are especially susceptible to double triggering. Accordingly, conscious attempts to lower tidal volume can paradoxically result in greater alveolar distension than occurs with conventional tidal volume settings (Fig. 53-17). An additional (and often unrecognized) factor that may produce alveolar distension is the tachypnea-associated increase in intrinsic PEEP that accompanies lowering of tidal volume.[107]

SETTING OF INSPIRATORY FLOW

When a patient is first connected to a ventilator, inspiratory flow is set at some default value, such as 60 L/min. Many critically ill patients, however, have an elevated respiratory motor output and the initial flow setting may be insufficient to meet flow demands. As a result, patients will struggle against their own respiratory impedance and that of the ventilator (Fig. 53-18). Consequently, the work of breathing increases. Clinicians sometimes increase flow so as to shorten the inspiratory time and increase the expiratory time. But an increase in flow causes immediate and persistent tachypnea; as a result, expiratory time may be shortened.[108] In healthy subjects, Laghi et al[109] found that increases in inspiratory flow from 30 L/min to 60 and 90 L/min caused increases in the respiratory rate of 20% and 41%, respectively.

A main reason that clinicians increase inspiratory flow is to decrease inspiratory time, in the hope of allowing more time for expiration and thus decrease PEEPi, especially in patients with COPD. Because increased flow usually leads to an increase in rate, the expected shortening of expiratory time might actually increase PEEPi. Laghi et al[110] studied this phenomenon in ten patients with COPD (Fig. 53-19). As with healthy subjects, an increase in flow from 30 to 90 L/min caused the respiratory rate to increase from 16.1 ± 1.0 to 20.8 ± 1.5 breaths/min. Despite the increase in rate, PEEPi fell from 7.0 ± 1.3 to 6.4 ± 1.1 cm H_2O. The decrease in PEEPi arose because of an increase in expiratory time, 2.1 ± 0.2 to 2.3 ± 0.2 seconds, which allowed more time for lung deflation. Why did expiratory time increase? An increase in inspiratory flow is usually achieved by shortening mechanical inspiratory time. The shortened inspiratory time combined with time-constant in homogeneity of COPD will cause overinflation of some lung units to persist into neural

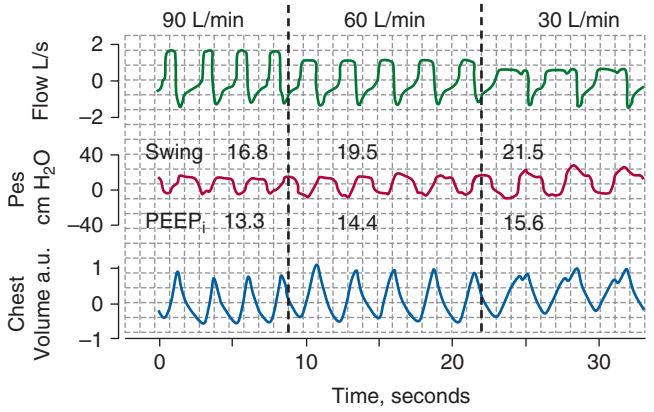

FIGURE 53-19 Continuous recordings of flow, esophageal pressure (*Pes*), and the sum of rib cage and abdominal motion in a patient with COPD receiving assist-control ventilation at a constant tidal volume. As flow increased from 30 to 60 and 90 L/min (from right to left; i.e., the opposite of the usual presentation), frequency increased (from 18 to 23 and 26 breaths/min, respectively), PEEPi decreased (from 15.6 to 14.4 and 13.3 cm H_2O, respectively), and end-expiratory lung volume also fell. Increases in flow from 30 L/min to 60 and 90 L/min also led to decreases in the swings in Pes from 21.5 to 19.5 and 16.8 cm H_2O, respectively. (Used, with permission, from Laghi et al.[110])

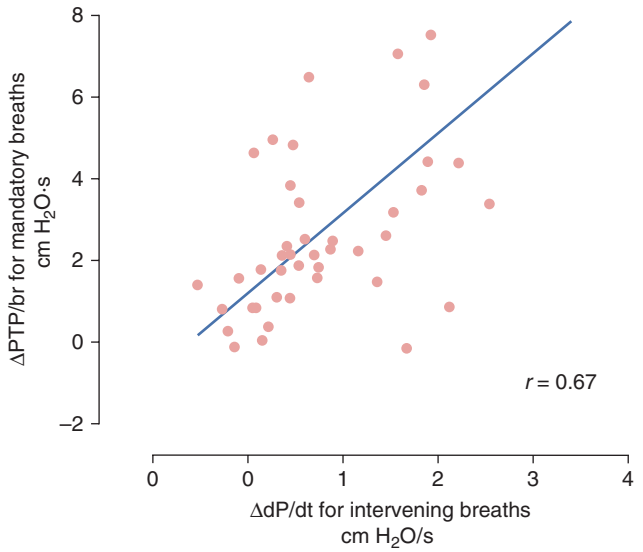

FIGURE 53-20 The change in pressure-time product per breath (*PTP/br*) during mandatory breaths (of IMV) consequent to the addition of pressure support of 10 cm H_2O to a given level of IMV was related to the change in respiratory motor output (dP/dt) effected by pressure support during the intervening breaths ($r = 0.67$; $p < 0.0001$). The more that pressure support decreased respiratory motor output during the intervening breaths, the greater was the reduction in patient work during the mandatory ventilator breaths delivered during IMV. (Used, with permission, from Leung et al.[99])

expiration. Continued inflation during neural expiration causes stimulation of the vagus nerve, which prolongs expiratory time.[111,112]

Mode-Specific Effects of Inspiratory Unloading

Pressure support and IMV are sometimes combined in a given patient. In an international survey of mechanical ventilation,[113] this combination tied with assist-control ventilation as the most commonly used mode of ventilation in North America (34% for each). The rationale for combining the two modes is unclear. Presumably, clinicians use pressure support to overcome the work imposed by the endotracheal tube and demand valve during the non-mandatory breaths.

Examining the response of the respiratory centers to this combination of modes provides useful insight into patient–ventilator interaction. A decrease in the number of mandatory breaths produces a decrease in the average V_T,[99] with inevitable increase in the ratio of dead space to V_T. To avoid a decrease in alveolar ventilation, the patients increased respiratory motor output, inspiratory effort, and rate. Adding pressure support of 10 cm H_2O caused a decrease in effort at any given IMV rate. The decrease in effort during the mandatory ventilator breaths was related to the decrease in respiratory motor output during the intervening breaths ($r = 0.67$) (Fig. 53-20).[99] In other words, the reduction in motor output during the intervening breaths achieved by adding pressure support was carried over to the mandatory breaths, facilitating greater unloading. Combining IMV and pressure support provides a sometimes useful means of achieving a high level of assistance; the combination has a clinical advantage when it is difficult to achieve a high inspiratory flow in the assist-control mode, as with the Siemens 900C ventilator (Siemens Corporation, New York, NY), although few of these machines are likely to be in current use.

Inspiration–Expiration Switching

In studies of interactions between patient effort and mechanical ventilation, remarkably little attention has been paid to the switch between inspiration and expiration. The most common mode of ventilation is some form of volume assistance,[113] such as assist control or IMV. "Cycling-off" of mechanical inflation, however, may be based only indirectly on volume. Instead, inspiratory flow is commonly preset and the ventilator adjusts inspiratory time to achieve a given V_T. This system is more precisely termed *time-cycled ventilation*. Inflation time is constant with a time-cycled machine, but patients invariably display considerable breath-to-breath variability in inspiratory time.[114] Accordingly, a patient's neural inspiratory time may be shorter or longer than the inflation time of the machine. If the machine delivers the set V_T before the end of a patient's neural inspiratory time, ventilator assistance will cease while the patient continues to make an inspiratory effort—with double triggering (two ventilator breaths for a single effort) a likely consequence.[104]

During assist-control ventilation, when a patient's neural inspiratory time is short, ventilator inflation may continue into neural expiration and thus decrease the time available

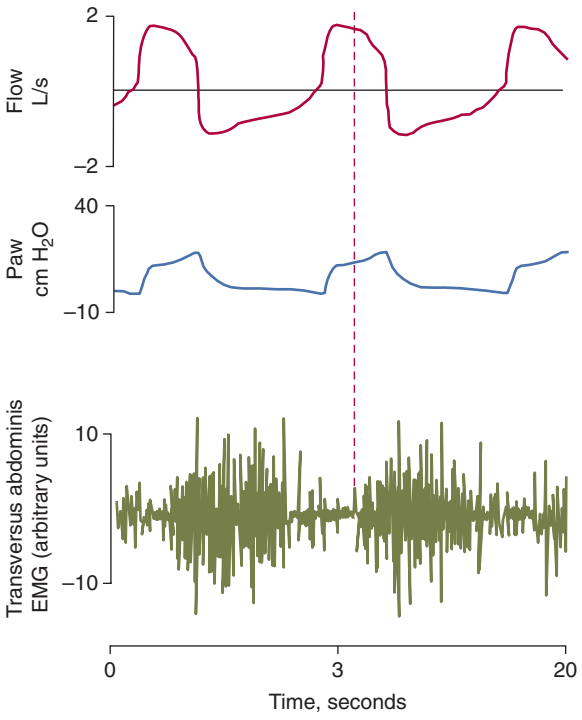

FIGURE 53-21 Recordings of flow, airway pressure (*Paw*), and transversus abdominis electromyography (*EMG*) in a critically ill patient with COPD receiving pressure support of 20 cm H_2O. The onset of expiratory muscle activity (*vertical dotted line*) occurred when mechanical inflation was only partly completed. (Used, with permission, from Parthasarathy et al.[97])

for lung emptying. The sense of being unable to empty the lungs may cause patients to activate the expiratory muscles with the result that the patient appears to fight or buck the ventilator (Fig. 53-21). The decrease in time for emptying also increases the likelihood for dynamic hyperinflation and thus inspiratory efforts that fail to trigger the ventilator.

With pressure support, the algorithm used for "cycling-off" of mechanical inflation varies among brands (see Chapter 8). On most ventilators, the termination of inspiratory assistance during pressure support is set at a default threshold, such as 25% of the peak inspiratory flow or inspiratory flow of 5 L/min. That is, when inspiratory flow falls to 25% of the peak value or below 5 L/min, inspiratory pressurization switches off. Such algorithms can be problematic in patients with COPD because increases in resistance and compliance produce a slow time-constant of the respiratory system. The longer time needed for flow to fall to the threshold value can cause mechanical inflation to persist into neural expiration. In twelve patients with COPD receiving pressure support of 20 cm H_2O, five recruited their expiratory muscles while the machine was still inflating the thorax.[115] The patients who recruited their expiratory muscles during mechanical inflation had an average time constant of 0.54 seconds, compared with an average of 0.38 seconds in the patients who did not exhibit expiratory muscle activity. The persistence of mechanical inflation into neural expiration is very uncomfortable, as is well recognized with use of inverse-ratio ventilation. Algorithms that achieve better coordination between the end of mechanical inflation and the onset of a patient's expiration may lessen this form of patient–ventilator asynchrony.[116,117]

Sleep–Wake State

The transition between sleep and wakefulness can lead to respiratory distress in the ventilated patient. More surprisingly, the transition between wakefulness and sleep can also cause distress. Specifically, the selection of ventilator mode and settings can provoke sleep disruption. Ventilated patients experience considerable sleep disruption, with as many as seventy-nine arousals and awakenings per hour.[118,119] Sleep disruption can adversely affect patient outcome.[120]

In eleven critically ill patients, Parthasarathy and Tobin[121] studied the interaction between ventilator mode and sleep. Sleep fragmentation was greater during pressure support than during assist-control ventilation: 79 versus 54 arousals and awakenings per hour (see Fig. 53-9). Six of the eleven patients developed central apneas during pressure support, but not during assist-control ventilation. V_T was 8 mL/kg during assist-control; pressure support was titrated to achieve the same V_T. The level of pressure support was 16.8 ± 1.5 cm H_2O in patients with apneas and 19.6 ± 2.6 cm H_2O in patients without apneas; thus, apneas did not result simply from a higher level of pressure support.

Sleep fragmentation, measured as the sum of arousals and awakenings, was greater during pressure support than during assist-control: 79 ± 7 versus 54 ± 7 events per hour. Disturbed sleep during pressure support was related to the development of central apneas ($r = 0.57$), which, in turn, was significantly related to the difference between P_{CO_2} during resting breathing and the patient's apnea threshold (end-tidal CO_2[$\Delta P_{ET}CO_2$]) ($r = -0.83$) (Fig. 53-22). $\Delta P_{ET}CO_2$ was the most important determinant for the development of apneas: As $\Delta P_{ET}CO_2$ grew wider, the number of central apneas increased. The addition of 100 mL of dead space to the ventilator circuit in the six patients who developed apneas produced a 4.3 mm Hg increase in end-tidal CO_2, decreased the frequency of central apneas, from fifty-three to four apneas per hour, and the frequency of arousals and awakenings, from eighty-three to fourty-four events per hour. This study shows that while critically ill patients have a background level of sleep disturbance, secondary to factors such as pain, medications, staff interruptions, noise, and light, the mode of mechanical ventilation can further aggravate sleep disruption.

The observation that ventilator mode can aggravate sleep disruption was confirmed by Bosma et al.[122] In thirteen patients undergoing polysomnography, these investigators adjusted the levels of pressure support ventilation and proportional-assist ventilation to achieve a similar degree of inspiratory muscle unloading. The number of arousals and awakenings were significantly greater with pressure support

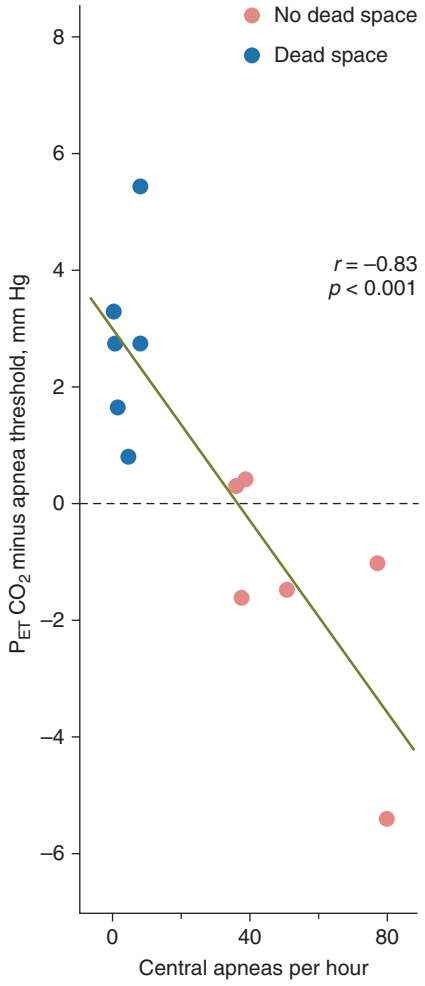

FIGURE 53-22 The difference between the average end-tidal CO_2 ($P_{ET}CO_2$) and the apnea threshold plotted against the number of central apneas per hour of pressure support alone (*red symbols*) and pressure support with added dead space (*blue symbols*) in six patients. The average end-tidal CO_2 was measured during both sleep and wakefulness. The mean number of central apneas per hour was strongly correlated with the end-tidal CO_2 during a mixture of both sleep and wakefulness (including the transitions between sleep and wakefulness) ($r = -0.83$, $p < 0.001$). (Used, with permission, from Parthasarathy et al.[121])

than with proportional-assist ventilation. Moreover, the number of patient–ventilator asynchronies per hour correlated significantly with the number of arousals per hour ($r^2 = 0.71$).

Cabello et al[123] compared sleep quality while patients were randomized between assist-control ventilation, pressure support set by the patient's attending physician, and pressure support continuously adjusted by a closed-loop knowledge-based system. In contrast to the report by Parthasarathy and Tobin,[121] sleep architecture, sleep quantity, and sleep fragmentation were equivalent with the three ventilator modes.

The different results in the two studies can be explained by the method of selecting tidal volume in the study of Cabello et al.[123] A tidal volume of 8 mL/kg was employed during assist-control ventilation, whereas a tidal volume between 6 and 8 mL/kg was targeted during pressure support.[123] The median (twenty-fifth to seventy-fifth percentile) tidal volumes were 500 mL (380 to 500 mL) during assist-control ventilation, 450 mL (357 to 521 mL) during clinician-adjusted pressure support, and 390 mL (330 to 492 mL) when a closed-loop knowledge-based system was used to continuously adjust pressure support. The findings of these three studies of mechanical ventilation during sleep in critically ill patients indicate that pressure support, when carefully adjusted to avoid hyperventilation, does not increase the amount of sleep fragmentation over that experienced with assist-control ventilation. If, however, pressure support is set in the manner of everyday clinical practice, it is likely to lead to sleep fragmentation.[121,122]

The alterations in breathing pattern and gas exchange induced by sleep have important implications for the selection of ventilator settings. During pressure support, sleep induced a 23% increase in inspiratory time and a 126% increase in expiratory time, as compared with wakefulness.[121] Sleep caused the respiratory rate to decrease by 33% during pressure support and by 15% during assist-control ventilation (Fig. 53-23). The level of pressure support is commonly titrated to respiratory rate, which provides a reasonable guide to patient effort.[115,124] Pressure support is commonly titrated during the daytime without the clinician being sure whether the patient is asleep or awake. If the patient is asleep

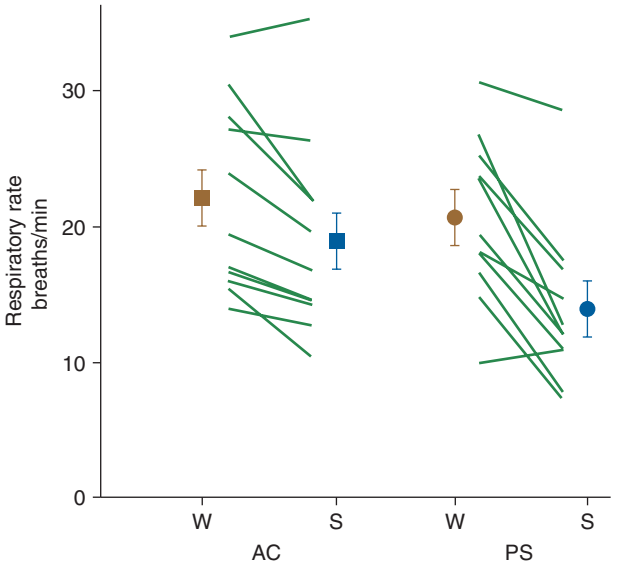

FIGURE 53-23 Respiratory rate during assist-control ventilation (*AC*) and pressure support (*PS*) in eleven critically ill patients. For each mode, the lines connect the mean value for each patient during wakefulness (*W, left*) and sleep (*S, right*). Compared with wakefulness, group mean respiratory rate was lower during sleep (*blue symbols*) than during wakefulness (*red symbols*). The difference between sleep and wakefulness was greater for pressure support than for assist-control ventilation. (Modified, with permission, from Parthasarathy and Tobin.[121])

at the time of the adjustment, a point at which respiratory rate will be relatively low, then, on awakening, the increase in a patient's rate may cause a considerable increase in effort.

PHARMACOTHERAPY

If a specific cause of acute distress cannot be detected and corrected (see Table 53-1) and reassurance provides no relief, pharmacologic agents are commonly employed. The agents most often used are derived from the following primary classes: opiate analgesics, benzodiazepines, selective α_2 agonist,[125] and neuromuscular blocking agents. Chapter 50 provides a complete discussion of these agents.

In managing the patient who is fighting the ventilator, neuromuscular blocking agents have several disadvantages: They mask a patient's complaints and physical findings; unrecognized disconnection of the ventilator circuit can produce apnea with catastrophic hypoxemia; elimination of cough predisposes to the development of atelectasis; and prolonged paralysis or weakness may persist after their use.

SUMMARY

Sudden distress in a ventilator-supported patient is a medical emergency. The first rule is to ensure adequate ventilation. The patient should be disconnected from the ventilator and manually ventilated with 100% oxygen. While this is being performed, a systematic effort should be made to try to determine the cause of distress and correct it. If the distress is the result of poor coordination of a patient's respiratory efforts with the rhythm of the ventilator, this can usually be resolved by careful adjustment of the ventilator settings and the administration of analgesic or sedative agents, or both.

PSYCHOLOGICAL PROBLEMS IN THE VENTILATED PATIENT

Yoanna Skrobik

Psychological and psychiatric disturbances occur frequently in mechanically ventilated patients, and cause patients, their loved ones, and their caregivers considerable distress. This chapter familiarizes the reader with commonly observed psychological and psychiatric symptoms in ventilated critically ill patients; briefly discusses the challenge of making a psychiatric diagnosis in the context of the ventilated patient; and describes what is known of the three disorders most commonly described in this patient population: delirium, depression, and posttraumatic stress disorder.

Traditional psychological and psychiatric assessments in the adult patient rely on the patient's ability to engage in conversation. Baseline psychological health and personality, a patient's relationship with his or her acute or chronic illness, a patient's emotional response to it, and the clinical context in which the patient is placed are typically considered in this evaluation. Assessment of the psychological and psychiatric state of a mechanically ventilated patient is hindered by the presence of an endotracheal tube, which makes verbal communication impossible. A tracheotomy with a talking valve, and a face mask, also limits speech. Beyond problems of verbal communication, the sudden and dramatic onset of a ventilated patient's illness, the use of pharmacologic sedation, the layout of an intensive care unit (ICU), and a critical care physician's unfamiliarity with psychological assessments have hampered descriptions of psychiatric and psychological issues.

Psychiatric diagnoses are made on the basis of clinical criteria. These criteria were, for many decades, highly variable depending on a school of thought and geographical provenance. Lobotomies, incremental electroshock therapy to re-create neuropsychiatric normalcy, and insulin-coma treatments exposed psychiatric professionals to scientific and public criticism. Over the last 40 years, psychiatric diagnoses have been structured more rigorously by experienced psychiatrists based on symptom and disease classifications through the use of systems such as the *International Classification of Diseases* (ICD) from the World Health Organization, and the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) from the American Psychiatric Association. The tenth revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) was published in 1991; the fourth revision of the *Diagnostic and Statistical Manual of Mental Disorders,* DSM-IV-TR, was published in 2000. The ICD-11 is expected in 2011 and the DSM-V update is anticipated in 2013.

The ICD-10 and the DSM-IV-TR rely on diagnostic criteria compiled by expert psychiatrists and, in the case of the DSM-IV, on the basis of described and published patient symptoms. Two problems become apparent when applying these diagnostic criteria to critically ill patients. The first is the challenge of applying diagnostic criteria to a mechanically ventilated patient if the symptom constellations have been gathered in a different—usually ambulatory—population. Apathy, for instance, a feature of depression, may be expected in a septic ventilated patient receiving propofol, making its value as a diagnostic criterion of depression in this context uncertain. The second is that these DSM or ICD criteria have not been investigated in terms of validity in ventilated patients, whether acutely or chronically ill, nor are the criteria correlated with outcomes in such patients.

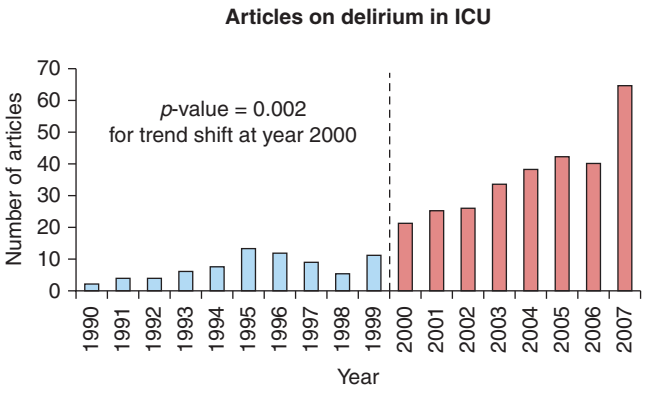

FIGURE 54-1 The number of publications on delirium in the critical care setting (in mechanically ventilated and nonmechanically ventilated patients) over 17 years. (Modified, with permission, from Morandi A, Pandharipande P, Trabucchi M, et al. Understanding international differences in terminology for delirium and other types of acute brain dysfunction in critically ill patients. *Intensive Care Med.* 2008;34:1907–1915.)

Psychiatric or psychological disturbances in the ventilated critically ill patients have been given many names, such as ICU psychosis, septic encephalopathy, and apathy. Semantic descriptions for disorders such as delirium[1] vary by geographic region. Over the last decade, publications on psychiatric topics such as delirium in ventilated patients have increased significantly (Fig. 54-1). Two factors may have influenced this change. Two intensivist-led publications in 2001[2,3] sensitized clinicians to the notion of screening ventilated patients for delirium through the use of simple screening tool, applicable at the bedside. More delirium-related publications followed, with subsequent interest in other psychiatric and psychological disorders, such as depression and posttraumatic stress disorder. Almost simultaneously, researchers with an interest in ICU outcomes in adult respiratory distress syndrome (ARDS), whose focus was initially on respiratory physiology, realized the main impediments to recovery for these patients were myopathy and psychological distress.[4,5] Three psychiatric syndromes—delirium, depression, and posttraumatic stress disorder—have since been identified with increasing frequency[6] in ventilated critically ill patients and ICU survivors.[7] The associations between these diagnoses and poor outcomes, including length of stay, quality of life, and cognitive impairment, have led to a cry for pharmacologic intervention for delirium by interventionists, and for further longitudinal studies[8,9] by those interested in the sequelae of what had traditionally believed to be rapidly reversible (and almost irrelevant) disorders.

What is understood of these three psychiatric syndromes is limited by the dearth and relative novelty of literature on the topic.[10] Current knowledge should be considered in light of the methodological limitations in establishing a diagnosis as described above.

Most publications reviewed for this chapter are focused exclusively or largely on mechanically ventilated patients, a group that some authors argue is particularly susceptible to psychiatric complications, such as delirium.[11] Information from nonventilated patients is discussed if it is consistent with what has been published on ventilated patients, but only if it provides insight not available from the literature on mechanically ventilated patients per se. Reviewed studies are limited to critical care and stepdown units; studies in patients receiving home ventilation or chronic ventilation on a hospital ward or a specialized institution were not considered. The disproportion between the delirium literature in critical care and that describing other syndromes, which is more modest, explains the discrepancy in content herein.

DIAGNOSTIC AND CONTEXTUAL CHALLENGES

Unsurprisingly, publications on the subject of psychological and psychiatric disorders in ICU patients have been driven by the medical perspective of the psychiatric diagnosis. Most physicians attempt to classify psychological or psychiatric symptoms as diseases, with attributable biologic alterations and reproducible symptoms. Medical culture[12] drives a rigid medical approach, and a rationalization of "disease"; the narrow view of biologic alterations and their diagnostic criteria is the focus of what we publish and read. Dimensions such as illness (the patients' perception of the self) and sickness (the social dimension and impact of the diagnosis, particularly a psychiatric one) are seldom addressed. In settings outside critical care, caregivers understand that a patient's well-being depends on psychological integrity. Such well-being, and perhaps even the will to survive, are hindered if the patient is unable to recognize his or her own self during disease, or if that very self is compromised, a common occurrence in the foreign, disturbing, and overwhelmingly technological setting of the ICU. This wretchedness is complicated by a complete dependence on machines and personnel. What little autonomy a patient retains is seldom fostered or encouraged. The relationship with the caregiver, or a significant person in the patient's life, also contributes to healing, or to a more serene journey toward death. The social impact of a psychological or psychiatric disease may interfere with this patient–caregiver or patient–significant person relationship, and constitute a dimension of "sickness." Establishing a diagnosis of depression and delirium requires descriptors; the dimensions of illness and sickness, however, may be what cause the greatest distress. Patient recovery and postdischarge outcomes may be related to these dimensions of illness and sickness; however, our limited understanding of these facets as experienced by patients, their caregivers, and loved ones limits a global understanding of the psychological and psychiatric issues and precludes a holistic approach to care.

Furthermore, context is important in establishing whether endogenous or exogenous factors trigger psychiatric or psychological disturbances. Some psychiatric diagnoses can be made with clarity. For instance, mania in an ambulatory outpatient has in many cases a recognizable pattern, associated biochemical abnormalities, and a predictable response to

medication. Syndromes such as depression can come from within, or be considered a normal response (in grieving, for example). Other mood states such as anxiety range from normal to pathologic, and have not been defined in the critically ill. Several symptoms (sadness, paranoid delusions, or harrowing flashbacks) could, arguably, be considered contingent, temporary, and normal responses to painful, traumatic, or near-death experiences. Overlapping syndromes of delirium and depression have been described.[13,14] The administration of psychotropic drugs in high doses over prolonged periods of time adds an important confounder, as do personality traits and the amount of cognitive reserve. This issue of context makes the attribution of a psychiatric diagnosis to a set of symptoms particularly challenging in the critical care setting. Dialog is a key element in differentiating these factors as potential contributors, in establishing the diagnoses, and in proffering expression as a form of early therapeutic intervention. Verbal dialog is challenging in the context of mechanical ventilation. Weakness, which precludes movement, facial expression, or both, further challenges (or is perceived as challenging) the examiner and contributes to the real or perceived barriers to communication.

The three most commonly described psychiatric syndromes in ICU patients and survivors are delirium, depression, and posttraumatic stress disorder. Each is discussed in turn.

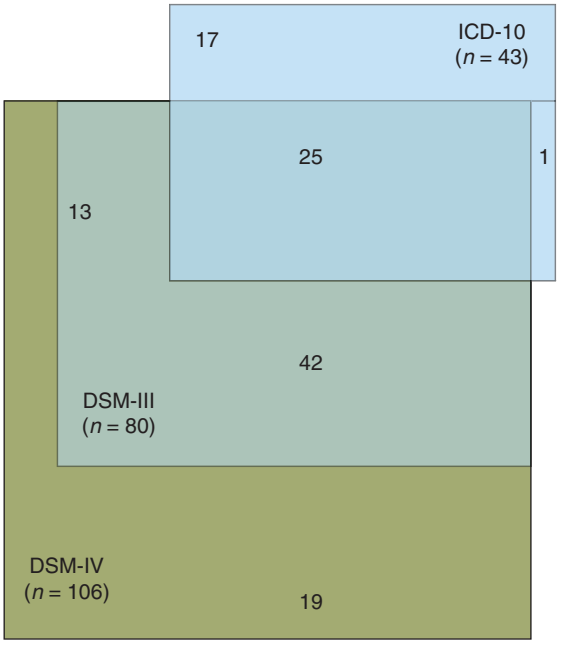

FIGURE 54-2 Comparison of different screening tools in the same population of 425 nonmechanically ventilated elderly medical or nursing home patients using DSM-IV criteria and earlier DSM criteria (DSM-III) as well as ICD-10 criteria. More ($n = 106$) patients were identified as having delirium with the DSM-IV than with any other set of diagnostic criteria. (Adapted, with permission, from Laurila JV, Pitkala KH, Strandberg TE, Tilvis RS. Impact of different diagnostic criteria on prognosis of delirium: a prospective study. *Dement Geriatr Cogn Disord*. 2004;18:240–244.)

DELIRIUM

The patient you spoke to and communicated with yesterday on ICU rounds is a little more difficult to rouse this morning. When you approach him, he initially looks surprised and frightened; as you introduce yourself and remind him of yesterday's conversation, he appears uncertain of who you are and of his surroundings. As you continue speaking, he looks away and appears to stare at something on the ceiling. The nurse reports that a few hours earlier he was grasping at what appeared to be imaginary objects in front of him. He did not sleep last night.

Delirium, with its traditional symptoms described here, frightens patients. The delusions and hallucinations they experience transiently and usually for the first time in their lives are upsetting; paranoid thoughts are common. When cognitive function normalizes in the fluctuating course that characterizes delirium, patients wonder if they are losing their minds and if they will ever return to the way they were before. Because 40% of patients present symptoms only between midnight and 8 AM, careful attention to the nurse's report of a patient's behavior is helpful in recognizing the problem.

Diagnosis

A diagnosis of delirium is based on the reference standard of symptoms described in nonventilated patients deemed clinically delirious, mostly among geriatric patients where the syndrome is prevalent. The DSM-IV criteria require a fluctuating disturbance in cognition and in consciousness in the context of an acute medical illness. Conversely the World Health Organization's ICD-10[15] includes different criteria for clinical and research use, both of which include a broad range of features that capture the phenomenologic complexity of the syndrome. Comparison of these two sets of criteria in a group of 425 nonventilated elderly medical or nursing home patients showed that applying the DSM-IV criteria identified more ($n = 106$) patients as having delirium than did the ICD-10 criteria, with twenty-five patients considered delirious by both sets of diagnostic criteria (Fig. 54-2).[16] Surprisingly, this study reported similar outcomes, in terms of mortality or length of stay, regardless of the criteria applied to diagnose delirium (Table 54-1).

Thorough descriptions of the natural history of delirium in ventilated patients are lacking, as is a good understanding of its basic scientific and biologic mechanisms. In 2001, two groups reported independently validated delirium screening scales for use in ventilated critically ill patients.[3,4] The first, the Intensive Care Delirium Screening Checklist (ICDSC), is an eight-point item scale, where four points or more correspond to a clinical diagnosis of delirium. The scale was validated against the clinical bedside opinion of a psychiatrist. The advantage of using this eight-item scale with a four-point cutoff is its ability to detect subsyndromal delirium in patients with scores of more than 0 but less

TABLE 54-1: OUTCOMES (MORTALITY OR LENGTH OF STAY) IN RELATIONSHIP TO THE CRITERIA (DSM IV, DSM III, AND ICD-10) USED TO DIAGNOSE DELIRIUM IN 425 NONMECHANICALLY VENTILATED ELDERLY MEDICAL OR NURSING HOME PATIENTS (OUTCOMES WERE SIMILAR)

Prognostic Variable	DSM-IV ($n = 106$)	DSM-III ($n = 80$)	ICD-10 ($n = 43$)	p-value[a]
Mortality/1 year, %	34.9	36.3	41.9	n.s.
Mortality/2 year, %	58.5	62.5	65.1	n.s.
Mean days in institutions/1 year[b]	220(150)	230(148)	211(157)	n.s.
New admissions to permanent institutional care/2 year, %	55.0[33/60]	60.0[24/40]	64.3[9/14]	n.s.
In permanent institutional care or deceased/2 year, %	90.6	93.8	97.7	n.s.

n.s. = Not significant. Figures in parentheses indicate standard deviations, those in brackets actual number institutionalized/total number from community care, *y* care.

[a]Proportions and their differences were tested by the χ^2 test, d.f. = 3.

[b]Means and their differences were tested by analysis of variance.

Source: Adapted, with permission, from Laurila JV, Pitkala KH, Strandberg TE, Tilvis RS. Impact of different diagnostic criteria on prognosis of delirium: a prospective study. *Dement Geriatr Cogn Disord.* 2004;18:240–244.

than 4 items. Subsyndromal delirium is considered clinically significant by psychiatrists[17,18] and, in ventilated and nonventilated ICU patients, predicts an intermediate risk of prolonged length of stay and mortality when compared with asymptomatic patients,[19] who did better, or delirious patients, whose prognosis was the worst. The second delirium scale was originally adapted as a simplification of the DSM-IV–based Confusion Assessment Method (CAM) scale, so as to make it applicable to ventilated patients; it was validated against the clinical opinion of a geriatrician. This modified scale, the Confusion Assessment Method in Intensive Care Units (CAM-ICU),[2] is binary. Other scales, such as the Delirium Detection Scale (DDS) and the Nursing Delirium Screening Scale (NuDESC), have also been assessed in critically ill patients; only the ICDSC and the CAM-ICU are presented here because of their broad application to and validation in ventilated patients, and because of their psychometric quality.

Clinicians are reported to underrecognize delirium.[20,21] This has led some critical care professional societies to promote routine critical care delirium screening.[22] Canadian governing bodies mandate it for hospital accreditation. Perusal of the literature on screening tools, however, shows that these validated screening tools yield a broad distribution of incidences of this condition. Studies describing the binary CAM-ICU in similar populations reveal delirium incidences that range from 10%[23] to over 80%. Sedation may confound the scale measurements.[24] In contrast, the range in reported delirium rates using the ICDSC is somewhat narrower: 32%[25] to 45%.[21] In addition to grading cognitive normalcy, subsyndromal delirium and delirium the ICDSC describes specific symptoms,[26] and with them, the prognosis conferred by each one. Whether these two tools screen for the same constellation of symptoms is unclear, given the conflicting results in the publications on the subject.[27,28] Because of the numerous methodological issues described above, comparisons of sensitivity and specificity of delirium screening scales to mechanically ventilated patients in and outside the ICU are difficult to address.

Awareness as to which patient is more likely to develop delirium in the ICU will identify patients most likely to benefit from preventive strategies and alert caregivers as to which patients will require more thorough evaluation for delirium symptoms. These risk factors for delirium cannot identify patients who will respond to therapeutic intervention. Different clinical features have been associated with a higher incidence of delirium.[29] The incremental likelihood of delirium symptoms increases with severity of illness and with excessive alcohol consumption.[29] Hypertensive patients are more likely to become delirious in the ICU,[25] as are patients with preexisting dementia and patients who are heavily sedated.[25,29] In contrast to patients admitted to a hospital ward, age is not consistently related to the likelihood of developing delirium among ventilated patients,[25,30] although there may be an association with age in mostly nonventilated patients older than 65 years when the CAM-ICU delirium detection tool is used.[31,32]

There are significant gaps in our knowledge regarding delirium in ventilated patients. Despite reports that mechanical ventilation confers a risk for delirium,[33] the question of whether the association is with mechanical ventilation per se or an independent feature linked to severity of illness or drugs administered has not been addressed in studies where known risk factors are taken into account. Cardiovascular patients, who are burdened with cognitive dysfunction after cardiac surgery and ICU discharge, remain understudied, as do neurologic patients, and trauma patients (including those with traumatic brain injury), perhaps because of the inherent difficulties in making an assessment as a result of confounding clinical features.

Prevention

Early physiotherapy and mobilization, when implemented to aid myopathy, significantly reduce delirium rates.[34,35] These results raise the question of whether nonpharmacologic interventions, which encourage patients to focus on their autonomy, may prevent or alleviate delirium. Sedatives and analgesics, when carefully titrated and administered

according to symptoms, are associated with lower rates of subsyndromal delirium and an increase in the probability of a patient being able to return home.[36] Whether the particular type of sedative agent makes any difference to the probability of delirium is not clear. Once delirium develops, however, continuous sedation with dexmedetomidine is associated with lower duration of delirium than continuous intravenous sedation with midazolam, a short-acting benzodiazepine,[37] in medical and surgical patients. It is not clear whether these results reflect an inherent problem with midazolam infusions or a therapeutic benefit of dexmedetomidine.[38] In cardiac surgery patients, the use of propofol as a sedative did not alter the risk of delirium as compared with dexmedetomidine.[39]

Treatment

Although administration of antipsychotics has been a mainstay in the pharmacologic management of delirium in critically ill patients,[40] there is no scientific basis for this practice or evidence of benefit of administering antipsychotic agents in delirious critically ill ventilated patients[41]: neither the duration of delirium nor its severity is reduced. A possible exception is the atypical antipsychotic, quetiapine,[42] which, in contrast to other pharmacologic agents,[8,41] produced a reduction in the duration of ICU delirium, albeit in a single pilot study.

Descriptions by observers, and stories[43] told by individual patients,[44] describe the anguish, fear, and harrowing nature of patient perceptions in a delirious state. Some narratives and recall studies describe the positive impact of reassuring or reality-orienting caregivers[45] within the critical care setting. The added contribution made by visiting family members and loved ones[29] are in keeping with the positive impact of nurse-facilitated family participation in the care of a delirious patient.[46]

Some investigators have made links between delirium in the ICU and long-term cognitive dysfunction.[47] These data should be considered with caution given the frequency of cognitive dysfunction in nondelirious patients,[48] given our difficulties in establishing the diagnosis of delirium, and given its many potential confounders, such as the risk of dementia in patients older than 65 years, which doubles every 5 years between the ages of 65 and 85 years.

DEPRESSION

On morning rounds, the patient whose ICU stay was marred by multiple septic complications of his intraabdominal surgery does not look interested in your informing him he is finally ready to be extubated. After the extubation and despite no longer receiving sedatives, he is lying in bed immobile, and answers questions monosyllabically. He tells the nurse he is not interested in sitting up in a chair or in spirometry with the physiotherapist. No amount of encouragement seems to make a difference. His wife tells you he is "not himself," and is concerned.

Is this patient depressed? Or is he reacting normally to a near-death experience during which his mood was affected by circulating inflammatory mediators and the sedatives he received? The patient's hypoactive reaction and mood alteration is not unusual, especially because he was septic. A diagnosis of depression cannot be excluded, and the patient's evolution should be monitored with careful attention to psychological symptoms. Depression is not reported in ventilated ICU patients; descriptions exist primarily in ICU survivors[49] and in patients who have been transferred from a critical care setting to a specialized center that focuses on weaning from prolonged mechanical ventilation.[50] To assess whether patients are depressed or at risk for depression, questionnaires, such as the Hospital Anxiety and Depression Scale (HADS),[51] have been used as substitutes or complements to clinical assessments.[52] Studies that describe clinical assessments, such as one-on-one interviews by an experienced caregiver (a psychologist or a psychiatrist) of ICU patients, weaning patients,[50] or survivors are rare. Depression in critically ill patients, whether mechanically ventilated or not, is associated with both the severity of illness on admission[53] and with the administration of benzodiazepines.[54] Observational studies are few, and potential confounders in making a diagnosis of depression are numerous.

Sickness behavior is a term coined to describe the behavioral changes that develop in ill individuals during the course of an infection. This sickness behavior,[55] described in sepsis, is associated with lethargy, sleepiness, inability to concentrate, and apathy. Whether these symptoms are a manifestation of underlying medical illness or related to depression per se is not clear.

Risk factors for developing depression in association with mechanical ventilation or ICU admission have not been well established; patients with different profiles may be at different risk and have a different prognosis. For instance, 28% of more than 66,000 veterans admitted to nonsurgical ICUs[56] had a history of an earlier psychiatric diagnosis, a feature associated with a greater likelihood of being subsequently diagnosed with depression or with posttraumatic stress disorder. Patients with diabetes who have experienced depression are more likely to end up in an ICU than are patients with diabetes who have no baseline psychiatric history.[57] ICU admission in patients with diabetes is independently associated with a higher probability of subsequent major depression.[58] These large descriptive studies included both ventilated and nonventilated patients. No validated assessment tools exist to screen for the presence or severity of depression in mechanically ventilated patients. In specialized critical care settings where psychologists are part of the ICU team, clinical assessments of depression are probably reliable. Most intensive care units do not include such experts. Longitudinal studies suggest post-ICU depression is frequent. Early expert screening may benefit patients and their familiesy. No clear epidemiologic descriptions of depression and its outcomes in ventilated patients have been published. Whether any particular form of therapy or none is preferable in the management of depression in ventilated patients is not clear from the literature to date.

POSTTRAUMATIC STRESS DISORDER

The patient you discharged from the ICU 5 weeks ago with epiglottitis comes to your clinic for a follow-up appointment. Since her return home, she describes waking up several times each night in a cold sweat from a recurrent dream that involves attempts at intubating her while she is developing an obstructed airway. She is jumpy and frightened when she goes about the simplest of her daily tasks, and lashed out at a grocery store attendant who asked her at the checkout whether she had change. Her sister confirms how unusual this behavior is for her, and expresses concern because the patient is not functional.

Posttraumatic stress disorder (PTSD) symptoms, such as those described here, is an anxiety disorder associated with a traumatic event that involved the threat of injury or death. Diagnostic symptoms for PTSD include reexperiencing the original trauma(s) through flashbacks or nightmares, avoidance of stimuli associated with the trauma, and increased arousal, such as difficulty in falling asleep or staying asleep, anger, and hypervigilance. Formal diagnostic criteria (both DSM-IV-TR and ICD-10) require that the symptoms persist for more than 1 month and cause significant impairment in social, occupational, or other important areas of functioning. Stressors believed to trigger PTSD include myocardial infarction and critical illness.

Increasing numbers of publications have addressed PTSD in mechanically ventilated and nonventilated ICU survivors[59,60] over the last decade. Its reported incidence varies from 8% to 51%. The amount of literature is low, particularly when one considers the frequency with which the disorder is diagnosed.

Questionnaire-based screening, telephone-based screening, and clinical assessments with and without questionnaires to aid in establishing the diagnosis have populated the studies to date. Questionnaires and clinical assessments, however, may not have the same correlation in mechanically ventilated critically ill patients as they do in other patients. When patients admitted to a weaning center (who had been or still were being mechanically ventilated) were assessed with a standardized PTSD questionnaire and a clinical assessment by a clinical psychologist,[61] the results revealed that the threshold on the questionnaire, which had been validated to predict PTSD in non-ICU patients, was in fact lower than the scoring threshold that corresponded to the clinical diagnosis of PTSD in ICU survivors. These data raise concerns about underestimating the prevalence of PTSD in ventilated patients if standard thresholds are applied.

The only study addressing the link between psychopathology in the ICU and PTSD did not document a link between delirium and PTSD, albeit in a cohort where the incidence of PTSD was low.[62]

PTSD seems to be a risk factor for fatal and nonfatal cardiac events after discharge from hospital.[33] ICU-related associations include lower factual recall and its corollary, higher sedative administration,[63] during the ICU stay.

One study suggests that early and targeted psychological intervention, consisting of five or six face-to-face meetings involving direct ICU patient counseling, stress management, support, and education by a clinical psychologist,[64] offers better outcomes from PTSD than standard ICU care.

What remains surprising is that this condition, which requires a profound precipitant, commonly of a life-threatening magnitude, has been so poorly studied in critically ill patients where exposure to this type of stressor is so predictable.

NONPHARMACOLOGIC INTERVENTIONS

Nonmedical interventions can be helpful in many psychiatric and psychological disturbances. Outside the ICU, prevention of syndromes such as delirium through the use of interventions such as rehydration, reorientation, and warm milk and massages in the evening can sometimes yield spectacular results[65] and are extremely cost-effective. Physiotherapy and early mobilization certainly appear to have a beneficial impact on ICU delirium.[34,35] Interventions such as music may help, and are extremely unlikely to do harm.[66] A bedside diary may aid the most severely traumatized survivor make sense of his or her experience.[67] Finally, opportunities for ICU survivors to tell their tale in a structured fashion may be therapeutic.[68] The narrative has also been described as a tool for healing in the context of illness[69,70] and as a crucial instrument in transforming suffering for the individual who is telling the tale.[71]

Which type of follow-up care, with narratives or without, would best profit ICU survivors is uncertain,[72] although routine screening after ICU discharge and as-needed referral services may be of benefit.[73,74]

SUMMARY

Psychological and psychiatric disturbances are extremely common in the mechanically ventilated critically ill patient. The natural history of such disturbances is not well understood. To date, three disorders have been described in some detail: delirium, depression, and PTSD. Nonpharmacologic approaches, such as early mobilization, adjustment and minimization of sedation, and psychological support, appear to offer some promise. No pharmacologic approach can be endorsed unequivocally.

CONCLUSION

Mechanically ventilated patients are now the subject of more focused investigations with regard to their psychological and psychiatric well-being, both in the acute setting and in terms of outcomes. Regardless of the specific psychological disturbance or psychiatric diagnosis, there appears to be a

link between psychological abnormalities and the severity of illness.[75] The probability of developing psychological or psychiatric complications may depend on vulnerabilities such as prior psychiatric diagnosis[76] or variability in what is referred to as cognitive reserve. Although the severity of illness on ICU admission and some clinical features, such as excessive alcohol consumption, are associated with the development of delirium, the risks or associations with other disorders are not known. Diagnostic categories (delirium, depression, and PTSD) have not been simultaneously and comprehensively compared with patient outcomes. Less discrete but important syndromes, such as adjustment disorder, generalized anxiety, and panic disorder, remained unexplored in this population. Better, more thorough, and more holistic explanations and approaches await future investigations.

ADDRESSING RESPIRATORY DISCOMFORT IN THE VENTILATED PATIENT

Robert B. Banzett
Thomas Similowski
Robert Brown

Although respiratory discomfort (dyspnea) is as common as pain in seriously ill patients,[1] there is no formal requirement to assess and manage it, such as the "fifth vital sign" requirement for pain assessment and management.

Mechanical ventilation is the most frequently used life-support measure in the intensive care unit (ICU). It is also used during anesthesia and the initial phase of postanesthesia awakening, and at home in patients with chronic respiratory failure. Many patients who are mechanically ventilated are thus conscious (or even fully awake), yet they can experience rapid and important changes in their respiratory status and metabolic needs. It is thus not surprising that ventilated patients do experience respiratory discomfort. They can report and quantify it, and there are strategies to address it. In this chapter we (a) propose that respiratory discomfort be routinely assessed in ventilated patients, and (b) suggest some approaches to managing this discomfort with minimal sedation. Together, these could be termed *patient-centered ventilation*.[2] There is, however, a paucity of studies directly addressing prevalence, outcomes, and mechanisms of dyspnea and its relief in acutely ventilated patients.

OCCURRENCE AND SEQUELAE OF RESPIRATORY DISCOMFORT IN VENTILATED PATIENTS

Although we lack large-scale studies on the prevalence of dyspnea in mechanical ventilation, there have been a few studies in which a small sample of acutely ventilated patients have been asked to rate dyspnea.[3–8] In three studies the severity of dyspnea was stratified: In a combined total of 204 patients, 19% of the respondents reported moderate to severe discomfort.[3,6,7] In one study, patients were asked to characterize the quality of their discomfort: 69% reported experiencing air hunger; 51% reported excessive work/effort. About a third of the foregoing patients experienced both air hunger and work/effort.[7] In another study, 29% of ventilated patients recalled after their stay in the ICU that

they had been moderately to extremely bothered by not getting enough air from the endotracheal tube, which we equate to air hunger.[9] Many patients, however, were too heavily sedated to respond; many of these latter patients had probably been heavily sedated in an attempt to alleviate respiratory discomfort. This clearly indicates that there is a problem to address. As discussed below, heavy sedation is not necessarily an adequate solution and may be harmful.

There is a clear association between anxiety and dyspnea in patients.[10–12] In laboratory subjects, experimentally induced air hunger produces more discomfort and more anxiety than tasks that require a great deal of respiratory work and effort.[13] In critically ill patients, emotional reactions such as panic, anxiety, and fear are significantly correlated with patient–ventilator dyssynchrony.[14] Dyspnea can cause anxiety, even in healthy subjects who experience dyspnea in a safe laboratory situation.[13,15,16] Conversely, anxiety can cause dyspnea. This is true even in the absence of cardiopulmonary pathology; for example, dyspnea is the most common symptom in anxiety and panic disorders.[17] Because of this reciprocal causation, the possibility of positive feedback exists in ventilated patients, with dyspnea causing anxiety, which then exacerbates the dyspnea. In a series of mechanically ventilated patients reporting dyspnea, multivariate analysis showed that the strongest statistical association with respiratory discomfort was with anxiety.[7] In the subset of these patients whose dyspnea was lessened by changes in ventilator settings, anxiety was also reduced, suggesting that the dyspnea caused the anxiety.

Survivors of mechanical ventilation in the ICU often carry surprisingly dark recollections of the experience. A recent study reported that 15% of patients recalled feeling at risk of being murdered, 17% felt betrayed, 39% felt at risk of imminent death, and 55% felt they were being suffocated.[18] Thus, it should not be surprising that posttraumatic stress disorder (PTSD) is now recognized as a common sequela of ICU experience.[18–21] PTSD symptom scores in the post-ICU population are significantly correlated with duration of mechanical ventilation,[19] and with recalled memories of respiratory distress.[20] A number of reasons for these connections can be postulated, but the possibility cannot be ignored that inescapable dyspnea is one of the traumatizing events leading to PTSD in this population.

ASSESSMENT OF DISCOMFORT IN THE VENTILATED PATIENT

Ask the Patient

The first step in addressing dyspnea is to determine how much and what kind of discomfort the patient is experiencing. A full assessment requires that the patient be alert enough to respond to simple direct questions regarding the intensity and quality of discomfort. In heavily sedated patients, the daily wake-up practiced in many ICUs[22] provides an opportunity to assess the intensity of dyspnea and attempt to reduce it with nonpharmacologic approaches before evaluating the need for further sedation.

TABLE 55-1: SAMPLE PATIENT ASSESSMENT QUESTIONNAIRE

Please indicate on this 10-point scale how your breathing feels:
10 EXTREMELY SHORT OF BREATH
9
8
7
6
5
4
3
2
1
0 BREATHING IS COMFORTABLE
Which of the following phrases describes the way you feel?
1. Not getting enough air (if yes, ask a and b and skip 2; if no, ask 2)
   a. Breaths are not deep enough
   b. Breaths are not fast enough
2. Getting too much air (if yes, ask a and b)
   a. Breaths are too deep
   b. Breaths are too fast
3. Too much effort to breathe
4. Chest feels tight or constricted

Several rating methods have been shown to be feasible in intubated and ventilated patients. Patients who are alert enough to respond but who cannot speak can provide information through simple number, word, or visual analog scales, similar to those routinely used in clinical pain assessment.[3,5,23] Patients can point to the appropriate responses but in some cases the interviewer will need to say or point to responses in succession and stop when the patient indicates with a blink or other sign. The intensity scale may be combined ad hoc with a list of descriptors from which the subject can choose; descriptor lists often make the process easier for patients who find it difficult to describe unfamiliar internal sensations.[24] Table 55-1 shows a brief sample assessment procedure. More extensive and sophisticated assessment may be required for research purposes.[25]

Physical Signs May Correlate Poorly with Discomfort Level

Many caregivers rely on physical signs such as respiratory rate, heart rate, use of accessory muscles, synchrony with mechanical ventilation, diaphoresis, and facial expression. Recently, a systematized Respiratory Distress Observation Scale (RDOS) was developed and validated in spontaneously breathing subjects.[26] This scale comprises measures of heart rate, respiratory rate, accessory muscle use, paradoxical breathing pattern, restlessness, grunting at end-expiration, nasal flaring, and fearful facial display. Some of these signs are likely to be altered by mechanical

ventilation, so adaptation and validation of the scale for ventilated patients is needed. Signs can be very useful when patients are unable to communicate, but they can be misleading.[5] Patients vary widely in their behavioral responses to discomfort; thus, as with pain, physical signs may overestimate or underestimate the degree of discomfort, and they give little information regarding its cause. Reliance on inconsistent physical signs was also a problem in pain assessment until accrediting organizations, such as Joint Commission on Accreditation of Healthcare Organizations (JCAHO), began to require more direct assessment and management of pain.[27] Caregivers should ask the patient whenever feasible.

Dyssynchrony of patient and ventilator is associated with discomfort. It has been suggested that it is a cause of discomfort and conversely that it is a result of discomfort (both may be true). The interaction between modern ventilators and patients is a result of the interface between two complex control systems, and the resulting pressure and flow waveforms can be complex. Dyssynchrony is usually assessed qualitatively by visual inspection of waveforms, but some investigators are attempting to formally quantify dyssynchrony.[28] When such methods have matured, they must be validated against subjective reports of patients. Again, we emphasize that when patients can report their discomfort, their reports should be weighed more heavily than physical signs. To date, the available studies of patient–ventilator synchrony have not measured its relationship to respiratory discomfort.

NEUROPHYSIOLOGIC SURROGATES OF DYSPNEA

There are a number of circumstances under which a ventilated patient will be unable to communicate verbally with caregivers and where physical signs of respiratory distress will be difficult to interpret. A particularly difficult instance is the patient paralyzed with neuromuscular blockers. Neurophysiologic surrogates of dyspnea would be particularly useful in this setting. Although in theory one might be able to assess respiratory discomfort using functional magnetic resonance imaging of the brain,[29] this is unlikely to become practical for clinical use in the foreseeable future.

Electroencephalography, however, may provide a more practical method. In normal volunteers under experimental conditions, preinspiratory potentials become apparent during noninvasive mechanical ventilation when respiratory discomfort is induced through the use of inappropriate ventilator settings.[30] Preliminary observations in mechanically ventilated patients suggest that similar monitoring of respiratory-related electroencephalography activity could help detect respiratory discomfort in noncommunicant patients. This approach would allow a continuous surveillance that would be particularly useful in patients liable to experience frequent changes in respiratory status. The clinical utility of these techniques and the spectrum of their applicability are important research targets.

In addition, assessing the electromyographic activity of inspiratory muscles can be useful as a measure of respiratory drive, one of the determinants of respiratory sensation discussed in the air hunger section. There is experimental and clinical evidence that "ventilator fighting" or patient–ventilator dyssynchrony can be associated with visibly increased activity of inspiratory neck muscles, parasternal intercostals, and upper airway dilators including the tongue.[31–33] Correlations between respiratory muscle activity and dyspnea have been observed.[31,33] The clinical usefulness of respiratory muscle electromyography to assess and monitor respiratory discomfort is another likely research topic.

Discomfort Can Be Caused by Dyspnea Combined with Other Sensations

A particular patient's discomfort may be caused by a mix of respiratory discomfort and nonrespiratory sensations, such as pain and nausea. Little is known about how these sum into total discomfort; in some cases, one noxious stimulus can occlude perception of another. The limited data available suggest that simultaneous dyspnea and pain can be separately scaled, and that the presence of one does not strongly affect the other, at least under controlled circumstances.[34] Sensations of respiratory discomfort other than dyspnea (e.g., secondary to cough or irritation from the endotracheal tube) may also be present. Different forms of dyspnea such as air hunger and excessive work of breathing may be simultaneously present, and are thought to be additive.[35] The problems of ventilated patients are therefore varied and complex; there is no single approach that will work in all patients.

PRIMER ON DYSPNEA

Different Forms of Dyspnea

Several different mechanisms give rise to respiratory discomfort; the mechanism(s) operating in an individual patient will guide the treatment approach selected. The quality of discomfort is one guide to understanding which mechanisms are in play; other clues come from physical examination and measurement of ventilatory variables (see "Approach to the Ventilated Patient with Dyspnea" below). There are at least three distinct qualities of uncomfortable breathing sensations: *air hunger, effort* or *work,* and *tightness.* These different forms of dyspnea are caused by different afferent mechanisms and are evoked by different physiologic stimuli.

Theories developed in the late 1960s and early 1970s attributed all dyspnea to excessive work or effort of breathing.[36] Although work of breathing has since been disproved as the sole origin of dyspnea,[37–39] this model still dominates thinking in the realm of clinical mechanical ventilation.[40,41] Attempts to understand a patient's discomfort based only on work of breathing will not be fully effective; in fact, extremely unpleasant dyspnea can be evoked in the absence of any respiratory work.

AIR HUNGER

Air hunger is the conscious perception of the need for more air that is typically described by subjects as "not getting enough air," "uncomfortable urge to breathe." This is the sensation felt by normal subjects at the end of a long breathhold.[15,38] Subjects comment that air hunger is a threatening or frightening sensation. Healthy subjects exposed briefly to air hunger in our laboratory have reported that "it's a feeling…you're going to die because you're not getting enough air." Even moderate air hunger is highly aversive if prolonged, with one subject commenting that "if I felt I had to live my life feeling like that I would jump out the window [commit suicide]." Quotes from patients with dyspnea can be remarkably similar: "When the shortness of breath was at its extreme I thought I was going to die," and "…wouldn't want to live if it continued."[42]

Air hunger arises from stimulation of arterial chemoreceptors and from other drives to breathe; a rise in partial pressure of arterial carbon dioxide (Pa_{CO_2}) or a fall in partial pressure of arterial oxygen (Pa_{O_2}) will evoke air hunger.[37,43–46] Air hunger is not caused by contraction of respiratory muscles; complete respiratory paralysis does not abolish or even diminish the air hunger response to CO_2.[37–39] It is hypothesized that air hunger is transmitted to the cerebral cortex by a corollary discharge of medullary respiratory center activity (also known as *ventilatory drive*). Such a corollary discharge has been described in the midbrain and thalamus of decorticate cats, presumably en route to the cortex.[47–49] Although air hunger is stimulated by medullary drive, the two are not equivalent; other processes modify the translation of drive into the perception of air hunger in the cerebral cortex. Air hunger is associated with activation of the paralimbic cortex in humans, a region of the brain long associated with emotional responses and learning. The principal activation reported in studies of experimental dyspnea is the anterior insula, with stronger activations on the right than on the left (Fig. 55-1A and B). The anterior insula is activated by several other unpleasant sensations that provide information on primal biologic drives, such as pain, thirst, and hunger.[29,50,51] Air hunger also activates the amygdala, which is implicated in the perception of fear and anxiety (Fig. 55-1C and D).

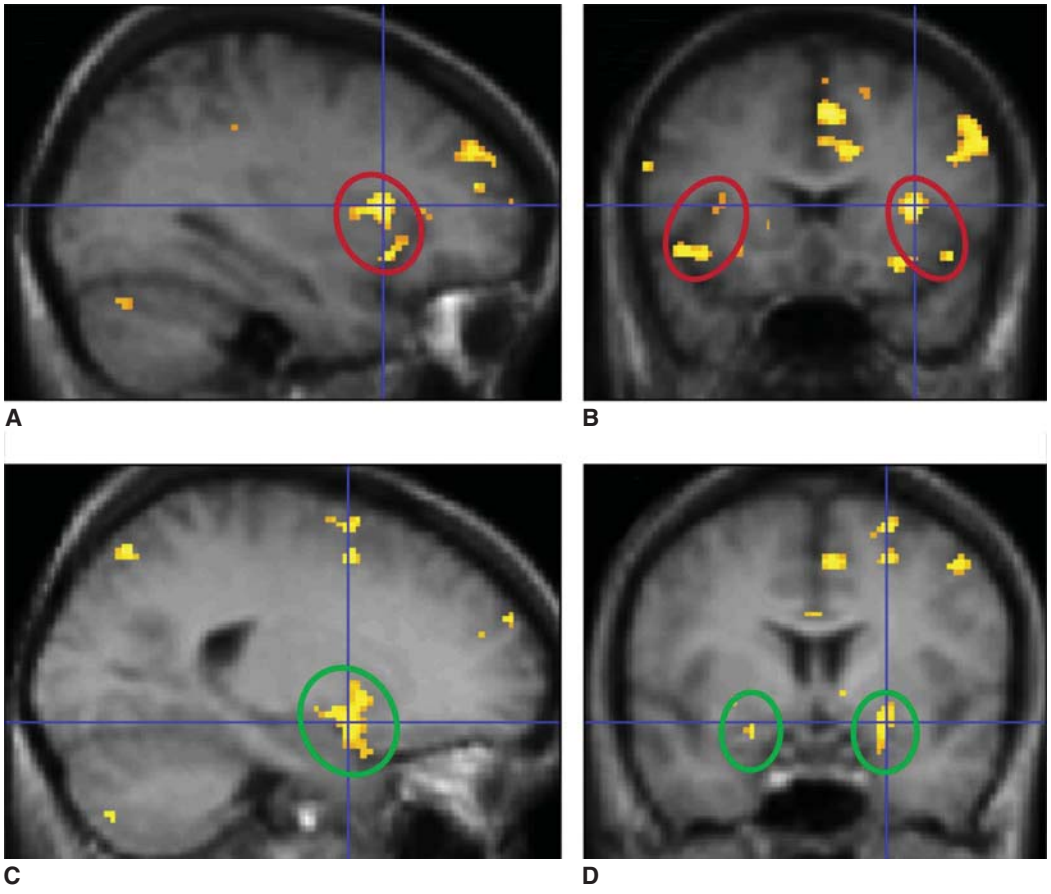

FIGURE 55-1 Functional brain images showing some important paralimbic activations during laboratory-induced air hunger (data from Evans et al[29]). Air hunger was induced during volume-control ventilation by lowering tidal volume (V_T); *red ovals* in *A* and *B* indicate activations in the anterior insular cortex (IC). The sagittal section (**A**) is in the right hemisphere, 34 mm from the midline; the coronal section (**B**) is 16 mm forward of the anterior commissure. The anterior insula is also involved in hunger, thirst, and pain. *Green ovals* in *C* and *D* indicate activations in the amygdala. The sagittal section (**C**) is in the right hemisphere, 24 mm from the midline; the coronal section (**D**) is 4 mm forward of the anterior commissure. The amygdala is implicated in states of fear and anxiety. These images were obtained using blood oxygen level dependent functional magnetic resonance imaging. All activations shown were statistically significant after correction for multiple comparison.

EFFECT OF BLOOD GASES ON AIR HUNGER

There is a substantial amount of information on the interaction of blood-gas levels, level of minute ventilation, and air hunger during mechanical ventilation in normal subjects and in patients who are ventilator-dependent secondary to neuromuscular paralysis. In a study of sixteen healthy subjects ventilated at 10 L/min, end-tidal carbon dioxide tension ($P_{ET}CO_2$) was raised by increasing inspired CO_2. An increase of 10 torr produced a level of respiratory discomfort that subjects could not tolerate even for a few minutes (Fig. 55-2).[15] This occurred despite a background of high oxygen and with minute ventilation ($\dot{V}_E$) greater than 150% of the normal resting level. In practical terms, this implies that modest acute increases in partial pressure of carbon dioxide (P_{CO_2}) that may seem clinically unimportant can be a source of profound discomfort.

An acute rise in Pa_{CO_2} evokes severely uncomfortable air hunger during volume-control ventilation in both healthy subjects and in alert patients ventilated for respiratory muscle paralysis.[23,38,39] The sensations of air hunger and work/effort produced by mild hypercapnia in spontaneously breathing healthy subjects are increased by partial neuromuscular block, even at $P_{ET}CO_2$ and $\dot{V}_E$ levels similar to those present before the block.[52,53] This may explain why exertional dyspnea occurs in patients with profound neuromuscular weakness.

How do responses to chronically altered blood gases compare to the acute stimulus–response relationships for air hunger detailed above (which were obtained in exposures of 10 minutes or less)? Common clinical experience leads to the hypothesis that there is adaptation to chronic changes in blood gases; for instance, the common observation that some patients with chronic obstructive pulmonary disease do not report dyspnea at resting P_{CO_2} in excess of 50 torr, a level that is intolerable to normal subjects at comparable ventilation levels. A direct test of the hypothesis was obtained in mechanically ventilated patients who adapted to a gradual 15-torr rise in Pa_{CO_2} produced by slowly raising inspired P_{CO_2} while holding ventilation and partial pressure of arterial oxygen (Pa_{O_2}) constant.[23] The air hunger response to acute hypercapnia was tested before and after the adaptation period. Within 2 to 3 days, the acute response to hypercapnia had also shifted by 15 torr, essentially complete adaptation (Fig. 55-3). The authors attributed this shift to neural adaptation, rather than acid–base compensation; thus, it may apply to other stimuli such as hypoxia.

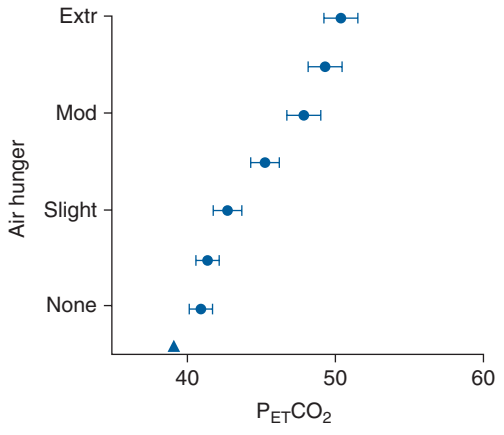

FIGURE 55-2 Air hunger response to an acute rise in end-tidal carbon dioxide tension ($P_{ET}CO_2$) produced by inspired CO_2 in normal healthy men and women (*closed circles*). The prevailing chronic level of $P_{ET}CO_2$ is indicated by *a triangle*. *Bars* indicate standard error of the mean. Volume-control ventilation was delivered via a mouthpiece at 0.16 $L \cdot min^{-1} \cdot kg^{-1}$. Subjects in these experiments were instructed to rate "discomfort due to your urge to breathe." "Extreme" (*Extr*) on the rating scale was defined to the subjects as an intolerable level, and "moderate" (*Mod*) was defined as a level that could be tolerated for several minutes. (Data were replotted from Banzett et al.[15])

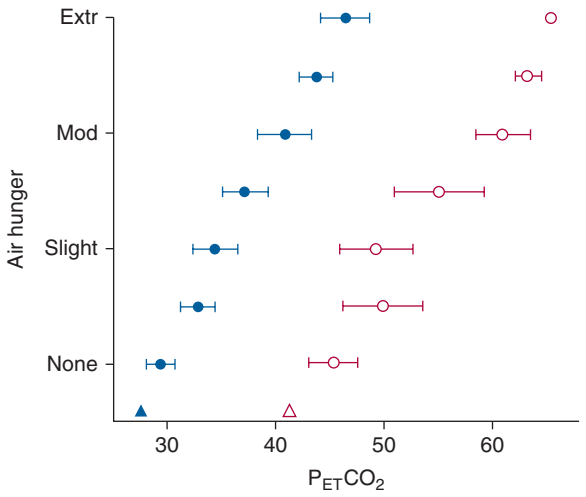

FIGURE 55-3 Adaptation of air hunger response to prevailing chronic level of $P_{ET}CO_2$ (*triangles*) in four ventilator-dependent patients. Response to acute hypercapnia (*circles*) is shown at baseline chronic level of $P_{ET}CO_2$ (*filled symbols*; mean of 27 torr in these chronically overventilated patients), and after adaptation for several days to a mean $P_{ET}CO_2$ of 41 torr (*open symbols*). Bars indicate standard error of the mean. The increase in chronic partial pressure of carbon dioxide (P_{CO_2}) was effected by adding inspired CO_2 at the same minute ventilation ($\dot{V}_E$). (Data replotted from Bloch-Salisbury et al.[23])

Subjects report little or no difference between the quality of air hunger evoked by hypoxia versus that evoked by hypercapnia.[46] If P_{CO_2} and ventilation are near normal, pronounced hypoxia is required to evoke air hunger; in healthy subjects an arterial partial pressure of oxygen (P_{O_2}) of 40 to 50 torr produces only mild air hunger if Pa_{CO_2} remains at eucapnic levels.[46] The effects of hypoxia are enhanced by hypercapnia.

EFFECT OF LUNG INFLATION ON AIR HUNGER

Mechanoreceptor input arising from breathing can dramatically reduce air hunger, as demonstrated by the classic experiment in which subjects held their breath until breakpoint and then breathed from a bag containing gas with alveolar concentrations of CO_2 and O_2, preventing improvement of arterial

blood gases.[16,54] Subjects reported immediate relief and could even continue with another breathhold. This phenomenon is manifested during mechanical ventilation as a decrease in dyspnea when tidal volume is increased, as was initially shown in polio patients.[55] Subsequently, mechanoreceptor relief of air hunger has been shown in normal subjects.[29,50,56] Studies of healthy subjects on volume-control ventilation, who have been initially made uncomfortable with mildly elevated P_{CO_2}, show that there is a decline in discomfort (air hunger) as $\dot{V}_E$ is increased with constant blood-gas levels (the solid line in Fig. 55-4). In these subjects, zero discomfort can be achieved, and further increases have no effect, or produce a different form of discomfort, "too much pressure." In normal subjects, the relationship between ventilation and air hunger is linear (A.P. Binks, personal communication). This relief is undiminished in C1–C2 quadriplegic patients who have no motor or sensory innervation of the rib cage and diaphragm, showing that pulmonary stretch receptors that send impulses via the vagus nerve, are able to produce the full response[57] (*dotted line* in Fig. 55-4). It is not clear, however, whether chest wall receptors form a fully redundant pathway capable of providing relief. Tidal volume provided somewhat less relief in double-lung transplant patients than in normal subjects;[56] however, even the diminished response present in these transplant patients may have been caused by reinnervation of the transplanted lung, because the patients were studied 1 to 9 years posttransplantation.[58]

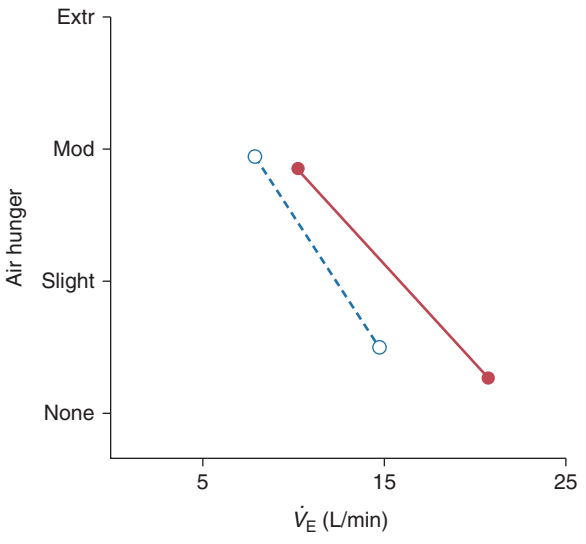

FIGURE 55-4 Relief of air hunger by increased minute ventilation at constant $P_{ET}CO_2$ in normal subjects (*solid line, closed symbols*) and patients with high cervical quadriplegia (*dotted line, open symbols*). In all cases, air hunger was generated by adding inspired CO_2 to increase $P_{ET}CO_2$ above the subjects' baseline $P_{ET}CO_2$. (Mean $P_{ET}CO_2$ in normal subjects was 44 torr and in quadriplegic patients, 34 torr, owing to their lower baseline P_{CO_2}.) $P_{ET}CO_2$ and respiratory frequency were held constant as ventilator tidal volume was varied. (Data for normal subjects combined from Harty et al[56] and Banzett et al[50]; data for quadriplegic patients combined from Manning et al[57] and Bloch-Salisbury et al.[90])

WORK OR EFFORT OF BREATHING

The sense of breathing work or effort arises both from muscle receptors and from corollary discharge arising from cerebral motor cortex activation during volitional respiratory efforts.[59] (Corollary discharge from medullary respiratory centers probably does not give rise to increased work or effort of breathing.) Although some studies of well-trained subjects have shown a distinction between effort and work, most normal subjects and patients do not distinguish the two; thus, we use work/effort to denote the sensation. Work/effort of breathing is perceived when the physical work of breathing is increased by loading the respiratory muscles with high $\dot{V}_E$ or increased impedance, or when increased cortical motor drive is necessitated by respiratory muscle weakness.[53,60–62] Breathing at high lung volume both weakens the muscles (by placing them at a disadvantageous point in the length–tension curve) and loads them by increasing preload and system elastance; this is thought to be an important source of dyspnea in obstructive pulmonary disease.[63–65] In normal subjects, high levels of respiratory work/effort unaccompanied by blood-gas derangements are not as unpleasant or threatening as air hunger.[13,60,62]

In theory, the ventilated patient need not do any respiratory work; ventilators have ample power to assume all work of breathing. Two sources of work, however, commonly arise in ventilated patients. The first we term *wasted work* (i.e., work that does not result in air movement); this includes respiratory efforts that are ineffective because they are out of synchrony with the ventilator, or efforts (although in synchrony) that do not alter airflow (e.g., inspiratory efforts during volume-control inspirations). The second, *productive work,* is performed to lower airway pressure to trigger inspiration during assist control, or to trigger and prolong inspiratory flow during pressure support. Some respiratory work may prevent deconditioning of respiratory muscles.[66,67] Even productive work, however, may be excessive, if for instance the trigger pressure or flow thresholds are set too high especially in the face of high respiratory impedance or respiratory muscle dysfunction. Dynamic hyperinflation (intrinsic positive end-expiratory pressure [PEEP]) is a typical cause of excessive work; in this case the patient must generate inspiratory muscle pressure to overcome the difference between ventilator PEEP and intrinsic PEEP before the ventilator can be triggered. In addition, dynamic hyperinflation is associated with elastic loading caused by flattening of the respiratory system pressure-volume relationship at high lung volumes, and with decreased inspiratory muscle effectiveness secondary to sarcomere shortening and geometry changes. Thus, the effort required to trigger the ventilator and sustain flow above the cutoff level can give rise to excessive work/effort at a time where muscle output is diminished. Depending on the ventilator setting, it can also cause inadequate ventilation, giving rise to air hunger. It is thus likely that dynamic hyperinflation can give rise to a mixed respiratory discomfort combining air hunger and an excessive work/effort.

DYSPNEA ARISING FROM PULMONARY AFFERENTS

There are several diseases in which dyspnea seems to arise from derangements of pulmonary afferent traffic; less is known about the neurophysiology of these forms of dyspnea. *Tightness* arises during bronchoconstriction.[68,69] Tightness is undiminished by mechanical ventilation, and preliminary evidence suggests that it is present during bronchoconstriction in quadriplegic patients with denervated chest walls, suggesting that it arises from pulmonary afferents.[70,71] Pulmonary embolism, pulmonary hypertension, and congestive heart failure all give rise to dyspnea that is disproportional to blood-gas changes or to increased work of breathing. All directly impinge on the lung or its vasculature. It has thus been speculated that these conditions give rise to dyspnea via pulmonary receptors, and there is some evidence implicating vagal afferents, perhaps unmyelinated J-receptors.[72–74]

APPROACH TO THE VENTILATED PATIENT WITH DYSPNEA

If the ventilated patient is experiencing dyspnea, steps should be taken to establish the reason for the dyspnea and corrective measures should be attempted. It may be useful to establish a routine protocol to suit the needs of the unit. If diagnosis and corrective measures are expected to take more than a few minutes, interim relief can usually be obtained by increasing the level of ventilator support. Sedation should be used as a last resort because of the related risks. There are several avenues to pursue before resorting to sedation: assess and remedy problems with obstructed airways, a stiff respiratory system, or weak respiratory muscles; improve ventilator settings; and address neuropsychiatric problems.

Essential information can be obtained from the physical examination (e.g., onset of wheezing, absence of breath sounds, new crackles, use of accessory muscles of ventilation, or pulsus paradoxus) and by measuring airways resistance (Raw), intrinsic PEEP, spontaneous and ventilator-assisted tidal volume, maximal inspiratory and expiratory pressures, and compliance of the respiratory system (sometimes with the use of an esophageal balloon-catheter system to obtain compliance of the lung and chest wall separately).

Reduce Respiratory Drive

Respiratory drive in excess of achieved ventilation is the cause of air hunger, the most common respiratory discomfort reported by mechanically ventilated patients.[7] The most straightforward way to address air hunger is to increase ventilation. When it is not possible or not advisable to increase achieved ventilation, other steps should be taken to reduce drive. Factors such as acidosis, hypoxia, hyperthermia, and anemia should be corrected.[75] Although patients may adapt to hypercapnia over the course of several days, acute increases in Pa_{CO_2} of only a few torr can cause substantial discomfort.[23] When addressing acidosis, it may be possible to use buffers such as tris-hydroxymethyl aminomethane (THAM) that do not increase P_{CO_2}.[76–78]

Correct Increased Respiratory Impedance

Increased resistive or elastic impedance may give rise to air hunger in the ventilated patient by reducing ventilation, either by causing patient triggering efforts to fail, or by reducing tidal volumes delivered by pressure-targeted ventilators. Increased impedance may also give rise to a sense of excessive effort by increasing both wasted and productive work.

EXCESSIVE RESISTANCE

Airways obstruction in ventilated patients as reflected by Raw greater than 10 cm H_2O/L/s is a frequent cause of dyspnea. Table 55-2 lists common causes of high Raw.

In addition to resistance and compliance measures, the pressure and flow waveforms from the ventilator can provide useful diagnostic clues: A sawtoothed pattern is usually caused by retained secretions or condensed water in the expiratory line. Interruption of exhalation by a new inhalation before flow reaches zero indicates the presence of intrinsic PEEP, the magnitude of which should then be measured. Intrinsic PEEP secondary to flow limitation can be distinguished by pressing on the patient's abdomen during expiration. If there is flow limitation, the expiratory waveform will not change. Many of the causes of high Raw listed in Table 55-2 can be identified easily by bronchoscopy. In other instances, the quality of dyspnea reported by the patient can provide important diagnostic clues. For example, our experience is that when bronchoconstriction is the cause, patients complain of chest tightness, whereas other causes of obstruction are usually associated with a sense of increased effort or work to breathe.

The goal is to reduce or eliminate excessive Raw if possible, for instance by suctioning, replacement of the obstructed endotracheal or tracheostomy tube, administration of

TABLE 55-2: COMMON CAUSES OF HIGH AIRWAY RESISTANCE

- Bronchoconstriction
- Inspissated debris in the endotracheal or tracheostomy tube
- Retained secretions in the trachea or bronchi
- Obstruction of the orifice of the endotracheal or tracheostomy tube by the posterior membranous sheath of the trachea secondary to tracheomalacia or a poorly fitting tube
- Granulation tissue (most often at the site of the cuff or tip of the tube or at the anastomosis site of a transplanted lung or lobe)
- Dislodged tracheostomy tube (most common in obese patients in whom selection of the proper size and shape of the tracheostomy tube can be difficult)

bronchodilators or corticosteroids, or removal of granulation tissue. Until these measures are successful in alleviating intrinsic PEEP, however, an important step in achieving relief is to set the PEEP to equal the intrinsic PEEP (which reduces the preload the patient must overcome before triggering inspiration).[79] An alternative is to switch to mandatory volume-control ventilation, in which intrinsic PEEP does not affect delivery of tidal volume.

LOW COMPLIANCE

Stiffness of the respiratory system, as reflected by compliance (Crs) values less than about 40 mL/cm H_2O, is also a common cause of dyspnea. Common causes of low Crs are disorders involving the parenchyma (airspace diseases, fibrosis, and pulmonary edema), pleura (large pleural effusions, pleural thickening secondary to empyema, fibrosis, and tumor), or chest wall (kyphoscoliosis, ankylosing spondylitis, thoracoplasty, or obesity, especially in supine patients). These problems tend to be associated with a sense of effort to breathe, and with air hunger if hypoxemia or hypercapnia occurs. Many of the causes can be identified by chest computed tomography scan. Relief is obtained by reversal of the problem when possible.

FIGHTING THE VENTILATOR

Respiratory efforts out of phase with the ventilator often reduce its effectiveness by increasing effective impedance. These counterproductive efforts can be both an effect of dyspnea and resultant anxiety, and conversely, the efforts and consequent reduction in ventilation can be a cause of further dyspnea.

Dyspnea Associated with Care Activities

Dyspnea is frequently associated with normal care activities such as planned turns, transfers, bathing, and suctioning.[5] Good oxygenation should be assured before the activity, and it may be desirable to administer a preemptive dose of a very short-acting sedative or narcotic agent before commencing. A hazard of using even short-acting drugs repeatedly is that the drug will accumulate and produce prolonged sedation.

Ventilator Settings

Very few research papers have reported measures of dyspnea in patients during mechanical ventilation, and fewer still report the effect of systematic manipulations designed to reduce dyspnea. In most of these studies, respiratory discomfort was not the primary outcome measure, and ventilator settings were optimized according to the investigators' criteria, not according to subjects' reports of comfort.[40,41,80,81] A few studies in normal subjects and none in patients have systematically examined independent variables such as flow rate while holding other known stimuli for dyspnea constant. Usually several mechanoreceptor stimuli changed simultaneously; for instance, in one study when flow rate was changed, tidal volume also changed. In other cases, important physiologic variables secondary to ventilation were not controlled, and were often not even measured. For instance, although it is well known that Pa_{CO_2} and Pa_{O_2} have a powerful effect on air hunger, these variables are frequently not controlled or reported. Despite these limitations, it is clear from these studies that changing ventilator settings can reduce dyspnea, and that patients can report these changes in dyspnea—the two essential features to enable patient-centered ventilation. In an observational study of ninety-six patients mechanically ventilated of whom forty-five (47%) reported dyspnea, altering ventilator settings and/or increasing the level of ventilator support partially alleviated dyspnea in 35% of cases. This corresponded to a median reduction of reported dyspnea by 40% of full scale.[7]

LEVEL OF VENTILATOR SUPPORT

Major relief of dyspnea in ventilated patients can be obtained by increasing the level of ventilator support.[7] There is, however, very little systematic information on this phenomenon; we are aware of only one study in which ventilator variables, work of breathing, and dyspnea were measured at different levels of support by invasive ventilation.[41] This study of patients with chronic obstructive pulmonary disease presents data on respiratory sensation at graded levels of assistance. Increasing the percentage of respiratory work done each minute by the ventilator proportionally decreased ratings of "difficulty breathing" (Fig. 55-5). The effect was large, with breathing difficulty ratings falling from 60% of scale with no support to 30% of scale with 80% support (ratings were not

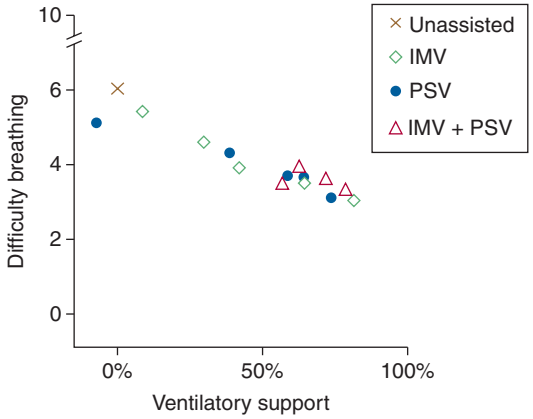

FIGURE 55-5 Effect of ventilator support on dyspnea. Subjects were instructed to rate "difficulty breathing" on a ten-point scale. Work of breathing was measured as the pressure-time product of inspiratory muscles, including all breaths, spontaneous and mandatory. Ventilator support is calculated as the difference from work of breathing in the unassisted control state. Data are shown for unassisted breathing, pressure-support ventilation (*PSV*), intermittent mandatory volume ventilation (*IMV*), and a combination of modes (*IMV+PSV*). (Data reanalyzed and redrawn from Leung et al.[41])

reported for full support). There were equally good correlations when ratings were replotted against a number of relevant physiologic indices (average tidal volume, frequency, minute ventilation, and work of breathing), so the afferent mechanism cannot be deduced from this experiment alone.

There are several mechanisms that could account for the relief achieved by increasing support. When support was increased in the above study, tidal volume also increased, as it would in most clinical situations. Relief correlated with tidal volume equally well as with percentage of support, and it is well known that increasing tidal volume can profoundly decrease air hunger (see the section above Effect of Lung Inflation on Air Hunger). Alveolar ventilation also increased with ventilator support in this study, presumably causing an improvement in blood gases, although these were not measured. Lowering Pa_{CO_2} has also been shown to have a profound effect on air hunger (see the section above Effect of Blood Gases on Air Hunger), providing another possible relief mechanism (not mutually exclusive).

OTHER ASPECTS OF VENTILATOR SETTINGS

Rate of inflation has been shown to have an effect on comfort. In healthy subjects on volume-control ventilation, inflation rates higher or lower than an optimum rate were less comfortable; there was, however, a broad range of comfortable inspiratory flow rates—the minimal comfortable flow, on average, was 0.6 L/s.[82] At inflation rates below the optimum, subjects reported air hunger. At inflation rates well above this minimal flow (average 1.8 L/s), subjects reported sensations of too much pressure. Optimal flow rate has also been shown in patients on pressure-support ventilation for conditions ranging from pneumonia to stroke; discomfort increased above and below the preferred setting.[40] In this latter study, however, there were concomitant changes in tidal volume that may have contributed to changes in discomfort ratings. Another study of ICU patients found a higher prevalence of dyspnea at inspiratory flow rates below 60 L/min (1 L/s), but concomitant changes in other key variables were not reported.[7] In a third study, a minimum inspiratory flow rate of 60 L/min was required to assure respiratory muscle relaxation in patients receiving assist-control ventilation.[83]

There is also evidence that PEEP level affects comfort via two distinctly different mechanisms: triggering effort and mean lung volume. The first, and best understood, arises from the interaction between ventilator PEEP and intrinsic PEEP in determining the effective trigger threshold. In this case, dyspnea can be reduced with little or no change in tidal volume by adjusting PEEP to minimize inspiratory muscle preload. The second effect is through the effect of lung volume on comfort. There is some evidence that chronic ventilator patients and mechanically ventilated healthy subjects are more comfortable (or require less tidal volume to achieve comfort) when end-expiratory lung volume is raised with PEEP,[84,85] possibly secondary to increased pulmonary mechanoreceptor activity.

EFFECT OF VENTILATOR CONTROL MODE

Most comparisons of sensation during different ventilator modes have not controlled the relevant physiologic variables. Leung et al[41] compared respiratory sensation during graded levels of support in two ventilator modes, pressure-support and intermittent mandatory ventilation, allowing meaningful comparisons of the two modes. The ratings of dyspnea ("difficulty breathing") depended only on the amount of assistance, not on the mode of ventilation (see Fig. 55-5). Both modes provided equivalent relief of dyspnea when ratings were replotted against a number of relevant physiologic indices. We conclude that judicious setting of volume-control ventilation parameters (see below) is likely to reduce dyspnea as effectively as subject-controlled ventilation when ventilatory demand is relatively constant.

A great deal of attention is paid to allowing patients to control the inspiration delivered by the ventilator; several clever schemes have been devised to perfect this control. It is thought by many that patient control of the ventilator is more comfortable, either because it ensures coincident timing of lung inflation with neural inspiration, or because it provides a sense of control to the patient. There is, however, no direct evidence that patient-triggered ventilation is inherently more comfortable than the same ventilator parameters set externally; differences appear to be more dependent on the parameter values chosen, and perhaps on the preference and familiarity of the operator for one mode versus another. There is growing evidence to show that use of the diaphragmatic electromyogram to initiate, control, and terminate pressure support (neurally adjusted ventilatory assist) improves patient–ventilator synchrony and allows more natural breathing variability.[86] The impact of neurally adjusted ventilatory assist on respiratory comfort, however, has not yet been determined.

If timing ventilator inflation to coincide with neural inspiration were crucial, spontaneous breathing in healthy subjects would be more comfortable than volume control; this is not the case. During hypercapnia in healthy subjects, spontaneous breathing was no more comfortable than volume-control mechanical ventilation at the same $\dot{V}_E$.[87] This may be because timing is irrelevant, or because neural timing adapts quickly to reasonable ventilator timing.[88,89]

If a psychological sense of control were important, giving the patient direct control of ventilator parameters would improve comfort; this is not the case, at least in chronically ventilated patients. When paralyzed patients on volume-control ventilation were allowed to control the tidal volume setting of the ventilator using a "sip/puff switch," they obtained no more relief from hypercapnia-induced discomfort than when the experimenter surreptitiously increased the volume.[90]

Patient-controlled ventilation may, however, have important advantages when ventilatory demand is highly variable. Two such instances are ambulatory patients assisted with noninvasive positive-pressure ventilation, whose ventilatory demand changes with physical activity,[80] and patients who use ventilator-delivered air to generate speech.

CHRONICALLY VENTILATOR-DEPENDENT PATIENTS

An illustrative case is that of the chronically ventilator-dependent neuromuscular patient. These patients are nearly always comfortable with their usual ventilator settings. The reason for this is that they are not sedated, and thus they clearly and insistently communicate their ventilatory desires to caregivers. In response, the caregivers set the ventilator to satisfy the patient. In our experience, this always results in high tidal volumes, frequencies of 10 to 15 breaths/min, and very low $P_{ET}CO_2$. In general, nearly all breaths are delivered by the ventilator as mandatory breaths, even when triggering is possible. Presumably this is because ventilation is high enough to suppress spontaneous efforts. Studies in which $P_{ET}CO_2$ is slowly raised show that complete comfort is maintained at normal $P_{ET}CO_2$, leading us to conclude that the factor suppressing dyspnea and spontaneous efforts is large tidal volume, rather than low P_{CO_2}. Patients with lung and heart disease present additional constraints that complicate the issue, but the general principle of obtaining feedback from the patient as part of the ventilator-setting process can probably be applied to most awake patients.

UNWANTED EFFECTS OF VENTILATOR ADJUSTMENTS

Ventilator-induced lung injury can be caused by overly high tidal volumes in vulnerable patients. It may not be necessary to give excessively high tidal volumes to achieve patient comfort. Although one observational study suggests that the tidal volume limit should be reduced in all patients, the study design limits the strength of the conclusions.[91] We also note that chronically ventilator-dependent neuromuscular patients are routinely maintained for years with much larger tidal volumes without experiencing ventilator-induced lung injury.[23,57,84,92] More restrictive limits should be observed in patients at risk for the acute respiratory distress syndrome, in which case other means must be used to avoid dyspnea. Clinicians should be sure to apprise themselves of the current state of the art for tidal volume limits, as this is a rapidly changing field. It seems particularly important not to extend attitudes and recommendations that have been developed for patients at high risk of lung injury to situations where their relevance is unknown. Exposing a patient to dyspnea and psychological trauma is not warranted if this patient is not at risk of acute lung injury.

Some clinicians become concerned if arterial P_{CO_2} falls below normal values. Again we note the experience of chronically ventilator-dependent neuromuscular patients, who invariably have arterial P_{CO_2} 10 to 20 torr lower than normal for many years without apparent ill effect.[57,83] It is important, however, to avoid acute increases in Pa_{CO_2} that give rise to dyspnea. Thus, for instance, if a patient is preparing to wean and is unlikely to have the ventilatory capacity to sustain low P_{CO_2}, the P_{CO_2} should be slowly raised over the course of a day or more to a level the patient is likely to be able to sustain with spontaneous breathing.

Sedation

It is commonly believed that heavy sedation is the best method to deal with patients who are uncomfortable during mechanical ventilation.[93,94] This is the usual approach in many hospitals. Mounting evidence suggests that this is a poor solution to the problem. It is intuitively evident that the loss of communication with loved ones and health care professionals is a serious disadvantage of sedation. It is also reasonably well established that heavy sedation worsens several outcome measures, such as length of ICU stay, length of hospital stay, and incidence of serious complications.[95] More recently, and more surprisingly, evidence has emerged suggesting that sedation worsens psychological outcome following discharge.[96,97]

Sedation may not eliminate discomfort even though it reduces outward signs of discomfort. What is known about the effect of sedation on pain suggests that some sedatives are ineffective in eliminating discomfort. For example, ratings of the discomfort of a controlled cutaneous pain stimulus were unaffected by propofol plasma concentrations up to 1.5 μg/mL (moderate sedation). Even at propofol concentrations that rendered subjects unresponsive, strong pain-related activations were seen in cortical regions associated with pain.[98,99] Although no similar studies exist for dyspnea stimuli, it is possible that cortical activation by dyspnea also persists during heavy sedation, providing a substrate for psychological trauma. It has been hypothesized that sedated patients can experience discomfort at some level, yet not have explicit recollections of stressful events.[100] They are therefore unable to construct a rational understanding of their discomfort, and are left with nightmarish recollection of the episode.[96,101]

Opioids are the only drugs recognized as effective in providing symptomatic relief of dyspnea. Relatively low doses of opioids can be effective. A recent meta-analysis showed a significant effect of opioids on clinical dyspnea, but the effect size was variable, probably because most of the included studies used oral dosing.[102] Parenteral doses are more consistently effective than oral doses.[103] In laboratory tests, morphine has been shown to specifically reduce air hunger,[103] the predominant symptom in ventilated patients.[7] Strom et al showed that it is possible to maintain ventilated patients with low doses of morphine and no other sedative; although no direct measurements of discomfort were reported, approximately 20% of patients required dedicated personal reassurance.[95] The duration of ventilation and ICU stay were shorter than in control patients sedated with propofol or midazolam.

COMFORT IMPLICATIONS OF THE PATIENT–VENTILATOR INTERFACE

Mechanical ventilation can be provided through a variety of patient–ventilator interfaces, including body tanks ("iron lungs"), endotracheal tubes, tracheostomy, masks, and helmets. It is customary to call support that does not involve tracheal cannulation as "noninvasive ventilation." Noninvasive ventilation is efficient as a life-support and symptomatic measure both during acute and chronic ventilatory failure. Noninvasive ventilation, when feasible, can

provide distinct advantages over endotracheal intubation for physical outcome,[104,105] and avoids major discomfort caused by the endotracheal tube.[106] Where conditions are suitable for noninvasive ventilation, it may even reduce posttraumatic stress disorder.[107] Patients supported by noninvasive ventilation, however, are not free from psychological trauma events.[18] It can be difficult to achieve both adequate gas exchange and comfort in the presence of leaks. Leaks promote patient–ventilator dyssynchrony[108] and may require the use of uncomfortable measures including high insufflation pressures and excessively tight application of masks.

Tracheotomy is probably the most ancient patient–ventilator interface. ICU mortality and morbidity are unaffected by tracheotomy;[109,110] although it has been associated with significant improvement of comfort in ventilated patients.[109,111] Tracheotomy can also allow spoken communication with caregivers and loved ones; more intubated patients are bothered by the inability to speak than by endotracheal tube discomfort,[112] although tracheotomy is often considered as very invasive by caregivers, patients, and relatives.

IMPORTANT UNKNOWNS AND THE FUTURE

Epidemiology

There are only a few small studies of the prevalence of dyspnea in mechanically ventilated patients. These pilot studies strongly suggest there is a reason for concern, but studies defining the extent of the problem and its variation in different categories of patients and in different care settings are needed. In addition, the connection between dyspnea in ICU patients and poor psychological outcomes needs to be more carefully studied. Having defined the extent of the problem, it will be necessary to study the effectiveness of patient-centered ventilation strategies on both immediate comfort and long-term medical and psychological outcomes.

Respiratory Interventions

Systematic studies of the effect of each of the multitude of ventilator setting modes on patient comfort are needed. These should be accomplished with state-of-the-art methods for dyspnea measurement, and with proper measurement and control of interrelated physiologic variables that may change. To date, there are no studies of ventilator settings that report measurements of discomfort together with measurements of the salient physiological variables that determine comfort (tidal volume, inspiratory time, frequency, blood gases, and so on). Further investigation is also needed to determine whether feedback on magnitude of discomfort will suffice as a practical guide to treatment of the mechanically ventilated patient, or whether obtaining further descriptions of the nature of discomfort will be useful.[13,69] On the basis of this mechanistic knowledge, a more systematic approach to achieving comfort can be devised.

Nonrespiratory Interventions

There are several potential schemes for altering afferent input without actually altering ventilatory variables, in a sense "fooling" the system to reduce perception of dyspnea. These have not been studied in the context of mechanical ventilation. Cool air directed over the face has a significant effect on dyspnea.[113] In some studies, phasic vibration of intercostal spaces has been shown to have an effect on work/effort dyspnea,[114–116] but no effect on air hunger.[117] Aerosolized furosemide has also been shown to reduce air hunger dyspnea.[118–120]

A complementary approach may be the provision of psychological support during the ICU stay. In one study, provision of a staff member to reassure and comfort those patients having difficulty with discomfort allowed lighter sedation. Such extra support was needed in only 20% of lightly sedated patients.[95]

SUMMARY AND CONCLUSION

Substantial respiratory discomfort is common in mechanically ventilated patients and is likely responsible for important emotional reactions, such as anxiety, fear, and PTSD. There is some irony in this, as mechanical ventilation is often instituted to relieve respiratory distress. Unfortunately, the current trend toward using low tidal volume ventilation in all patients exposes patients to dyspnea more often and for more prolonged periods. It will be of the utmost importance to explicitly recognize this trade-off, and to balance the clinical need for lung protection against the suffering that low tidal volume may engender.

Although it is not common current practice, we have recommended that, in ventilator units, there be routine formal assessment of the quality and intensity of the discomfort, for example, when vital signs are obtained. The cause(s) of the dyspnea should be sought and corrective measures attempted. The patient's description of the discomfort, the physical examination, and physiologic measurements, such as airways resistance and respiratory system compliance, provide important clues about the cause of the dyspnea. Increasing the level of mechanical support usually provides relief, but the best method for this is not yet known and may vary with the cause. Heavy sedation should be used only when necessary because it is associated with an increase in days requiring mechanical ventilation, occurrence of pneumonia, and length of stay in the hospital. Whether the patient-centered ventilation approach that we have recommended will yield beneficial outcomes remains to be determined and should be the subject of future research.

VENTILATOR-SUPPORTED SPEECH

Jeannette D. Hoit
Robert B. Banzett
Robert Brown

Under normal circumstances, the respiratory system supplies the aeromechanical drive that allows the vocal folds, tongue, lips, and other structures to create the sounds of speech. Although a simplification, this drive can be understood as the tracheal pressure. Usually this pressure is exquisitely and actively controlled by muscles of the chest wall. When speech is produced with ventilator support, however, the ventilator and the respiratory system must work together to produce the pressure that drives speech production. In most cases, this pressure is markedly different from that of normal speech production. As a result, the act of speaking can be challenging for patients, and they often require assistance from their pulmonologists, respiratory therapists, and speech-language pathologists. The views presented here are that patients should be enabled to speak whenever possible, and that ventilator-supported speech can often be improved by using interventions such as those described in this chapter.

THE IMPORTANCE OF SPEECH

Communication is critical to maintaining good quality of life. Communication is the key to being able to express needs, participate in social activities, and retain control over important life decisions.[1–5] It can be especially important in intensive care or during end-of-life care.[6,7] There are many ways to communicate, but of these, speech is the fastest and most convenient. It works in the dark and across telephone lines, and it conveys meaning and emotions through words and tone of voice (i.e., pitch, loudness, quality, and timing).

Patients who are ventilator-supported often complain of speech problems, especially unwanted pauses and inadequate loudness.[8] This is illustrated in the following quotation,[9] which comes from a patient who was asked, "Do you have any problems with your speech?" Note that the pauses between phrases were 3 to 4 seconds (• = 1 second),

and that some words were produced without voice (shown in parentheses). To appreciate the severity of the speech problem, this quotation should be read aloud with timed pauses:

"Yes •••• Um, getting cut (off) •••• people interfering with me ••• trying to finish my sentences (for me) •••• that's the most frustrating (part)."

Fortunately, it is nearly always possible to improve ventilator-supported speech. The following quotation comes from the same patient, after she received speech interventions. Pauses were reduced to approximately 1 second, and the amount of speech per breath increased by approximately 50%.

"Since I've been able to talk better • I've par- participated in talking with more people and • and in conversation instead of just doing the listening • and talking as little as possible • I've joined in and, and • I don't know, I've just been part of a group more • Very few people try to finish my sentences now and • second guess what I'm going to say • It's, it's helped a lot."

FUNDAMENTALS OF SPEECH BREATHING

Speech comprises the tones, hisses, pops, and buzzes that are the acoustic representation of language.[10] Speech is usually produced by the coordinated efforts of more than 100 muscles spanning the chest wall, larynx, and upper airway structures (pharynx, velum, jaw, lips, and tongue). Speech breathing is the process by which the driving forces are supplied to downstream structures to generate speech, and it is tailored to simultaneously serve speech-related functions and meet gas exchange requirements.[11]

The normal speech breathing cycle has an inspiratory phase ranging from 0.5 to 0.7 second.[12–16] Inspirations during speaking are so short that the pauses they create are hardly noticeable. The longer, more variable expiratory phase of the cycle is the speaking phase. Its duration averages 3 to 5 seconds, but varies substantially as a function of linguistic factors, cognitive variables, mechanical constraints, and ventilatory needs.[13,14,16–18] Speech is usually produced throughout most of the expiratory phase, although nonspeech expirations are likely to occur in senescent subjects,[19] with high cognitive-linguistic demands,[20] and under conditions of elevated ventilatory drive.[16,21,22] The tidal volumes used in speech breathing are typically about twice as large as those of resting tidal breathing.[23]

The normal speech breathing cycle has a characteristic tracheal pressure profile. During inspiration, pressure is substantially and briefly negative, and during expiration (speaking), it is moderately positive and relatively steady. For speech of conversational loudness, pressure is generally in the range of 5 to 10 cm H_2O.[24,25] Pressure usually remains relatively constant throughout expiration so that loudness and voice quality remain relatively constant.[26,27] An increase in pressure generally causes an increase in loudness. To produce voiced speech sounds (such as vowels), the vocal folds must oscillate, which requires a minimum pressure of approximately 2 cm H_2O.[28,29] When voiced sounds are produced with a constricted oral airway (such as the plosive /d/ or the fricative /v/), slightly higher pressures are needed.

The pressures of normal speech breathing are controlled actively throughout the cycle by muscles of the chest wall.[27] Inspiration is driven by the diaphragm (with activation of other muscles that serve to stabilize the chest wall), and expiration (speaking) is driven by both expiratory rib cage and abdominal muscular pressures (with the latter predominating) when in upright body positions, and by expiratory rib cage muscular pressure alone when in the supine body position. These muscular pressures are usually supplemented by positive recoil pressure, because most conversational speech is produced above the resting expiratory level. On rare occasions, when speech is initiated at a very large lung volume (i.e., near total lung capacity), positive recoil force may be so great that inspiratory muscular pressure must be called into play to counteract (i.e., "brake") the high positive pressure.

A FRAMEWORK FOR UNDERSTANDING VENTILATOR-SUPPORTED SPEECH

During ventilator-supported speech breathing, tracheal pressure reflects the combined contributions of the patient's prevailing respiratory recoil pressure, active muscular pressures (if the patient is able to activate chest wall muscles), and inspiratory and/or expiratory drive from the ventilator, among other factors. A useful framework for understanding, evaluating, and managing ventilator-supported speech is to relate speech to tracheal pressure.[9,11,30]

SPEECH WITH INVASIVE POSITIVE-PRESSURE VENTILATION

Invasive positive-pressure ventilation (InPPV) is used here to mean intermittent positive-pressure ventilation via tracheostomy. Because an endotracheal tube prohibits vocalizing and can damage the vocal folds, speech is one of several factors to consider when deciding whether and when to perform a tracheotomy (see Chapter 40). Speaking with InPPV is substantially different from speaking with other forms of ventilation, but it can be very successful. The primary differences stem from the fact that the ventilator-delivered air enters below the larynx.

Deflate the Tracheostomy Tube Cuff

For a patient to speak, the first and most critical step is to configure the tracheostomy tube so that flow (and thus pressure) can reach the larynx. This means that the cuff on the

tube must be deflated (and/or the tube must contain a fenestration). If cuff deflation or use of a fenestrated tube is deemed inadvisable, alternative forms of speech or communication must be sought (see Chapter 40 and "Alternatives to Ventilator-Supported Speech" below).

Cuff deflation is feasible in most chronically ventilated patients[31,32] and in acutely ventilated patients who are otherwise stable. Indeed, in some patients, the cuff can be deflated and speech training initiated on the first day after the tracheotomy has been performed. Unfortunately, cuff deflation and speech training are often delayed (or not performed at all) because of unfamiliarity with the procedure, concerns about aspiration, and fear of causing hypoventilation and hypoxemia. Hypoventilation and hypoxemia can be avoided by increasing the ventilator-delivered tidal volume. In many stable patients, the cuff can remain deflated all day (and inflated only for sleep). In less-stable patients, cuff deflation may need to be brief (to allow communication with family members or caregivers) and performed only in the presence of a pulmonologist or respiratory therapist (see Clinical Scenario 1). It is sometimes helpful to deflate the cuff only partially in patients who tend to lose too much of the inspired tidal volume through an open larynx. The recommended procedure for initial cuff deflation is described in "Important Cautions" below.

CLINICAL SCENARIO 1

Mrs. Z was a 52-year-old woman with breast cancer that had metastasized to her lungs, causing her to be very short of breath and unable to breathe on her own. She obtained relief from assisted ventilation via a tracheostomy and could not be weaned from the ventilator. She was frustrated by not being able to speak to her caregivers, husband, and daughters about the nature and intensity of the care she wished to receive and about her impending death. Communication by writing was tedious. She was advised that the cuff of her tracheostomy tube could be deflated so that she could speak, but that she would likely experience periods of breathlessness at first while ventilator adjustments were being made. She was very fearful of this, but with encouragement and reassurance the procedure was successful. For several minutes at a time, with only slight shortness of breath, she was able to speak and communicate her wishes to her family. She went home on the ventilator and died peacefully there.

After cuff deflation, the patient's voice should be assessed. If voice problems are noted, the resistance to "bypass" gas flow around the cuff should be estimated to determine if it is sufficiently low to allow good vocalizing. Bypass resistance can be estimated by blocking expiratory flow where it exits the ventilator and observing tracheal pressure during expiration. When the resistive pressure drop is less than 5 cm H_2O, cuff deflation is generally successful, but when pressure exceeds 10 cm H_2O, cuff deflation often fails. Bypass resistance can usually be reduced by downsizing the tracheostomy tube. If the patient still cannot vocalize, the upper airway, larynx, and upper trachea should be viewed via nasendoscopy to rule out conditions such as excessive secretions, laryngeal edema, granulation tissue, tracheal scar formation, or vocal fold paralysis.

Figure 56-1 illustrates the flow routes for inspiration and expiration with an inflated cuff (closed system) and deflated cuff (open system). When the cuff is inflated, no flow reaches the larynx. When the cuff is deflated, flow reaches the larynx during inspiration and expiration, making it theoretically possible to produce speech during both phases of the ventilator's cycle. The ventilator's settings, however, are strong determinants of when within the cycle speech can be produced. Speech produced with InPPV is often plagued by long pauses, short phrases, variable loudness, and variable voice quality.[30,33,34] These speech features are most easily explained by relating them to the tracheal pressure.

Speech Production with Volume-Controlled Ventilation

Figure 56-2 illustrates tracheal pressure with volume-controlled ventilation compared with that of normal speech production. During normal speaking pressure is low and constant. This steady pressure allows vocal fold oscillations to be relatively constant in amplitude and waveform, translating perceptually to relatively constant loudness and voice quality. Also, pressure remains above the vocalizing threshold throughout expiration.

By contrast, during volume-controlled InPPV pressure rises quickly during inspiration, falls sharply when the expiration valve opens, and then remains below the vocalizing threshold for a substantial portion of the cycle. The rapidly changing pressure is the primary cause of loudness and voice quality problems, and the periods of low pressure (below the vocalizing threshold) explain the long pauses and the short phrases.

Ventilator Adjustments That Can Improve Speech

Abnormal magnitude and time course of tracheal pressure are at the root of the speech problems associated with volume-controlled InPPV. Therefore, the unifying principle for improving speech is to adjust the ventilator so as to generate a pressure that is better suited for speech production, while accommodating the patient's respiratory needs and comfort. Ventilator adjustments to improve speech are designed to (a) increase the portion of the cycle during which pressure remains above the vocalizing threshold (i.e., at least 2 cm H_2O), and (b) reduce the rate and magnitude of pressure changes during the period in which speech is produced. Many adjustments are possible, and the optimal combination for a given patient must be determined empirically.

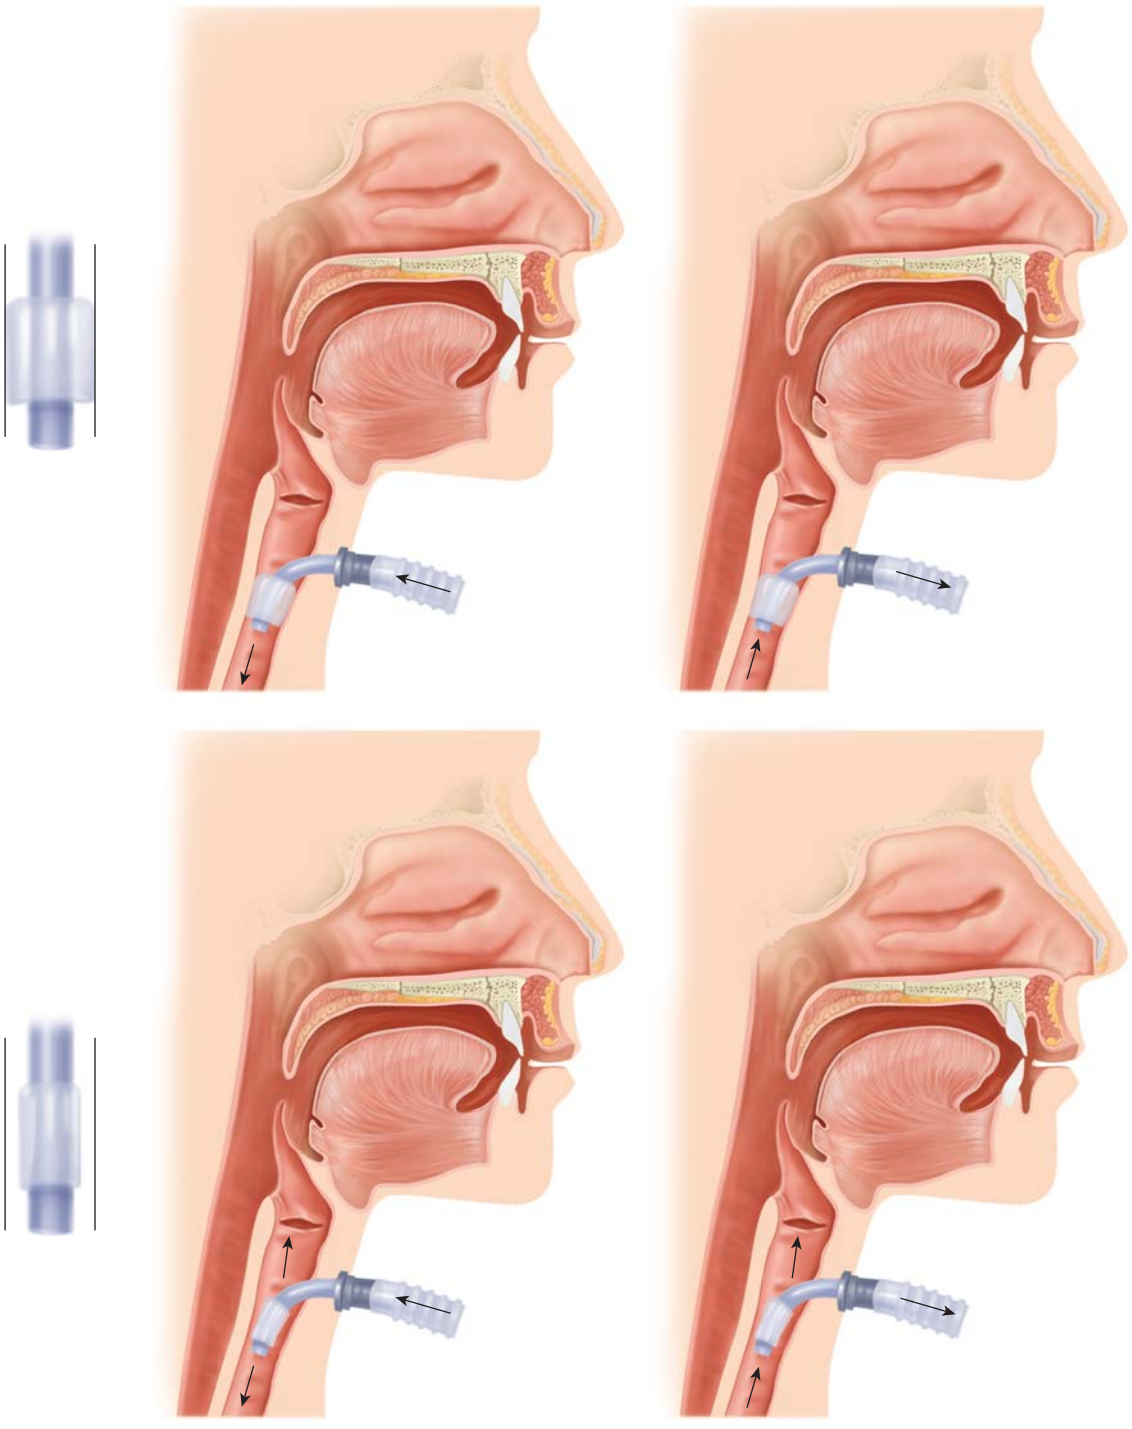

FIGURE 56-1 Inflated and deflated tracheostomy tube cuff during inspiration (*left*) and expiration (*right*). When the cuff is inflated, no flow reaches the larynx, and when the cuff is deflated, flow reaches the larynx during both inspiration and expiration. (Adapted and used, with permission, from Hixon and Hoit.[11])

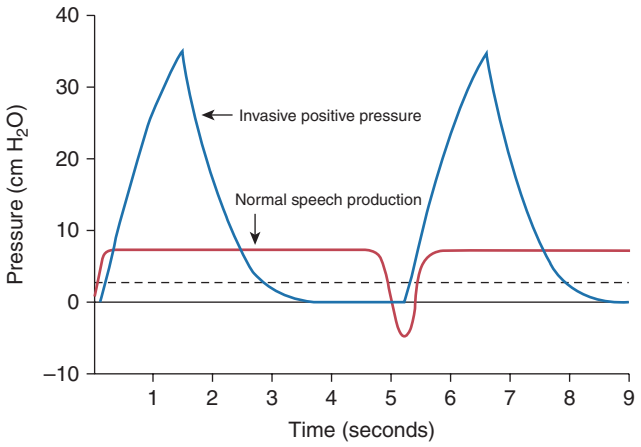

FIGURE 56-2 Tracheal pressure during volume-controlled InPPV and during normal speech production. The *dashed line* shows the minimum pressure needed for vocalizing. (Used, with permission, from Hixon and Hoit.[11])

The success of this approach has been well documented in patients with spinal cord injury and neuromuscular disease,[30,34–36] and is likely to be effective in others. Examples of ventilator adjustments and their predicted influences on speech are given below.

LENGTHENED INSPIRATORY TIME, POSITIVE END-EXPIRATORY PRESSURE, AND REDUCED TIDAL VOLUME

One of the easiest and most successful adjustment combinations is lengthened inspiratory time and the application of positive end-expiratory pressure (PEEP). When inspiratory time is lengthened, more speech can be produced during the inspiratory phase of the ventilator's cycle, because pressure is above the vocalizing threshold for a longer period. In general, as inspiratory time increases, the amount of speech produced during inspiration increases. Also, because the rate of pressure change is more gradual when inspiration is prolonged, loudness and voice quality variability may be reduced. The addition of PEEP extends speaking time during the expiratory phase by adding resistance to the ventilator's expiratory line, which keeps pressure above the vocalizing threshold longer. In most cases, pressure will eventually fall to zero secondary to flow through the larynx.

Sometimes it is physiologically appropriate to also reduce the ventilator-delivered tidal volume in patients whose tidal volumes are too large. When tidal volume is reduced, peak pressure is lowered, which helps to smooth out loudness and voice quality. Although patients are usually uncomfortable when tidal volume is reduced, they are often comfortable if PEEP is added first.

An example of the effect of these adjustments on tracheal pressure and the acoustic speech signal is shown in Figure 56-3 as a comparison of a patient's "usual" and "best" ventilator settings. Although the ventilator adjustments resulted in only subtle changes in the pressure waveform, the changes in speech were substantial and easily perceptible to listeners.[30] On average, an increase in inspiratory time of 17% to 25% combined with PEEP of 5 to 10 cm H_2O results in an increase in speaking time of 55% per cycle.[34] As shown in Figure 56-4, the increase in syllables/minute for lengthened inspiratory time and the PEEP adjustment is additive.

PRESSURE-CONTROLLED VENTILATION AND POSITIVE END-EXPIRATORY PRESSURE

Pressure-controlled ventilation (and its variants, such as pressure-support ventilation) target a given airway pressure (rather than a volume). Thus, inspiration may be associated with a relatively steady pressure, somewhat similar to that associated with normal speech production (except higher). With this form of ventilation, pressure remains above the vocalizing threshold throughout inspiration. And, when pressure is steady, loudness and voice quality are more apt to be constant. When PEEP is added, pressure can be maintained above the vocalizing threshold during expiration. Figure 56-5 shows that vocalizing can continue throughout the entire ventilator cycle[35] (as it can with appropriate volume-controlled adjustments).

POSITIVE END-EXPIRATORY PRESSURE REPLACES A ONE-WAY VALVE

A one-way valve can improve speech in a patient with a tracheostomy who breathes spontaneously with a tracheostomy (see Chapter 40). Such a valve can also improve speech in a patient with InPPV; however, its use with InPPV can be dangerous. For instance, if the tracheostomy tube cuff is inflated and the valve is inadvertently left in place, the patient cannot expire. This can be lethal by causing asphyxia, by impeding venous return, or, if the pressure-limit device fails, by rupturing the lungs. A safer approach is to add PEEP.[37] With PEEP (Fig. 56-6), speech can be indistinguishable from that produced with a one-way valve,[34] even with PEEP as low as 5 cm H_2O.[38]

RISKS AND BENEFITS OF VENTILATOR ADJUSTMENTS

Ventilator adjustments can have adverse effects if not properly chosen and implemented. For instance, when inspiratory time is lengthened with volume-controlled ventilation, the patient may hypoventilate while speaking, because there is more time for inspiratory flow to "bleed off." If this happens, most patients experience air hunger and intuitively stop speaking to catch their breath,[39,40] but patients with diminished chemosensitivity may be at risk. If too much of the total cycle is devoted to inspiration, the shortened expiratory time may lead to dynamic hyperinflation, especially in patients with severe obstructive airways disease. Any adjustment that excessively increases intrathoracic pressure may reduce cardiac output and impede venous return. To

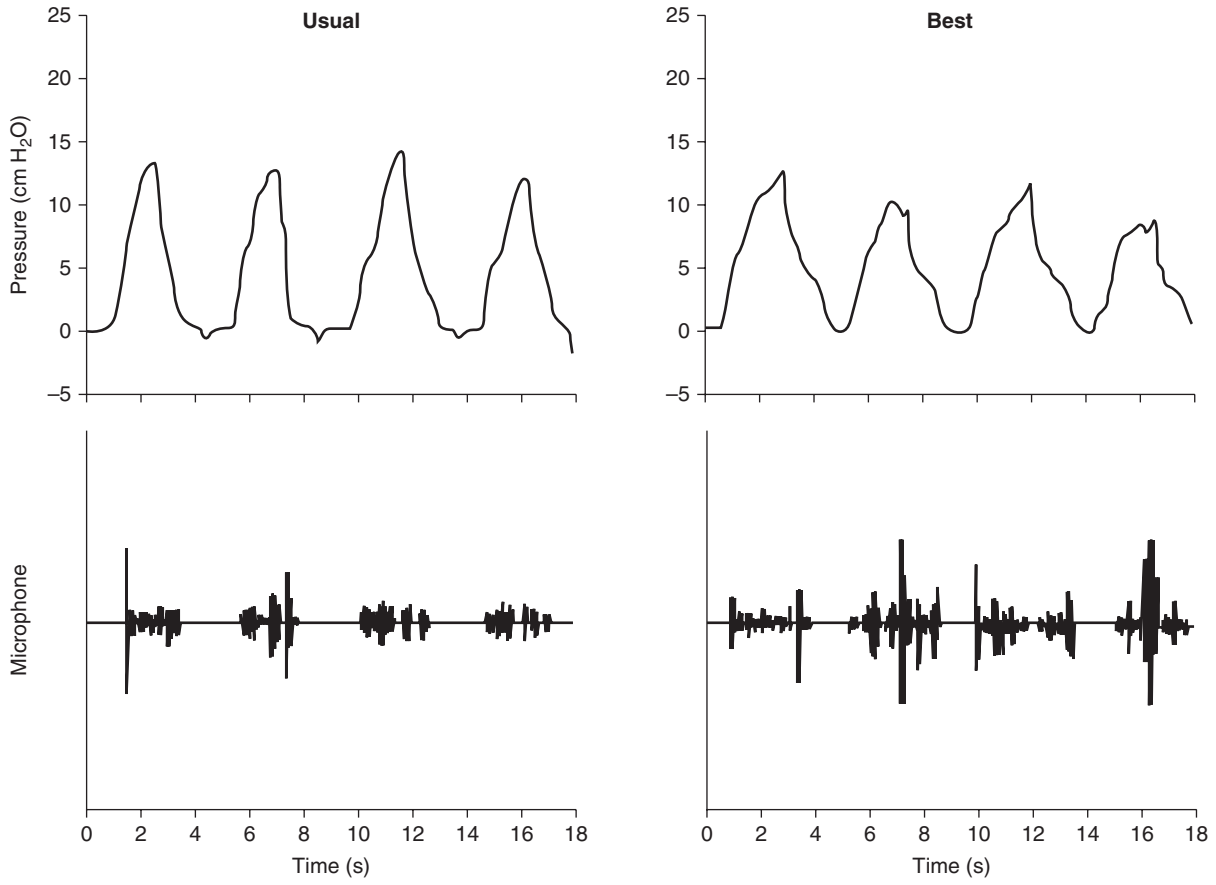

FIGURE 56-3 The tracheal pressure and speech signal under the usual (*left*) and best (*right*) ventilator conditions. The best settings represented the following adjustments: (a) inspiratory time was lengthened by 0.5 second; (b) 4 cm H_2O of PEEP was added; and (c) tidal volume was reduced by about 0.3 L. (Adapted and used, with permission, from Hoit and Banzett.[30])

minimize this risk, the lowest level of PEEP adjustment that reaps adequate speech improvement should be used, and dynamic hyperinflation (intrinsic PEEP) should be assessed following any changes to the ventilator. Also, ventilator adjustments can cause patient discomfort (e.g., "not enough air" or "too much pressure"). The potential for discomfort may be lessened if adjustments are made gradually and in small steps. Fortunately, most adjustments that improve speech also fortuitously improve comfort. Although there are risks to ventilator adjustments, they are usually minimal, especially when compared to the more serious risks posed by a one-way valve.

The most obvious benefits of these ventilator adjustments include improved speech, decreased speaking effort, and,

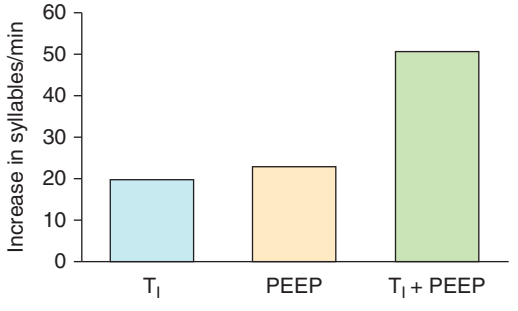

FIGURE 56-4 Changes (from usual) in syllables/minute for lengthened inspiratory time, PEEP, and combined lengthened inspiratory time (T_I) and positive end-expiratory pressure (PEEP). (Adapted and used, with permission, from Hoit et al.[34])

in some cases, increased breathing comfort. There may be other benefits as well. For example, if a patient is chronically hyperventilated,[41] speech adjustments may move ventilation toward normal (e.g., because the patient is comfortable with a smaller tidal volume if PEEP is applied; see Clinical Scenario 2).

CLINICAL SCENARIO 2

JT, a man with a C2 spinal cord injury and InPPV, was referred to the speech-language pathologist for a speech evaluation. The evaluation revealed that JT spoke in short phrases (three to four syllables per breath) with excessively long pauses (up to 5 seconds), and he complained that he was "interrupted all the time." The speech-language pathologist recommended to JT's pulmonologist that ventilator adjustments be tested to improve his speech. The pulmonologist agreed and wrote the order, adding that "if the ventilator adjustments can also reduce his ventilation, that would be a bonus." Ventilator adjustments were tested (with the pulmonologist, respiratory therapist, and speech-language pathologist present) and it was found that lengthened inspiratory time, a PEEP adjustment, and reduced tidal volume improved his speech dramatically. Preadjustment and postadjustment measures revealed a moderate increase in arterial partial pressure of carbon dioxide (P_{CO_2}) (from 22 to 29 torr) and greater breathing comfort. The patient, his speech-language pathologist, his pulmonologist, and his family and friends were delighted with the outcome.

Behavioral Interventions That Can Improve Speech

Once appropriate ventilator adjustments have been made, behavioral interventions, guided by a speech-language pathologist, may further improve speech (see reference 11 for an extensive discussion of this topic). For example, linguistic strategies may be helpful for patients who continue to have long pauses between phrases despite ventilator adjustments. These linguistic strategies might take the form of pausing at appropriate linguistic junctures (e.g., at phrase, clause, or sentence boundaries) when speaking didactically, but intentionally pausing at inappropriate linguistic junctures (e.g., within a phrase or following a conjunction) when speaking conversationally to reduce the likelihood of being interrupted. It may be useful to teach buccal speech (i.e., "Donald Duck"-type speech) as a compensatory strategy. This type of speech, which is produced entirely within the upper airway and requires no drive from chest wall muscles,[42] can be used to add a syllable or two after the pressure has fallen below the vocalizing threshold.

SPEECH WITH OTHER FORMS OF VENTILATOR SUPPORT

Whereas speech can be produced during both inspiration and expiration with InPPV, it is produced only during expiration with other forms of ventilator support (see Table 56-1 and Chapters 16, 17, 18, and 62). Although research is sparse, ventilator adjustments and behavioral interventions have strong potential to improve speech produced with these other forms of ventilator support. Noninvasive positive-pressure ventilation (NPPV) and phrenic nerve pacer ventilation are discussed below as illustrations of how this might be done.

TABLE 56-1: SUMMARY OF SPEECH PRODUCED USING DIFFERENT TYPES OF VENTILATOR SUPPORT

Type of Ventilator Support	Speech Production	Can Ventilator Adjustments Improve Speech?	Can Behavioral Interventions Improve Speech?
Invasive positive pressure	Inspiration/ expiration	Yes	Yes
Noninvasive positive pressure	Expiration	Yes	Yes
Negative pressure	Expiration	Yes	Yes
Phrenic nerve pacer	Expiration	Yes	Yes
Rocking bed	Expiration	No	Yes
Abdominal pneumobelt	Expiration	Yes	Yes

Included here are the phase(s) of the ventilator cycle during which speech is produced and whether or not ventilator adjustments and behavioral interventions have potential to improve speech.

Noninvasive Positive-Pressure Ventilation

An important speech consideration when using NIPPV is selection of the patient-ventilator interface.[43] Choices for interfaces include mouthpieces, nasal pillows, nasal masks, and face masks. Of these, the clear choice for speech breathing is a mouthpiece that is not secured to the patient's mouth. To use this interface, the patient places his or her lips around the mouthpiece during inspiration and pulls the lips away during expiration. Thus, the patient's face is completely unencumbered during speech production. The next best interface options are nasal interfaces, because they allow the lips and jaw to move freely during speaking. Nevertheless, they encumber the nasal airway and can distort nasal consonants (*m*, *n*, and *ng*, in English). By far the least desirable interface is the face mask, because it encumbers both the oral and nasal airways, dampens and distorts the speech signal, and removes visual cues that a listener might use to help compensate for reduced intelligibility.

For many patients who use NIPPV, one of the best strategies for improving speech is to increase inspiratory volume.[11] In the case of the patient with neurologically complete chest wall paralysis, pressure (and loudness) at the beginning of expiration is determined primarily by inspiratory volume and respiratory system elastance, and the rate at which pressure drops (and loudness decreases) is determined by the rate at which volume is expended during speaking. By increasing inspiratory volume, speech can be louder (at least at the beginning of expiration) and last longer.

One way to increase inspiratory volume is to adjust the ventilator's tidal volume. Another way is to train the patient to use glossopharygneal breathing. Glossopharyngeal breathing can be effective, not only for increasing tidal volume, but also for replenishing volume (and pressure) while speaking.[44]

Phrenic Nerve Pacer Ventilation

In patients with paralysis from cervical spinal cord injury, speech with phrenic nerve pacer ventilation may be characterized by low loudness, fading loudness, short breath groups, and long inspiratory pauses.[45] Phrenic nerve pacers can be adjusted, within limits, to alter tidal volume, breathing frequency, and inspiratory time.[46] Such adjustments can increase speech loudness and duration and decrease the length of inspiratory pauses.

Tidal volume can be increased by applying an abdominal binder.[47,48] An abdominal binder or truss can improve speech in patients with chest wall paralysis who use phrenic nerve pacers[49] as well as in those who can breathe on their own.[50,51] Speech improvements include louder speech, longer breath groups, and better voice quality. Glossopharyngeal breathing is also a good strategy for increasing tidal volume in patients who use phrenic nerve pacers.

WHICH PATIENTS ARE CANDIDATES FOR SPEECH INTERVENTIONS?

Many of the speech interventions described in this chapter have been tested systematically in patients with neuromotor impairments who were chronically ventilated. Nevertheless, acutely ventilated patients, including those with other medical conditions, are also candidates for these interventions, especially cuff deflation. Cuff deflation and speech training are performed routinely in the postcritical respiratory care stepdown unit and even in the intensive care units at Massachusetts General Hospital.

There are several issues to consider when determining if a patient is a candidate for ventilator adjustments. Most importantly, ventilator adjustments must be deemed medically safe and should not be attempted if the pulmonologist, cardiologist, or other physician judges them to be unsafe for a given patient. The patient should also have motivation to speak, functional cognitive and language skills, and adequate laryngeal and upper airway control to benefit from such adjustments.

Behavioral interventions can be even more broadly applied than ventilator adjustments. There is a vast repertoire of behavioral interventions that include strategies for improving speech intelligibility, use of augmented communication, and many others.

IMPORTANT CAUTIONS

The initial deflation of the tracheostomy tube cuff should be done in a cautious and organized manner. To begin, the patient should be advised to expect flow of air through the mouth (as many are surprised by the sensation). Before deflating the cuff, the patient's oropharynx should be suctioned thoroughly and adequate oxygen saturation should be assured (often by increasing the fractional inspired oxygen concentration). An anesthesia bag supplied by oxygen should be attached to the tracheostomy tube and, at the moment of cuff deflation, a positive-pressure breath should be given to propel secretions that lie between the larynx and cuff into the pharynx for further suctioning. This technique minimizes aspiration of the retained secretions.

Cuff deflation usually causes patients to cough, likely from secretions above the cuff that move distally. If the cough does not subside quickly, it is useful to instill 5 mL of 2% lidocaine into the tracheostomy tube and occlude the opening of the tube briefly. The lidocaine will anesthetize the distal trachea and, when the patient coughs, the lidocaine will be propelled above the cuff as well. Patients who have had endotracheal intubation before tracheostomy are at increased risk for aspiration secondary to laryngeal dysfunction and should be evaluated accordingly before more than brief cuff deflation.

Cuff deflation may cause hypoventilation, hypoxemia, or dyspnea because some of the ventilator-delivered inspiration exits through the larynx. Thus, it is important to increase the tidal volume during cuff deflation. In addition, it may be

beneficial to deflate the cuff only partially, rather than completely. The added resistance through the laryngeal pathway results in more of the ventilator-delivered tidal volume reaching the lungs.

Although dynamic hyperinflation and intrinsic PEEP are observed rarely when inspiratory time is lengthened, it is nevertheless a risk in patients with obstructive lung disease. Positive end-expiratory intrathoracic pressure can lead to decreased cardiac output and hypotension. Cardiovascular reflexes usually compensate, but may be impaired in patients with autonomic dysfunction. These include patients with diabetes or with neurologically complete cervical spinal cord injury (particularly during the phase of spinal shock).

Ventilator adjustments to improve speech should only be made with the approval and oversight of a pulmonary or critical care physician. While adjustments are being made, cardiopulmonary variables should be monitored (e.g., O_2 saturation, heart rate, and blood pressure), and the patient should be systematically asked about comfort (see Chapter 55).

ALTERNATIVES TO VENTILATOR-SUPPORTED SPEECH

Sometimes it is impossible for a patient to speak. When this results from severe laryngeal and/or upper airway impairment, it is usually necessary to provide the patient with augmentative and alternative communication (see Chapter 40). Some patients, however, with good laryngeal and upper airway function can benefit from a talking tracheostomy tube,[8,52,53] which provides a separate air source to produce speech while the tracheostomy tube cuff is inflated (Fig. 56-7). Flow is adjusted to determine what produces the best voice quality and is comfortable for the patient.[52,54,55] Common problems include discomfort from drying of the mucosa, crimping of the tubing, inability to vocalize, and inability to turn the air source on or off independently.[56]

Another device is called a voice tracheostomy tube.[57] The cuff on this specially constructed tracheostomy tube inflates during inspiration (preventing speech production) and deflates during expiration. Thus, nearly all of the ventilator-delivered inspiration reaches the patient's lungs, whereas some or all of the expired air can be used for speaking. A newer tracheostomy tube operates on similar principles and incorporates additional safety measures.[58] These devices may be useful for patients with poor laryngeal control, but most patients can speak using a conventional tracheostomy tube with a deflated cuff and some form of volume compensation.[59]

ROLES OF HEALTH CARE PROFESSIONALS

Speech management for patients who are ventilator-supported requires a team of health care professionals. Pulmonary and critical care physicians and respiratory therapists operating under them can make substantial improvements in speech. Speech-language pathologists can further optimize speech by evaluating speech, language, and communication, and recommending a management plan to the medical team. If evaluation or management includes ventilator adjustments, it is important for a physician or suitable proxy to be present to assess cardiopulmonary effects of the adjustments as they are made. The physician in charge must decide whether such adjustments should be made permanently or only when essential for communication. Behavioral interventions (such as glossopharyngeal breathing and linguistic strategies) can be offered by the speech-language pathologist.

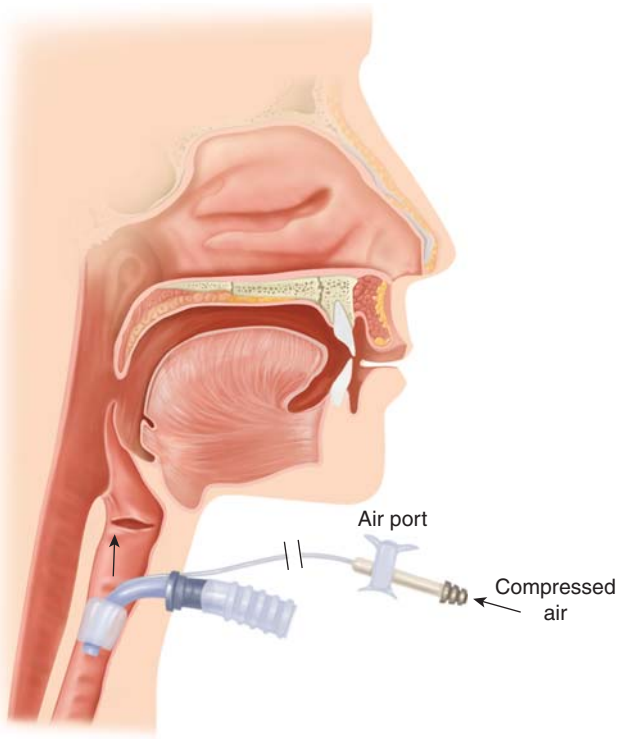

FIGURE 56-7 Talking tracheostomy tube. The air port is occluded to route flow from a compressed air source to the larynx for speaking. (Used, with permission, from Hixon and Hoit.[11])

IMPORTANT UNKNOWNS AND FUTURE RESEARCH

Research on ventilator-supported speech has largely been limited to patients with spinal cord injury and neuromuscular disease. Much needs to be learned about the influence of ventilator adjustments on speech in other patients, especially those with obstructive airways disease. The speech effects of ventilator adjustments with certain forms of ventilator support (such as NIPPV) and various behavioral interventions also have yet to be studied systematically.

SUMMARY AND CONCLUSIONS

For most people, speech is an important requisite to good quality of life. Thus, a patient should be given the opportunity to speak, if medically possible. For the patient who is ventilated invasively, this means deflating the tracheostomy tube cuff. For the patient who is already able to speak, there are often ways to improve speech by modifying the tracheal pressure. Ventilation requirements always have primacy over speech improvements, but these are often complementary, rather than competing, goals. A patient's speech can be optimized through the collaborative efforts of competent and creative physicians, respiratory therapists, and speech-language pathologists.

ACKNOWLEDGMENTS

This chapter is dedicated to the late Susan Kropoff, who used a ventilator for nearly 40 years, and who has taught us more about ventilator-supported speech than anyone else we know. We are grateful to Thomas J. Hixon and Robert W. Lansing for their helpful suggestions on this chapter.

SLEEP IN THE VENTILATOR-SUPPORTED PATIENT

Patrick J. Hanly

It is well recognized that sleep is abnormal in mechanically ventilated patients in the intensive care unit (ICU). Although this has been described for decades, there is still no consensus on the underlying pathogenesis and the best way to manage it. Moreover, the assumption that abnormal sleep is not good for patients who are critically ill is based primarily on extrapolation from models of sleep loss and sleep disruption in other patient populations and not on evidence that abnormal sleep affects the clinical outcomes of patients in the ICU. Nevertheless, there is growing interest in this topic as the technology to measure sleep evolves and new ways are sought to improve patients' ability to recover from their critical illness. This chapter outlines the current understanding of the causes and potential consequences of sleep disruption in ventilator-supported patients and how this may be further researched and treated.

NORMAL SLEEP

Sleep is objectively assessed by means of polysomnography, the simultaneous recording of several electroencephalographic and physiologic parameters.[1] Sleep periods are classified as non–rapid eye movement (NREM) and rapid eye movement (REM) sleep. NREM sleep is further subdivided into four stages, with stages 3 and 4 also referred to as slow-wave sleep (SWS). Each sleep stage is recognized by characteristic changes on the electroencephalogram and, in addition, REM sleep has distinctive, intermittent rapid eye movements. During normal sleep, periods of NREM and REM alternate throughout the night in a recognizable pattern, so that most SWS occurs during the first half of the night and most REM sleep occurs during the second half (Fig. 57-1). The "normal" duration of sleep required and the proportion of time spent in each stage of sleep depends on many factors including age and genotype.[2] In healthy, middle-aged individuals, however, nocturnal sleep lasts 7 to 8 hours, and 5% to 10% of that time is spent in stage 1 NREM sleep, 50% in stage 2 NREM sleep, 15% to 20% in SWS, and 25% in REM sleep.[1] There are also standardized electroencephalographic criteria for identifying arousals and awakenings on the polysomnograph;[3,4] up to 10 arousals per hour of sleep is considered to be within normal limits.[5] The term *sleep architecture* refers to the amount of time spent in each sleep stage and *sleep disruption* is reflected by an increased frequency of arousals and awakenings.

SLEEP IN THE INTENSIVE CARE UNIT

Patient Perception

When questioned after discharge from the ICU, patients consistently report sleep disruption during their stay.[6–11] In one study,[10] 200 patients from four different ICUs received questionnaires that evaluated the quality of their sleep at home and in the ICU and the effect of noise and a variety of activities (such as nursing interventions, phlebotomy, and diagnostic procedures) on their sleep quality. Sleep quality in the ICU was perceived as significantly poorer than sleep quality at home. In addition, sleep quality did not change significantly over the course of the ICU admission, and no differences were reported between ICUs or between ventilated and nonventilated patients. Ventilated patients, however, reported greater daytime sleepiness, perhaps because of the greater administration of sedatives or more severe illness. Patients selected the recording of vital signs and phlebotomy as the most sleep-disrupting environmental factors. Noise was not rated as the primary cause of sleep disruption; of the many forms of environmental noise stimuli, however, communication between staff members and telemetry alarms were perceived as the most disruptive. Although very thorough in design and statistical analysis, the study was limited by potential recall bias, lack of objective sleep assessment by polysomnography, and the absence of a control group.

Polysomnography

Since the mid-1970s, numerous polysomnographic studies in ICU patients have consistently revealed both sleep fragmentation and sleep loss.[6,12–19] Hilton[6] studied nonventilated patients by 24-hour polysomnography and found a decreased total sleep time, an increase in stage 1 NREM sleep, and a concomitant decrease in SWS and REM sleep. Hilton also observed an apparent uncoupling of sleep from the day–night circadian pattern: Only 50% to 60% of sleep occurred at night.[6] These characteristic sleep patterns have also been observed in subsequent 24-hour polysomnography studies.[12,16,20]

Cooper et al investigated sleep in ventilated patients in the ICU and categorized patients into three groups based on polysomnographic findings: disrupted sleep, atypical sleep, and coma.[12] As seen in other ICU cohorts, patients in the disrupted sleep group (Fig. 57-2) showed the abnormal temporal distribution of sleep described earlier as well as reduced amounts of SWS and REM sleep and an increased frequency of arousals and awakenings. Patients in the atypical sleep group had electroencephalogram (EEG) features intermediate between sleep and coma, characterized by a virtual absence of stage 2 NREM sleep and REM sleep (Fig. 57-3). In addition, patients displayed "pathologic wakefulness," where behavioral correlates of wakefulness (such as saccadic eye movements and sustained chin muscle activity) coincided with EEG features of SWS (Fig. 57-4). The coma group was characterized by EEG features of coma according to the classification of Young et al.[21] The authors concluded that sleep could not be identified by polysomnography in all critically ill patients. They proposed the following criteria to select ICU patients in whom sleep can be reliably measured by polysomnography: acute physiology score less than 13, Glasgow Coma Scale score greater than 10, and sedative doses of lorazepam equivalents and morphine equivalents less than 10 mcg/kg per hour. These cutoffs approximated the point estimate of the atypical sleep group. Subsequent data suggest that sleep disruption can be measured by polysomnography in approximately 50% of patients in a general ICU.[22]

Once polysomnography has been performed, what is the most reliable way to score sleep in the ventilator-supported patient? Sleep is conventionally assessed by manual scoring of the EEG according to the criteria of Rechtschaffen and Kales.[4] The reliability, however, of this methodology to score sleep in the critically ill patient has been questioned.[23] Ambrogio et al compared manual scoring of sleep in fourteen ventilator-supported patients in the ICU and seventeen age-matched ambulatory patients in the sleep laboratory and reported that interobserver and intraobserver reliability was weaker for critically ill patients ($k = 0.52 \pm 0.23$) than for those in the sleep laboratory ($k = 0.89 \pm 0.13$; $P = 0.03$). Furthermore, they suggested that computer-based spectral analysis of the EEG with fast Fourier transformation is a better way to monitor sleep in this patient population. It appears that improved

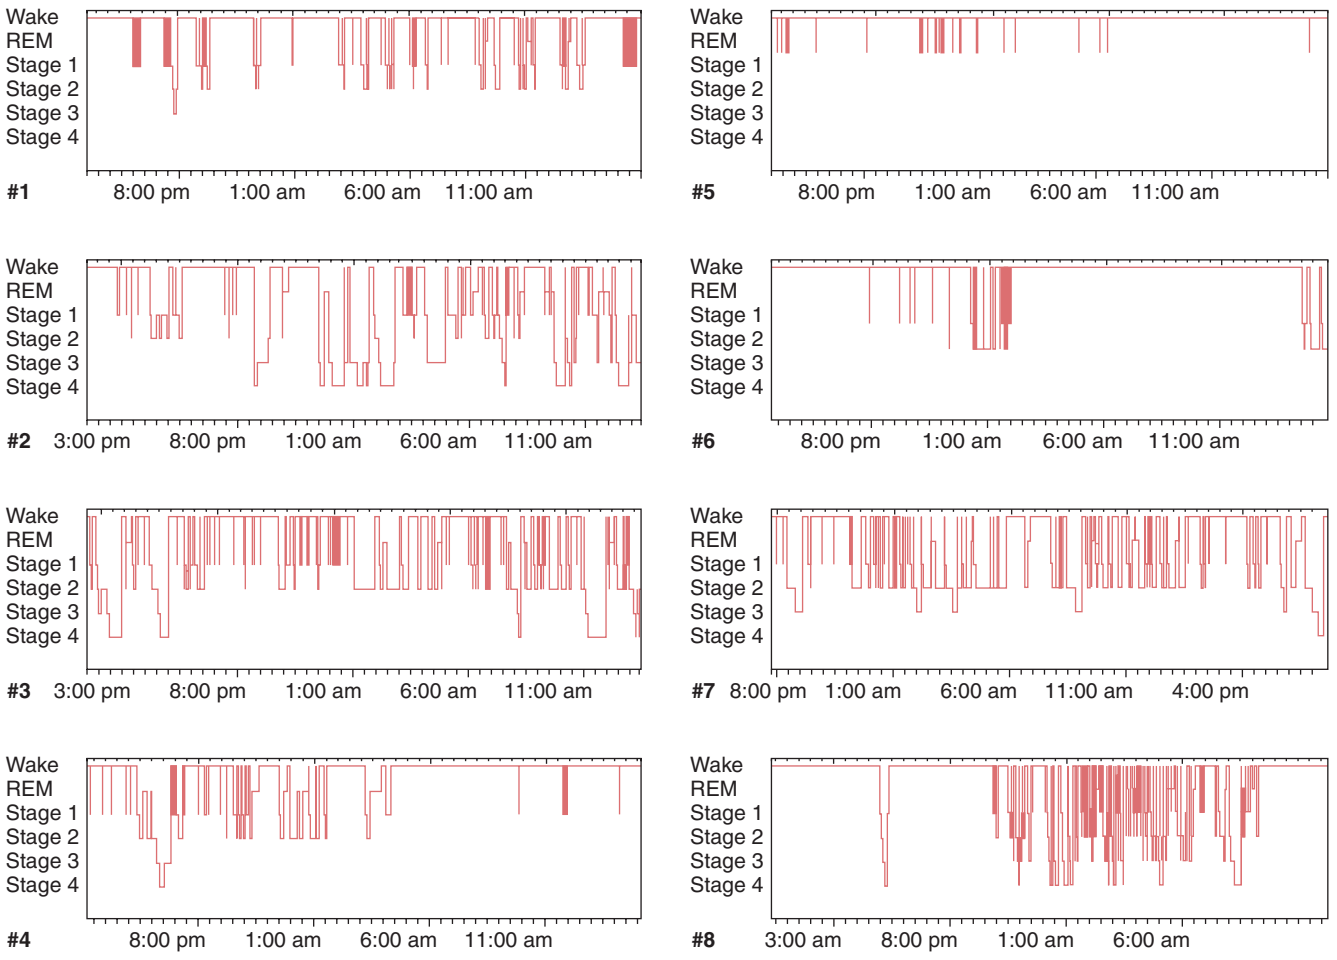

FIGURE 57-2 Disrupted sleep in the ICU (24-hour hypnograms in eight patients). *Vertical axis: REM*, rapid eye movement sleep; *NREM*, non–rapid eye movement sleep stages 1, 2, 3, and 4. *Horizontal axis:* Time in hours. Note (1) sleep was distributed throughout the 24-hour period in all patients except patient 8, in whom sleep was predominantly nocturnal; (2) frequent awakenings; and (3) prolonged wakefulness, especially patients 4, 5, and 6. Sleep in critically ill patients requiring mechanical ventilation. *Chest.* 2000;117:809–818.)

and innovative analysis of the EEG holds the best promise for further progress, particularly because less-invasive methodologies to monitor sleep such as assessment by the bedside nurse and actigraphy, are unreliable (Fig. 57-5).[24–26]

CAUSES OF SLEEP DISRUPTION IN THE INTENSIVE CARE UNIT

Medical Disorders

Patients may enter the ICU with preexisting medical or sleep disorders, such as asthma or sleep apnea, which cause disruption of sleep if inadequately controlled. More importantly, the acute illness that precipitated the ICU admission, such as major surgery, can disrupt sleep. A very consistent finding in surgical patients is the reduction or absence of both SWS and REM sleep in the immediate postoperative period. This is characteristically followed by "REM rebound," an increase in both the number of phasic eye movements and the overall amount of REM sleep.[13,15,18,19] REM rebound may result from the withdrawal of REM-suppressing medications, such as narcotics,[18] analgesics, and benzodiazepines,[27] and/or a decrease in illness-related sleep disruptors such as pain.

Medications

Several medications can alter sleep. A comprehensive review of this topic has been published.[27–29] Table 57-1 summarizes the effects of some medications that are commonly used in the ICU. Although benzodiazepines can increase total sleep time, they are known to reduce both SWS and REM sleep and are associated with rebound insomnia once they are stopped.[30] Opiates also decrease SWS and REM sleep, increase the amount of wakefulness after sleep onset, and are associated with withdrawal hypersomnolence.[27,30,31] Glucocorticoids are often associated with insomnia[29] and many selective serotonin reuptake inhibitors increase alertness and restlessness, in addition to exacerbating sleep

disorders such as restless leg syndrome and periodic limb movement disorder.[32]

Altered Circadian Rhythm

Almost all biologic functions have a circadian rhythm, which synchronizes interactions both among themselves and with the external environment. Alteration of the circadian rhythm that regulates sleep and wakefulness is a recognized cause of insomnia in patients who are not critically ill[33] and may contribute to sleep disruption in the ICU. The circadian clock has been evaluated in critically ill patients by measuring either core body temperature or melatonin levels in the blood or urine. Two retrospective studies, which measured core body temperature, found that circadian rhythm was absent in 20% to 80% of patients.[34,35] Gazendam et al[36] recorded core body temperature in twenty-one patients and reported that a 24-hour rhythm was detectable in all patients. The rhythm, however, was advanced or delayed by several hours compared with control subjects, and the degree of displacement was correlated with the severity of illness, reflected by Acute Physiology and Chronic Health Evaluation (APACHE) III scores. Several studies have measured melatonin levels in ICU patients.[37–41] Melatonin is secreted by the pineal gland and its release is closely synchronized with sleep in healthy individuals;[42] it starts to rise between 9 and 11 PM, peaks between 1 and 3 AM, and

TABLE 57-1: EFFECTS OF MEDICATIONS ON SLEEP

Medication	Clinical Effects	Changes on Polysomnography
CNS medications		
Narcotics	Varies with agent; withdrawal hypersomnolence	Acute: ↑WASO, ↓SWS, ↓REM
Benzodiazepines	Sedation, withdrawal insomnia	↑TST, ↓SL, ↓W, ↓SWS, ↓REM
Tricyclic antidepressants	Improve sleep; may be sedating	Generally ↑TST, ↓W, ↓REM
Selective serotonin reuptake inhibitors	May worsen sleep; few daytime complaints	Generally ↓TST, ↑W, ↓REM
Barbiturates	Sedation, withdrawal insomnia	↑TST, ↓W, ↑ ↓SWS, ↓REM
Phenytoin	Sedation	↓SL
Carbamazepine	Sedation	↓SL and ↑TST
Cardiac medications		
β-antagonists	Insomnia, nightmares	↑W, ↓REM
α_2-agonists (clonidine, methyldopa)	Insomnia, nightmares, sedation	↑TST, ↑↓REM
αβ-antagonists	Insomnia, fatigue, somnolence	No studies
Diltiazem	Insomnia, abnormal dreams, sleepiness	No studies
Amiodarone	Insomnia, nightmares	No studies
Other medications		
Aspirin	—	Acute: ↓SWS
Glucocorticoids	Insomnia	↑W, ↓REM
Theophylline	Insomnia	↑W, ↓TST

Adapted, with permission, from Wooten[27] and Schweitzer.[29]

falls to low baseline values between 7 and 9 AM. The characteristic nocturnal rise in melatonin is absent in critically ill patients, and this has been correlated with the use of mechanical ventilation,[40,41] sepsis,[39] and the postoperative period.[38] Although altered circadian rhythm may contribute to sleep disruption in the ICU, this has yet to be proven. Moreover, the extent of its role is likely to vary among individual patients depending on factors such as the ICU environment, illness severity, the length of stay, and the impact of competing sources of sleep disruption.

Intensive Care Unit Environment

Several studies have examined the role of light, patient-care activities, and noise in causing sleep disruption in the ICU.[43–49] Meyer et al[47] found that circadian light levels were maintained in the ICU, and modern ICUs minimize light intensity at nighttime. Consequently, light does not appear to be a significant source of sleep disruption. Nursing interventions occur at least hourly in the ICU[47] (Fig. 57-6), and have been associated with arousals.[13] The presence of excessive noise in the ICU has been thoroughly documented.[43,46–49] Aaron et al observed a strong correlation between the number of sound peaks of greater than 80 A-weighted decibels and arousals from sleep in a group of ICU patients.[48] Balogh et al reported that alarms were the most irritating noise, and observed that even during the night, the longest "quiet" interval was only 22 minutes.[46]

Another investigative approach has been to simulate the noisy ICU environment in a controlled setting such as

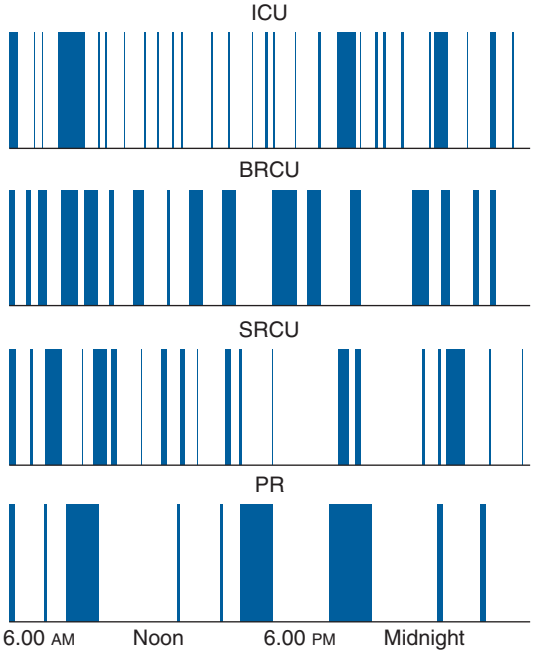

FIGURE 57-6 Patient interruptions by staff over 24 hours in four areas: a three-bed medical ICU, a three-bed respiratory care unit (*BRCU*), a single respiratory care unit room (*SRCU*), and a private room (*PR*) on a general medical floor. The *dark areas* represent interruptions and the *clear areas* represent time available for sleep. (Reproduced, with permission, from the American College of Chest Physicians. Meyer TJ, Eveloff SE, Bauer MS, et al. Adverse environmental conditions in the respiratory and medical ICU settings. *Chest.* 1994;105:1211–1216.)

a sleep laboratory. Exposure of healthy subjects in a sleep laboratory to recorded ICU noise–induced sleep disruption similar to that observed in patients in the ICU.[44,45,49] These studies in the ICU and sleep research laboratory led to the assumption that sleep disruption in the ICU was predominantly caused by noise and patient-care activities. The ICU studies, however, did not include simultaneous monitoring of noise and arousals. Consequently, the association was, at best, indirect. Furthermore, the simulated ICU environment is limited by the fact that it evaluates the impact of noise in isolation without the interaction of other competing sleep disruptors that are found in the ICU. Consequently, the role of the ICU environment, specifically noise and patient-care activities, were reassessed. Freedman et al,[50] using polysomnography and time-synchronized recording of environmental noise, directly linked noise to arousals. They determined that noise was responsible for only 15% of all arousals and awakenings. Although it was the first study to demonstrate that common noise elevations directly cause arousals in ICU patients, other environmental factors such as patient-care activities were not assessed.

Gabor et al subsequently evaluated the contribution of the ICU environment to sleep disruption in both ventilated patients and healthy subjects, and also evaluated the effectiveness of a noise-reduction strategy (moving the subject from the open ICU to a single room).[51] They performed comprehensive, synchronized monitoring of sleep by polysomnography, noise (calibrated sound meter), and all patient-care activities (audiovisual recording) for 24 hours. Although loud noise and frequent patient-care activities were prevalent in the ICU environment, they were responsible for less than 30% of the observed sleep disruption (Fig. 57-7). Healthy individuals slept relatively well in this potentially disruptive environment. Although noise accounted for a significant proportion of sleep disruption in this group, its extent was not pathologic. A quantitative improvement in sleep quality was observed as a result of noise reduction; however, there was no change in sleep architecture. The cause of 68% of arousals and awakenings in these mechanically ventilated patients could not be attributed to noise or any patient-care activity (Table 57-2).

Mechanical Ventilation

In addition to the noise associated with ventilators and their alarms, mechanical ventilation can disrupt sleep by producing periodic breathing with recurrent central apneas, or through the development of patient–ventilator dyssynchrony. Recurrent central apneas occur when the ventilator assist is excessive relative to the patient's ventilatory demand.[52] This is most likely to occur during sleep when demand is lowest and has been observed in critically ill patients.[53]

Dyssynchrony occurs when cycling of the ventilator is not in phase with the patient's efforts. Thus, the ventilator may be delivering gas when the patient wants to exhale, and vice versa. This dyssynchrony is common during conventional mechanical ventilation. Leung et al found that 28% of patients' inspiratory efforts occur during the ventilator's expiratory phase (ineffective efforts).[54] When one considers that ineffective efforts are the most extreme form of dyssynchrony, the incidence of less extreme forms of dyssynchrony (e.g., excessive delay in triggering or in cycling off the

ventilator) may be even more common. In awake individuals, such dyssynchrony is very uncomfortable. Thus, it would seem reasonable to expect dyssynchrony to result in arousals from sleep. Subjectively, 30% of patients in an ICU reported "agony/panic" during mechanical ventilation, which was associated with difficulties to synchronize the patients' breathing with the ventilator.[55]

In one of the first studies that investigated the impact of ventilator mode on sleep in the ICU, Parthasarathy and Tobin[56] reported a higher frequency of arousals and awakenings during pressure-support ventilation versus assist-control ventilation (79 ± 7 vs. 54 ± 7 per hour) in eleven critically ill patients (Fig. 57-8). Six patients, with underlying heart failure, had a high frequency of central apnea (53 ± 8 per hour) during pressure support, which was reduced (to 4 ± 2 per hour) by the addition of dead space (which eliminated the central apneas by increasing ventilatory demand). The decrease in central apneas was accompanied by a fall in the frequency of arousals and awakenings (83 ± 12 to 44 ± 6 per hour). The very high frequency of arousals and awakenings, particularly during pressure support, supports the notion that patient–ventilator dyssynchrony is an important source of sleep disruption in the ICU, and that it can be influenced by the mode of mechanical ventilation.

POTENTIAL CONSEQUENCES OF SLEEP DISRUPTION

Sleep is a biologic requirement for survival, which has been well documented in laboratory animals.[57,58] Prolonged sleep-deprivation experiments (5 to 9 days) in healthy subjects have produced marked cognitive impairment,[59] some objective neurologic signs,[60,61] and collapse requiring hospitalization.[62] In addition, there are five specific areas in which

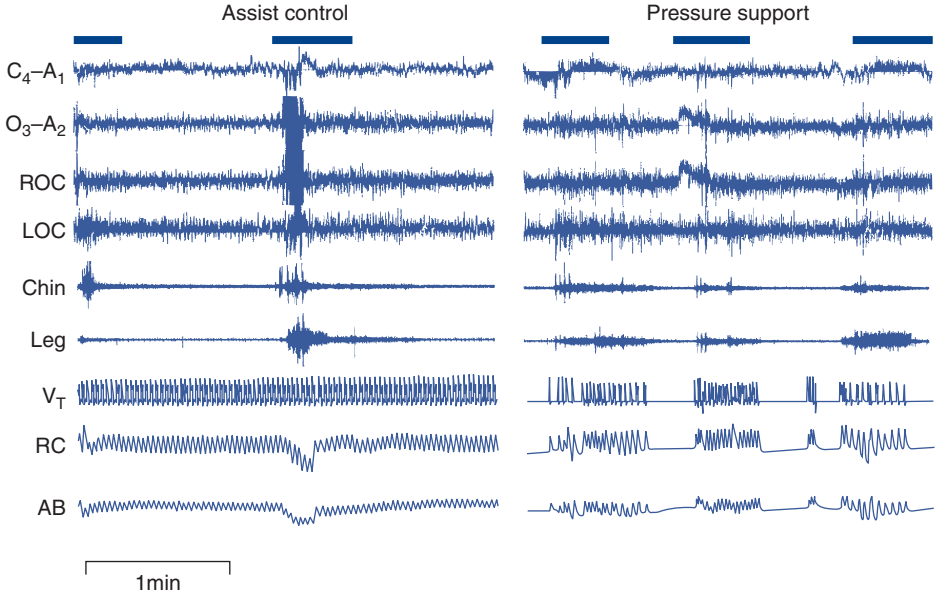

FIGURE 57-8 Sleep disruption during mechanical ventilation. Polysomnographic tracings during assist-control ventilation and pressure-support ventilation in a single patient. Electroencephalogram (*C4 – A1*, *O3 – A2*), electrooculogram (*ROC*, *LOC*), electromyograms (chin and leg), integrated tidal volume (V_T), and rib cage (*RC*) and abdominal (*AB*) excursions on respiratory inductance plethysmography. Arousals and awakenings, indicated by *horizontal bars*, were more numerous during pressure-support than during assist-control ventilation. Official Journal of the American Thoracic Society.)

sleep disruption can adversely affect the clinical outcome of patients in the ICU.

Intensive Care Unit Psychosis

This refers to a state of delirium that characteristically starts after admission to the ICU.[63,64] Delirium is estimated to occur in 19% to 32% of patients in the ICU.[63,65] The pathogenesis is multifactorial, but includes sleep disruption associated with the patient's acute illness.[66,67] In addition, the rebound of REM sleep referred to earlier can be associated with delirium and nightmares. Persistence of this altered mental state impairs the ability of patients to interact with their caregivers, and can increase morbidity and delay weaning from the ventilator and discharge from the ICU.[64,66,68]

Rebound of Rapid Eye Movement Sleep

During REM sleep, heart rate, respiration, and blood pressure are highly variable[1] and can exhibit transient irregularities, making REM sleep, and more specifically REM rebound, potentially dangerous to a recuperating critically ill patient. It has been hypothesized that REM rebound, with associated episodes of hypoxemia, variable blood pressure, and cardiac arrhythmias, may play a role in the etiology of postoperative myocardial ischemia and infarction.[15,18,19] This is supported by the observation that REM rebound peaks at approximately the same time that these delayed complications of anesthesia and surgery occur most frequently.[18] This cardiovascular instability has particular relevance in patients who have significant vascular comorbidities.

Delayed Weaning from Mechanical Ventilation

Studies in healthy volunteers and animal models show that sleep deprivation can cause negative nitrogen balance,[57,69] decreased respiratory muscle endurance,[70] and a blunted genioglossus electromyogram response to carbon dioxide, which becomes more severe with advancing age.[71] Other investigators report decreased ventilatory responsiveness to hypoxemia and hypercapnia[72–74] and increased upper airway compliance[75] following sleep deprivation. The combination of decreased central drive and reduced respiratory muscle endurance can be further aggravated by the fact that sleep deprivation is associated with increased oxygen consumption and carbon dioxide production.[76] Weaning difficulty is related to inability of respiratory muscles to cope with the demands imposed by ventilatory requirements and mechanical load.[77–79] Accordingly, the consequences of sleep disruption (decreased respiratory muscle endurance and increased metabolic rate, and, hence, ventilatory requirements) may delay weaning, particularly in patients who have limited respiratory reserve.

Host Defense

Studies in animals indicate that sleep deprivation leads to failure of host defense.[80] During 3 weeks of sleep deprivation, rats developed a progressive negative energy balance and sympathetic activation.[58,81] This culminated in host-defense failure manifested by bloodstream infection and a cachectic-like moribund state.[80] Sleep deprivation in rats is also associated with early infection of the mesenteric lymph nodes by both aerobic and facultative anaerobic intestinal bacteria with migration to major organs.[82] The translocation of bacteria and endotoxin from the intestinal mucosa and their dissemination to extraintestinal sites is thought to drive a systemic inflammatory state and multiorgan failure in critically ill patients.[83–86] The contribution of sleep disruption to this syndrome in patients has not been determined, although sleep loss in humans is associated with changes in some parameters of host defense.[87–89]

Chronic Insomnia

Chronic insomnia has been reported in a subset of acute respiratory distress syndrome survivors 6 months or more following discharge from hospital.[90] None of these patients had insomnia before their hospitalization, which raises the possibility that it was related to their acute illness. This hypothesis, however, was not supported by a subsequent study of 497 patients who required admission to the ICU and whose sleep quality was assessed by questionnaire before their hospitalization, and again 6 and 12 months after discharge.[91] Compared to a community-based control group, these patients were more likely to have disturbed sleep (odds ratio [OR] 3.62, 95% confidence interval [CI] 2.93 to 4.47). Disturbed sleep, however, was strongly associated with concurrent illness (OR 3.29, 95% CI 2.80 to 3.88) and not with indices of their ICU admission, such as diagnosis, APACHE, and length of stay. Moreover, in previously healthy patients, sleep improved over 6 to 12 months after discharge from hospital, in contrast to patients with concurrent disease whose sleep quality remained the same. These results imply that the sleep disturbance associated with critical illness resolves over time and whatever remains is predominantly caused by concurrent disease.

STRATEGIES TO IMPROVE SLEEP IN THE INTENSIVE CARE UNIT

No studies have systematically evaluated strategies to improve sleep in the ICU. Nevertheless, several options can be considered based on our current understanding of the pathogenesis of sleep disruption in this patient population and on anecdotal experience.

Treatment of the Underlying Illness

All sources of sleep disruption related to a patient's underlying medical condition should be reduced as much as possible. This includes management of the acute illness, such as optimal control of postoperative pain, as well as maintaining preexisting treatment for chronic medical disorders such as chronic cough associated with chronic obstructive pulmonary disease or restless legs syndrome. Detailed management of all such conditions is beyond the scope of this chapter.

Optimization of the Intensive Care Unit Environment

Although this has the greatest intuitive appeal to improve sleep in the ICU, it has not been shown to have a dramatic effect. Studies that minimized disruption from light, noise, and nursing interventions did not decrease sleep disruption.[16] Successful reduction of ICU noise and light levels was not associated with improved sleep quality as assessed by the nursing staff.[92] The use of earplugs subjectively improved sleep in a group of acutely ill patients compared to a control group.[93] When healthy volunteers were exposed to recorded ICU noise in a sleep laboratory,[94] subjects without earplugs displayed an increased number of awakenings and decreased REM sleep, similar to previous studies.[44,45,49] More recently, white noise has been shown to reduce arousals during exposure to recorded ICU noise in the sleep laboratory;[95] however, this has not been studied in the ICU. Overall, modification of the ICU environment yielded modest improvement in sleep quality, which is consistent with the observation that the ICU environment is not the major source of sleep disruption.[51] Nevertheless, it is important that all reasonable measures be taken to avoid an excessively disruptive ICU environment.

Several nonpharmacologic therapies have been used successfully in the management of chronic insomnia.[96,97] These therapies can be applied to patients in the ICU, despite the fact they have not been evaluated in this population. Reestablishment of a regular sleep schedule and avoidance of excessive sleep during the day may be feasible in ventilated patients once they have recovered from their acute illness and are being weaned from the ventilator.

Medication

Patients in the ICU receive multiple medications that should be reviewed for their potential to cause sleep disruption or sleep loss (see Table 57-1). Medication can also be used to consolidate sleep, either a pure hypnotic, such as zopiclone, or medication that treats the underlying cause of sleep disruption such as anxiety, depression, or delirium. Few studies have addressed the impact of such interventions on sleep in critically ill patients. One study randomized ICU patients to nocturnal infusions of either midazolam or propofol.[98] Although sleep was not assessed objectively by polysomnography, daily self-assessment questionnaires showed improved sleep with both agents. An alternative approach by Shilo et al[37] found that patients on the hospital ward had the typical nocturnal peak in melatonin levels, whereas nocturnal secretion was blunted in ICU patients. Administration of melatonin to nonventilated ICU patients improved the duration and continuity of sleep, as assessed indirectly by actigraphy.[99] It is possible that other strategies to resynchronize circadian rhythm, such as bright-light therapy, which has been used successfully in ambulatory patients,[42] may improve sleep in some ICU patients.

Mode of Mechanical Ventilation

The study by Parthasarathy and Tobin[56] quoted earlier supports the notion that some modes of mechanical ventilation are more "sleep-friendly" than others. Although assist-control ventilation is not free of dyssynchrony,[54] and may contribute to sleep disruption, they found that sleep fragmentation was less during assist-control ventilation than with pressure support, predominantly because of a reduction in the frequency of central apnea. Central apnea may occur either secondary to underlying disease, such as heart failure, excessive ventilator assistance, or both.[53]

In a randomized crossover study of twenty patients with chronic lung disease who were ready for extubation, Toublanc et al[100] compared polysomnography during assist-control ventilation and pressure support. Pressure support was set at a low level, 6 cm H_2O, whereas assist-control ventilation was titrated "until complete disappearance of spontaneous inspiratory efforts." Sleep architecture was superior during assist-control ventilation than with pressure support, as reflected by reduced wakefulness and increased NREM sleep. A further study compared assist-control ventilation, clinically adjusted pressure support, and automatically adjusted pressure support in fifteen mechanically ventilated patients and found no differences in sleep fragmentation across the three modes.[101] This may reflect appropriate adjustment of ventilator settings because minute ventilation was similar in all three groups of patients. Indeed, in patients with neuromuscular disease, Fanfulla et al[102] demonstrated that tailoring pressure support to the patient's respiratory effort resulted in improved sleep architecture by reducing the frequency of ineffective efforts.

Proportional-assist ventilation is a mode of ventilation that provides ventilatory support in proportion to the patient's inspiratory effort,[103] thereby optimizing patient–ventilator synchrony. The impact of pressure support and proportional assist ventilation on sleep was compared in thirteen patients as they were being weaned from mechanical ventilation.[104] Ventilator settings for both modes were titrated during a spontaneous breathing trial to reduce inspiratory work by 50%. The frequency of

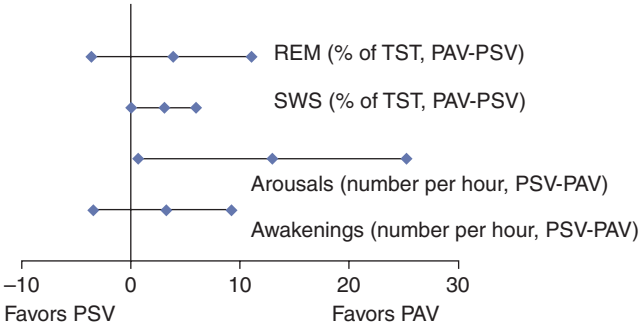

FIGURE 57-9 Multivariate analysis of variance of the effect of modes of ventilation on comprehensive sleep quality. Central diamond indicates the mean absolute difference between proportional-assist ventilation (*PAV*) and pressure-support ventilation (*PSV*); *horizontal bar* indicates the 95% confidence interval. The combined effect of fewer arousals per hour, fewer awakenings per hour, greater rapid eye movement (*REM*) sleep, and greater slow-wave sleep (*SWS*) accounted for the significant ($p < 0.05$) overall improvement in sleep quality with PAV. *TST*, total sleep time. (Used, with permission, from Bosma et al.[104])

patient–ventilator dyssynchrony events was lower with proportional-assist ventilation than with pressure-support ventilation (24 ± 15 vs. 53 ± 59 per hour, $p = 0.02$), which resulted in a lower number of arousals (9, range: 1 to 41 vs. 16, range: 2 to 74) and improved sleep architecture (Fig. 57-9). In summary, the impact of mechanical ventilation on sleep depends upon the underlying disease, the stability of the control of breathing, the mode of mechanical ventilation and the ventilator settings.

IMPORTANT UNKNOWNS

Despite increasing interest and research on sleep disruption in ventilator-supported patients, there is much that we do not know. We do not have a comprehensive understanding of the pathogenesis of sleep disruption in this patient population and the relative contribution of all of the potential sources of sleep disruption discussed above. We also do not know how sleep disruption changes over time in the ICU. Second, we do not know the impact of sleep disruption on outcomes such as weaning, length of stay in the ICU, and hospital morbidity and mortality. Third, it is not clear how much sleep can be improved in ICU patients and what treatment strategies work best.

THE FUTURE

Two issues need to be addressed to facilitate further research on this topic. First, the methodology to monitor sleep in the ventilator-supported patient needs to be addressed. Although attended polysomnography is the reference standard for monitoring sleep, it is labor intensive, costly, cumbersome for staff and patients, and not suited to repeated measurement, especially in the ICU environment. Alternative methodologies that address these limitations and are validated in mechanically ventilated patients are required. Second, larger studies are needed. To date, most studies have consisted of small numbers of patients from a single academic center. Although they have provided new and valuable data, their small sample size limits their applicability to the general ICU population and their ability to measure important clinical outcomes. These concerns could be addressed by multicenter studies that recruit larger numbers of patients.

SUMMARY AND CONCLUSIONS

There is strong evidence that sleep is severely disrupted in mechanically ventilated patients in the ICU, which has the potential to increase their morbidity and mortality through its effect on neurocognitive, cardiorespiratory, and immune function. Although sleep disruption has been attributed predominantly to the ICU environment, noise and patient-care activities account for less than 30% of sleep disruption. Further research is required to provide a comprehensive understanding of the causes of sleep disruption in this patient population, which will form the basis for the evaluation of therapeutic strategies and their impact on both short-term and long-term clinical outcomes.

WEANING FROM MECHANICAL VENTILATION

Martin J. Tobin
Amal Jubran

Thirty years ago, the weaning of patients from the ventilator was relegated to nurses and respiratory therapists. It aroused little interest among physicians. It certainly wasn't thought worthy of serious scientific inquiry. All this has changed. No other area of critical care has undergone so great a transformation. But the illumination has also cast shadows. In particular, discussion of weaning is now bedeviled by imprecise language. This can be seen as just deserts insofar as few clinicians use the term *weaning* in the strict literal sense—a gradual reduction in the level of ventilator support. Instead, most patients today are taken off the ventilator cold turkey. It would be fine if the confused language stopped there. But this is only one small example of how fundamental scientific misunderstanding has arisen from imprecise word choices.

Under the cloak of imprecise language, much muddled thinking, flawed logic, and misinterpretation has crept into the field. These language problems are not just pedantic quirks. Instead, they impede the rigor of research in this area, as well as interpretation of the findings. Communication is also hindered by the lumping together of many distinct components of this complex process. To enhance clarity, we divide weaning into seven stages.

SEVEN STAGES OF WEANING

We divide weaning into seven stages to draw attention to areas that receive minimal attention (Fig. 58-1). Stage 1 is preweaning, when no attempt at weaning is desirable. For example, when a patient is receiving 80% oxygen and positive end-expiratory pressure (PEEP) of 15 cm H_2O, performing any disconnect from the ventilator (for measurement of

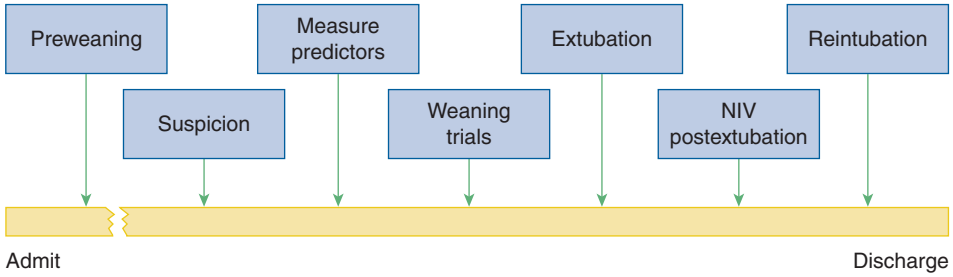

FIGURE 58-1 Seven stages of weaning. Stage 1 is preweaning, a stage that many patients never get beyond. Stage 2 is the period of diagnostic triggering, the time when a physician begins to think that the patient might be ready come off the ventilator. Stage 3 is the time of measuring and interpreting weaning predictors. Stage 4 is the time of decreasing ventilator support (abruptly or gradually). Stage 5 is either extubation (of a weaning-success patient) or reinstitution of mechanical ventilation (in a weaning-failure patient). Stage 6 is use of noninvasive ventilation after extubation. Stage 7 is reintubation. Failure to appreciate stage 2 probably leads to the greatest delays in weaning.

weaning predictors) is inappropriate and may even be dangerous. Every ventilated patient begins at stage 1, and some patients never get beyond that stage. For example, in a prospective study of 249 ventilated patients,[1] sixty-five patients (26%) died during mechanical ventilation without any attempt at weaning. In another report of 357 patients entered into a trial of weaning techniques,[2] 12.9% never reached the stage of any active weaning attempt. We identify this preweaning stage to emphasize the importance of the transition between it and the next stage of a patient's clinical course.

Stage 2 is the period during which the clinician contemplates the possibility that the patient is ready for weaning. This statement may seem obvious to the point of banality. But the point at which this thought first enters the mind of a physician managing a complex patient is not so straightforward. In such a patient, the key act is for a physician to think that the patient just might come off the ventilator successfully. Except for self-extubations, this decision is not made by the patient. The idea has to begin in the doctor's brain. Several large studies have documented that many patients are ventilated for a week or more and the ventilator is then successfully discontinued on the first day that weaning predictor tests are measured.[3,4] A physician has to ask himself or herself whether the patient might have tolerated extubation a day or so earlier. Failure to recognize this second stage may be the greatest obstacle to expeditious weaning.

Psychologists have undertaken extensive research into how probabilistic reasoning is employed in making decisions, investigating how people perceive, process, and evaluate the probabilities of uncertain events.[5–7] Studies have clarified how interactions between the demands of a task and the limitations of a thinker negatively impact cognitive processes. Research on inferences that involve a sequence of steps has revealed that people make wrong decisions because they are more confident in their judgments (such as deciding that a patient is not ready for a T-tube trial) than is validly justified by the data on which the decisions are based.[5]

In his recently published book, *Thinking, Fast and Slow,* the Nobel laureate, Daniel Kahneman, brings together the voluminous research conducted by his group and other investigators on human decision making over the past five decades.[7] Kahneman presents human thinking as involving two independent systems. System One is amazingly fast, intuitive, and effort-free—but prone to error. System Two is the slow process of forming judgments based on conscious thinking and deductive reasoning. To activate System Two requires mental effort and hard work. Consequently, people turn to System One for most decisions. One of the discoveries cited by the Nobel committee was Kahneman's demonstration that overreliance on simple "seat-of-the-pants" decisions (characteristic of System One) can lead to large systematic errors, which have serious and persistent consequences.[6,7] An example of a System One error in ventilator weaning is a clinician's intuition that a patient is not ready for a T-tube trial. Another System One error pertinent to weaning, and highlighted by Kahneman's research, is a clinician's failure to pay close attention to prior probability (Bayesian reasoning)—a failure that leads to major errors in decision making.[6] When taking care of a ventilator-supported patient, physicians should be mindful of these cognitive processes and employ compensatory tactics such as the use of screening tests to spot a patient's readiness for weaning. By alerting an unsuspecting physician to a patient's readiness to tolerate unassisted ventilation—hours or days before he or she would otherwise order a spontaneous breathing trial—weaning-predictor tests circumvent the cognitive errors inherent in clinical decision making.[8]

Stage 3 is the time of obtaining physiologic measurements that serve as predictors, and interpreting the data appropriately in the context of each patient's unique clinical condition. The critical word here is *interpretation*. It is imperative to be clear about why these predictor tests are being performed, the influence of a patient's preexisting condition on the interpretation of the results, what action to take based on the results, and when it is prudent to adjust the thresholds for taking action. These points may seem self-evident, but the literature is replete with evidence of cloudy thinking on each point.

Stage 4 is to decrease ventilator support. Support is either removed abruptly and completely (T-tube trial) or gradually decreased over hours or days. Stage 5 is extubation of a patient who tolerated stage 4 or reinstitution of mechanical

ventilation in a patient who failed the weaning trial. Stage 6 is continued ventilator support after extubation using noninvasive ventilation; this stage applies to only a minority of patients. Stage 7 is reintubation, usually accompanied by the reinstitution of mechanical ventilation.

PATHOPHYSIOLOGY OF WEANING FAILURE

Over the last 20 years, understanding of the mechanisms that cause patients to fail their first attempt to recommence spontaneous breathing has increased considerably. Advances in this aspect of weaning research have been enormously greater than change in clinical management. Greater understanding of pathophysiology has led to new approaches to the timing of the weaning process, prediction of outcome, and techniques used for weaning. Delineation of pathophysiologic principles led to the undertaking of clinical trials. The trials, in contrast, have contributed little to our understanding of the pathophysiology of weaning failure.

Research on pathophysiology has been limited to failure of attempts at spontaneous breathing when a still-intubated patient is first disconnected from the ventilator. Virtually no pathophysiologic research has been conducted in patients who develop acute respiratory failure in the hours immediately after extubation. Likewise, very little research has been conducted in patients who fail repeated weaning attempts, and, as a consequence, may be transferred to centers that specialize in the delivery of mechanical ventilation in the post–intensive care setting.

When intubated patients are disconnected from the ventilator and left to breathe on their own, about a fifth are unable to sustain spontaneous ventilation. If the trial is extended, these weaning failure patients will develop hypercapnia unless severe hypoxemia first intervenes. The pathophysiologic mechanisms that cause weaning failure can be divided into those occurring at the level of control of breathing, mechanics of the lung and chest wall, the respiratory muscles, the cardiovascular system, and gas-exchange properties of the lung.

Control of Breathing

The physiologic processes that fall under the heading of control of breathing primarily include afferent and efferent signals, and the processing of these signals in the brainstem. Clinical research on control of breathing has primarily focused on the overall level of respiratory motor output, termed respiratory drive. In human research, it is not realistic to obtain electrode recordings from the respiratory centers, and it is extremely difficult to measure phrenic nerve traffic. Consequently, a number of indirect methods have been used to assess respiratory drive. Measurement of the ventilatory response to hypercapnia or hypoxia is used in ambulatory patients, but difficult to apply in weaning failure patients. Electromyographic (EMG) recordings from the diaphragm reflect phrenic nerve traffic, but are difficult to standardize among patients.

Most data on respiratory drive in weaning failure patients has been obtained with two techniques: the airway occlusion method ($P_{0.1}$) and mean inspiratory flow (V_T/T_I) of breathing pattern analysis. In a spontaneously breathing patient, it is not possible to measure $P_{0.1}$ on every breath or even at frequent intervals. If $P_{0.1}$ is measured repeatedly, the act of measurement will alter respiratory drive.[9] As such, continuous measurements of respiratory drive over the evolution of weaning failure have been limited to V_T/T_I. V_T/T_I suffers from the limitation that oral airflow is far removed from the brainstem. Any intervening impediment, such as abnormal lung mechanics, can cause a decrease in V_T/T_I. Thus, there is always the possibility that V_T/T_I is providing an underestimate of respiratory drive. An advantage, however, of breathing pattern analysis over other methods of measuring respiratory drive is that it also provides information on respiratory timing.

Tobin et al[10] studied seventeen patients who underwent a T-tube trial of weaning. Seven patients developed severe distress, and arterial carbon dioxide tension (Pa_{CO_2}) rose from 42 to 56 mm Hg, and pH fell from 7.43 to 7.35. Between the beginning and end of the trial, which lasted 40 ± 11 minutes, the patients developed an increase in V_T/T_I: 265 ± 27 to 328 ± 32 mL/s. These findings were surprising. At that time, it was expected that acute hypoventilation—the physiologic terminology for an increase in Pa_{CO_2}—would have been accompanied by a decrease in drive. Yet, not one patient had a value of V_T/T_I below the 95% confidence limits of normal subjects. Although V_T/T_I was not depressed in the weaning failure patients, it was not higher than in the weaning success patients. Subsequent studies, using $P_{0.1}$, revealed that respiratory drive is higher in weaning failure patients than in weaning success patients.[11–15]

The patients also showed marked changes in respiratory timing (Fig. 58-2). Upon resumption of spontaneous breathing, the weaning-failure patients exhibited immediate and marked shortening of inspiratory time (T_I): 0.81 ± 0.11 versus 1.41 ± 0.27 seconds in weaning-success patients. Within the respiratory centers, expiratory time (T_E) is strongly coupled to T_I. Consequently, T_E was also shorter in the weaning-failure patients than in the weaning-success patients: 1.24 ± 0.27 versus 2.48 ± 0.47 seconds. The combined changes in T_I and T_E led to a marked increase in respiratory frequency (f): 32.3 ± 2.3 versus 20.9 ± 2.8 breaths/min. Because the rate of inspiratory flow (V_T/T_I) was equivalent in the two patient groups, the short T_I resulted in a lower tidal volume (V_T) in the weaning-failure patients: 194 ± 23 versus 398 ± 56 mL. The decrease in V_T was balanced by the increase in f, and thus minute ventilation ($\dot{V}_E$) was equivalent in the two groups. A decrease in V_T without an increase in $\dot{V}_E$ must result in higher overall dead space ventilation (V_D/V_T). Indeed, the combined changes in V_T and f accounted for 81% of the increase in Pa_{CO_2} observed in the weaning-failure patients. From the above discussion, it is evident that the

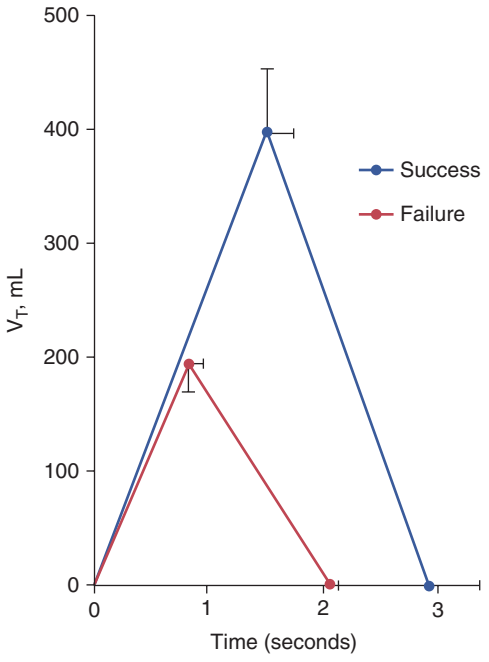

FIGURE 58-2 The mean respiratory cycle during spontaneous breathing in seven weaning-failure and ten weaning-success patients. The early termination of inspiratory time in the weaning-failure patients leads to a decrease in tidal volume (V_T). The decrease in inspiratory time, coupled with a decrease in expiratory time, results in a faster respiratory frequency. Bars represent 1 standard error (SE). (Used, with permission, from Tobin et al.[10])

fundamental abnormality in control of breathing in weaning failure is a shortening of T_I.

Several groups of investigators have shown that the combination of increased f and low V_T is a characteristic abnormality in weaning-failure patients. Vassilakopoulos et al[16] studied thirty patients at two points in time. Measurements were first obtained shortly after the patients failed a T-tube trial. Measurements were repeated approximately 9 days later, shortly before the patients were successfully extubated. The investigators found that an index of rapid shallow breathing, frequency-to-tidal-volume ratio (f/V_T), was lower in weaning failure than in weaning-success patients: 62 ± 21 versus 98 ± 38. They obtained additional detailed measurements of lung mechanics and respiratory muscle function, and found that only two variables, tension–time index and f/V_T, were significant determinants of weaning failure.

Research indicates that most weaning-failure patients develop an increase in respiratory drive as they experience progressive ventilatory failure. Clinical experience, however, suggests that at least some patients have depressed respiratory drive. Jubran and Tobin[15] observed that two of seventeen (11.8%) weaning-failure patients developed Pa_{CO_2} values of greater than 70 mm Hg during a T-tube trial, and yet detailed measurements of their lung mechanics and respiratory muscle function were within the range of the weaning-success patients. These limited data suggest that perhaps 10% of patients who develop hypercapnia during a failed weaning trial may do so primarily because of respiratory center depression.

Respiratory Mechanics

Physiologic variables for quantifying lung mechanics can be grouped under three major headings: resistance, elastance, and gas trapping. The most detailed data on respiratory mechanics in patients being weaned from mechanical ventilation comes from a study by Jubran and Tobin of thirty-one patients with chronic obstructive pulmonary disease (COPD) undergoing a weaning trial.[17] Over the course of a trial of spontaneous breathing lasting 45 ± 8 minutes, seventeen patients developed acute distress and an increase in Pa_{CO_2} (from 45 to 58 mm Hg), requiring the reinstitution of mechanical ventilation. The remaining fourteen patients tolerated the trial and were successfully extubated; these served as a control group.

At the start of the trial, inspiratory lung resistance was equivalent in the weaning-failure and weaning-success patients: 9.0 ± 1.7 versus 5.3 ± 1.1 cm H_2O/L/s (Fig. 58-3).[17]

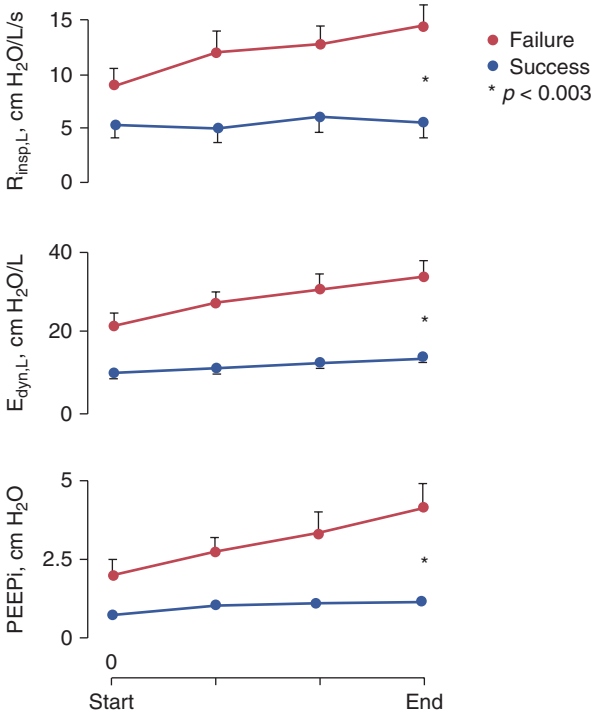

FIGURE 58-3 Inspiratory resistance of the lung ($R_{insp,L}$), dynamic lung elastance ($E_{dyn,L}$), and intrinsic positive end-expiratory pressure (*PEEPi*) in seventeen weaning-failure patients and fourteen weaning-success patients. Data displayed were obtained during the second and last minute of a T-tube trial, and at one-third and two-thirds of the trial duration. Between the onset and end of the trial, the failure group developed increases in $R_{insp,L}$ (p <0.009), $E_{dyn,L}$ (p <0.0001), and PEEPi (p <0.0001) and the success group developed increases in $E_{dyn,L}$ (p <0.006) and PEEPi (p <0.02). Over the course of the trial, the failure group had higher values of $R_{insp,L}$ (p <0.003), $E_{dyn,L}$ (p <0.006), and PEEPi (p <0.009) than the success group. (Used, with permission, from Jubran and Tobin.[17])

By the end of the trial, resistance increased to 14.8 ± 2.0 cm H_2O/L/s in the failure patients, but it did not change in the success patients. Four factors may account for the increase in resistance: (a) an increase in inspiratory flow (unlikely because the increase in flow was no higher in failure patients than in success patients); (b) a decrease in lung volume (unlikely because most patients also develop gas trapping); (c) accumulation of secretions (unlikely because all patients had been suctioned before the trial, and secretions were no different in the two groups); and (d) bronchoconstriction. Bronchoconstriction appears to be the most likely explanation in that patients with COPD have heightened airway reactivity—although it is not clear why this should be greater in weaning-failure than in weaning-success patients.

Dynamic lung elastance was higher in weaning-failure patients than in weaning-success patients at the start of the trial: 21.2 ± 3.4 versus 9.9 ± 1.7 cm H_2O/L (see Fig. 58-3).[17] At the end of the trial, elastance increased to 34.1 ± 4.0 cm H_2O/L in the failure patients and to 14.0 ± 2.0 cm H_2O/L in the success patients. The elevated elastance at the start of the trial was probably secondary to frequency dependence of elastance. Three factors may account for the increase in elastance over the course of the trial: (a) dynamic hyperinflation (this possibility is supported by a twofold increase in intrinsic PEEP [PEEPi] by the end of the trial); (b) development of subclinical pulmonary edema secondary to increased left ventricular afterload; and (c) microatelectasis (a possibility supported by the marked decrease in V_T).

PEEPi, an indirect measure of gas trapping, was higher in the failure patients than in the success patients at the onset of the trial: 2.0 ± 0.5 versus 0.7 ± 0.1 cm H_2O. By the end of the trial, PEEPi increased to 4.1 ± 0.8 cm H_2O in the failure patients and to 1.1 ± 0.2 cm H_2O in the success patients (see Fig. 58-3).[17]

Jubran and Tobin did not partition total PEEPi into the component resulting from expiratory muscle contraction and that resulting from an increase in end-expiratory lung volume. This information was subsequently obtained by the same group of investigators,[18] who partitioned total PEEPi into that resulting from expiratory muscle contraction (abdominal muscles, expiratory rib cage muscles, or both) by calculating the rise in gastric pressure (Pga) between the onset of expiratory flow and the point of rapid decline in esophageal pressure (Pes), and the remaining portion, suggesting an increase in end-expiratory lung volume. After correcting for expiratory-muscle contribution, the remaining portion of total PEEPi increased between the start and end of the weaning trial in seven of the ten patients.[18] These data suggest that many weaning-failure patients develop dynamic hyperinflation. Expiratory flow limitation[19] and tachypnea, through a decrease in time available of exhalation,[10] are the most likely determinants of dynamic hyperinflation. It should be recognized that it has not been possible to obtain direct measurements of end-expiratory lung volume in patients experiencing acute respiratory failure, and the use of esophageal pressure to estimate this entity is based on many assumptions.[20]

Other investigators have also reported a worsening of lung mechanics in weaning-failure patients. An innovative approach was employed by Vassilakopoulos et al.[16] They first studied patients at the end of a T-tube trial. Then they reinstituted ventilation in the assist-control mode, sedated the patients, and hyperventilated them to abolish spontaneous respiratory muscle activity. Next they adjusted the ventilator settings to simulate a patient's pattern of spontaneous breathing, and measured lung mechanics under passive conditions. The investigators studied the patients at two points in time: shortly after they first failed a T-tube trial, and approximately 9 days later, shortly before they were successfully extubated. Between the time of weaning failure and weaning success, airway resistance decreased from 9.6 ± 3.4 to 7.9 ± 3.3 cm H_2O/L/s, static PEEPi decreased from 6.1 ± 2.5 to 3.8 ± 2.7 cm H_2O, and static respiratory compliance did not change. The investigators also disconnected the patients from the ventilator (after first delivering some breaths simulating spontaneous breathing), and allowed them to exhale freely until zero expiratory flow was reached. This point was taken as the elastic equilibrium volume of the respiratory system, and the increase in functional residual capacity secondary to gas trapping (PEEPi) was taken as the difference between inspired and expired volume. This volume was 327 ± 180 mL during weaning failure, and it fell to 213 ± 175 at the time of weaning success.

The observation that weaning-failure patients display more severely deranged lung mechanics than do weaning-success patients raises the question of whether the derangements might be detectable ever before patients reattempt spontaneous breathing (i.e., while patients are still receiving full ventilator support). Jubran and Tobin[21] studied lung and chest wall mechanics of patients before the onset of a weaning trial. Inspiratory resistance was about fourteen times higher than that in healthy subjects but it was equivalent in the failure and success patients: 13.9 and 13.0 cm H_2O/L/s, respectively. Static elastance of the lung and the chest wall were similar in the two groups.[21] Dynamic elastance of the lung was higher in the failure patients than in the success patients, 28 ± 3 versus 17.8 ± 2 cm H_2O/L, and this was the only measurement of passive mechanics that differentiated the two groups. Dynamic PEEPi during passive ventilation was equivalent in the groups. This picture contrasts with the more severely deranged mechanics in failure patients than in success patients during a weaning trial.[17] The difference indicates that something in the act of spontaneous breathing, rather than an intrinsic abnormality in respiratory mechanics, is responsible for the marked difference between failure and success patients during a weaning trial.

Patient Effort

The deterioration in lung mechanics during a failed weaning trial leads to increased work of breathing. The increased respiratory work is made manifest by greater swings in esophageal pressure (Fig. 58-4). In the study of

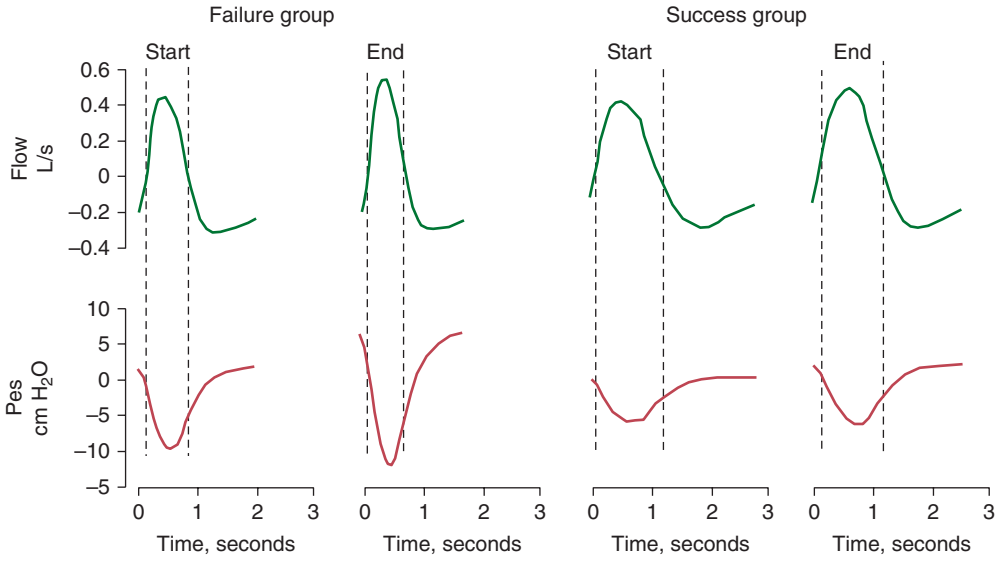

FIGURE 58-4 Ensemble average plots of flow and esophageal pressure (*Pes*) at the start and end of a T-tube trial in seventeen weaning-failure patients and fourteen weaning-success patients. At the start of the trial, the inspiratory excursion in Pes was greater in the failure patients, and it increased further by the end of the trial. To generate these plots, flow and Pes tracings were divided into twenty-five equal time intervals over a single respiratory cycle for each of the 5 breaths for each patient in the two groups. For a given patient, the 5 breaths from the start of the trial were then superimposed and aligned with respect to time, and the average at each time point was calculated. The group mean tracings were then generated by ensemble averaging of the individual mean from each patient. The same procedure was performed for breaths at the end of the trial. (Used, with permission, from Jubran and Tobin.[17])

Jubran and Tobin, pressure-time product was not different in the weaning-failure and weaning-success patients at the onset of a spontaneous breathing trial: 255 ± 59 and 158 ± 23 cm H_2O*s/min (normal: 94 ± 12).[17] At the end of the trial, pressure-time product increased more in the failure patients than in the success patients: 388 ± 68 versus 205 ± 25 cm H_2O*s/min. The increase in effort in the failure patients resulted from worsening of all elements of respiratory mechanics. Partitioning of the increase in pressure-time product at end of the trial revealed that the fraction caused by PEEPi increased by 111%, that caused by the non-PEEPi elastic component increased by 33%, and the fraction caused by the resistive component increased by 42%.[17]

In sixty patients being weaned from mechanical ventilation, Jubran et al[22] characterized the changes in esophageal-pressure swings over the course of a trial of spontaneous breathing (Fig. 58-5). The median time to reach ±10% of the average value of esophageal pressure during the last minute of the trial was 7.5 (interquartile range [IQR]: 4.2 to 14.8) minutes in the weaning-failure patients and 5 (IQR: 2 to 8.5) minutes in the weaning-success patients (Fig. 58-6). In contrast, f/V_T, a measure of rapid shallow breathing, reached ±10% of its final average value at 2 (IQR: 1 to 2) minutes in both the weaning-success and weaning-failure patients. The more gradual and progressive increase in esophageal pressure over time may have resulted from a slow increase in partial pressure of carbon dioxide (P_{CO_2}), as commonly occurs in weaning-failure patients.[10,17] The relative constancy in f/V_T may be related to the increases in both inspiratory resistive and inspiratory elastic loads that occur in weaning-failure patients. These loads have opposing effects on breathing pattern. A resistive load slows respiratory frequency while preserving tidal volume, thereby producing a decrease in f/V_T.[23,24] In contrast, an elastic load increases respiratory frequency accompanied by a decrease in tidal volume, both of which will produce an increase in f/V_T.[25,26]

Respiratory Muscles

Research into the mechanisms whereby abnormalities of the respiratory muscles might contribute to weaning failure has focused on inspiratory muscle strength and respiratory muscle fatigue. Muscle strength has been assessed by measuring the pressure generated during a maximal inspiratory effort against an occluded airway.[27] Early investigators reported that maximal inspiratory pressure ($P_I$max) was lower in weaning-failure patients than in weaning-success patients, but later investigators reported no difference between the two groups.[14,28–31] The pattern of reporting suggests the possibility of test-referral bias, whereby patients with the lowest values of $P_I$max were deliberately excluded from the subsequently conducted studies.[32] Another consideration is the well-recognized difficulty of ensuring reliable measurements of $P_I$max, given its total dependence on patient motivation and cooperation—an even greater challenge in critically ill patients.[27] Studies using phrenic nerve stimulation, and specifically the technique of twitch interpolation, revealed that patients being weaned from mechanical ventilation typically make submaximal efforts when $P_I$max is being measured. Moreover, Laghi et al[29] found that six of nine weaning-failure patients

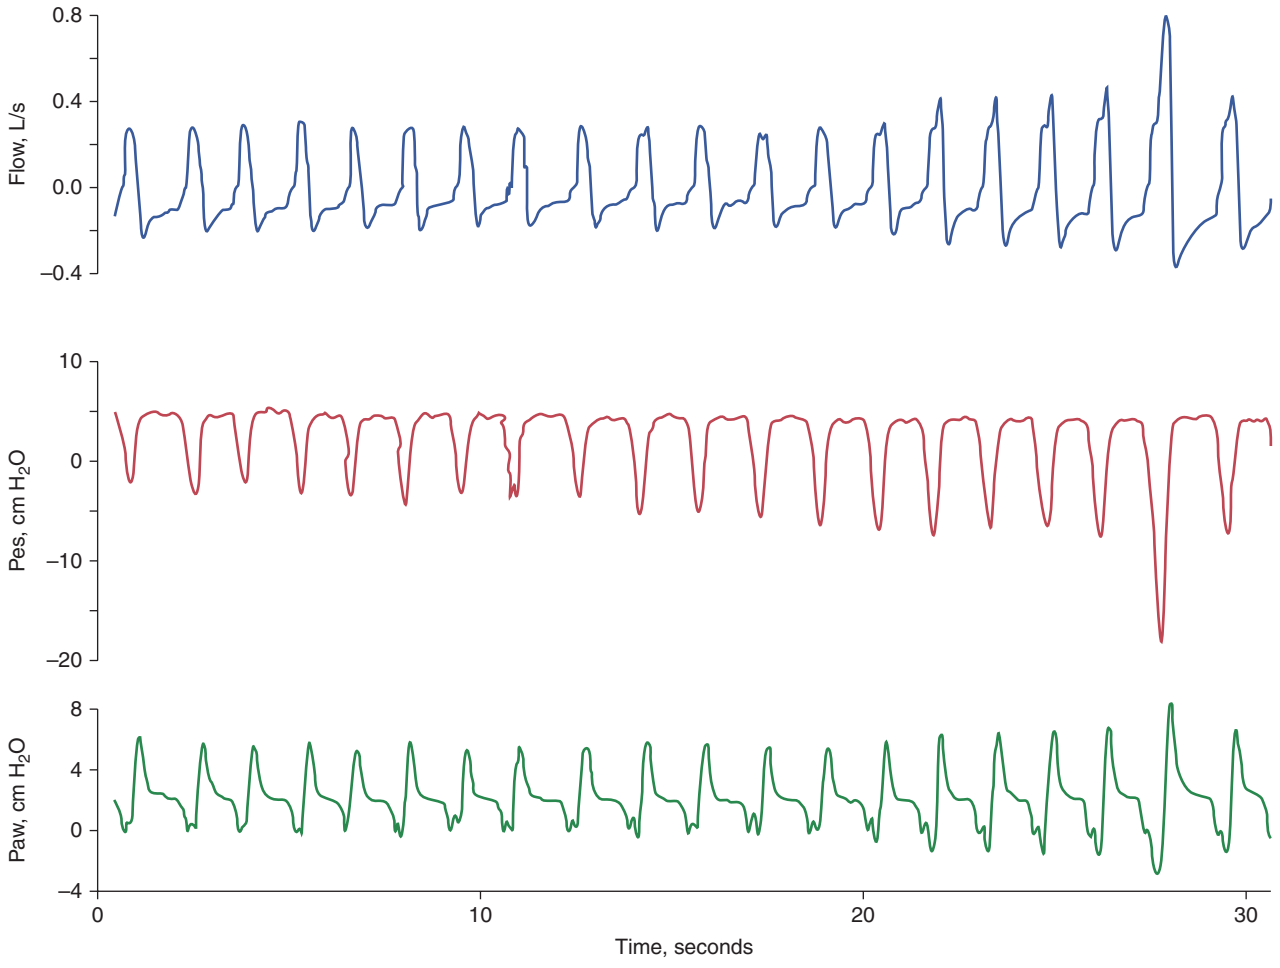

FIGURE 58-5 Progressive increase in inspiratory effort in a weaning-failure patient. Flow (*top panel*), esophageal pressure (Pes, *middle panel*), and airway pressure (Paw, *bottom panel*) in a patient who developed severe respiratory distress while receiving continuous positive airway pressure of 5 cm H_2O. The patient had developed respiratory failure (requiring mechanical ventilation) after developing a pulmonary embolus subsequent to undergoing lobectomy for lung cancer. The swings in esophageal pressure became progressively more negative over the first 30 seconds of the trial.

had twitch transdiaphragmatic pressure (Pdi) values below 10 cm H_2O. Healthy subjects have twitch Pdi values of 35 to 39 cm H_2O, and stable patients with COPD have values of 17 to 20 cm H_2O. Contrary to previous thinking, these data indicate that weaning-failure patients may have considerable muscle weakness.

For years, researchers and clinicians have believed that most if not all weaning-failure patients develop respiratory muscle fatigue by the time a failed weaning trial is stopped. This belief has been largely based on observations made by Cohen et al.[33] These investigators studied twelve patients who exhibited difficulties during weaning. Seven patients developed a shift in the power spectrum of the EMG signal recorded from the diaphragm, a finding judged to signify muscle fatigue. Six of the seven patients also exhibited paradoxical motion of the abdomen (inward displacement of the abdomen during inspiration) and four exhibited respiratory alternans (phasic alternation between the contribution of the rib cage and abdominal compartments to V_T). The changes in rib cage–abdominal motion were not observed in the five patients who did not develop EMG changes. The investigators concluded that respiratory muscle fatigue was a common cause of weaning failure, and that its presence could be detected by finding paradoxical motion of the abdomen.

Subsequent detailed recordings of rib cage–abdominal motion revealed that when paradoxical motion of the abdomen occurs in weaning-failure patients, it occurs immediately upon discontinuation of the ventilator and displays no progression over time.[34] When quantified objectively, the extent of abdominal paradox was no greater in weaning-failure patients than in weaning-success patients. In studies of healthy volunteers, fatigue was found to be neither necessary nor sufficient to induce abnormal rib cage–abdominal motion.[35] These data indicated that rib cage–abdominal motion could not be used for detecting respiratory muscle fatigue. The studies, however, did not exclude the possibility that fatigue is common in weaning-failure patients.

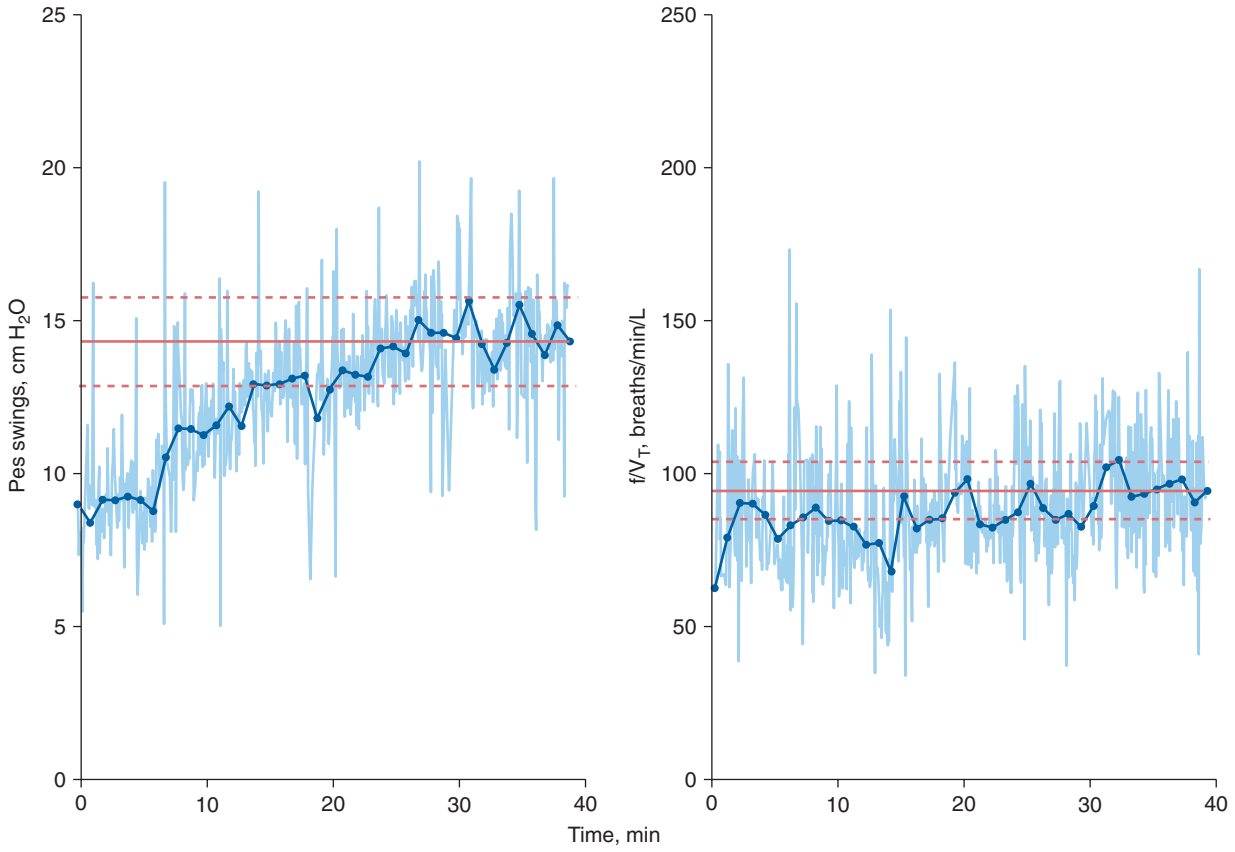

FIGURE 58-6 Time-series plot of swings in esophageal pressure (*Pes*; *left panel*) and frequency-to-tidal-volume ratio (f/V_T; *right panel*) during a trial of spontaneous breathing in a weaning-failure patient. *Dots* represent 1-minute averages. The *solid horizontal line* indicates the average value of Pes swings and f/V_T during the final minute of the trial. The *dashed lines* indicate ±10% of the final minute values for Pes swings and f/V_T. The time taken to reach ±10% of the final value was 14 minutes for Pes swings and 2 minutes for f/V_T. (Used, with permission, from Jubran et al.[22])

Investigators also evaluated a more complex measure of fatigability, tension–time index. Tension–time index is the product of two fractions:

$$(\text{mean pressure per breath}/P_I\text{max}) \times (T_I/T_{TOT})$$

Studies in healthy volunteers show that respiratory muscle fatigue becomes inevitable when subjects breathe against an inspiratory load that causes tension–time index to rise above a threshold of 0.15. In a number of studies,[16,17,36] many more weaning-failure patients than weaning-success patients were found to exhibit tension–time index values above 0.15. As such, weaning-failure patients experience workloads that are sufficient to induce respiratory muscle fatigue.

The EMG power spectrum and tension–time index provide only indirect evidence of fatigue, and do not provide direct proof of its occurrence. In neurophysiologic terms, fatigue means that a muscle is generating less force in response to a given neural stimulus than it had generated in the past. The most direct method for detecting fatigue in patients is to stimulate the phrenic nerves in the neck and measure the resulting change in Pdi. The challenge with use of phrenic nerve stimulation in critically ill patients is to ensure that successive twitches are all generated at the same end-expiratory lung volume, a constant degree of neural depolarization is achieved by the stimulator, and twitch potentiation (the increase in pressure that occurs with a recent forceful contraction) is avoided. Laghi et al[29] measured twitch Pdi using phrenic stimulation in eleven weaning-failure patients and eight weaning-success patients before and after a T-tube trial. Twitch Pdi was 8.9 ± 2.2 cm H_2O before the trial and 9.4 ± 2.4 cm H_2O after the trial in the weaning-failure patients (Fig. 58-7). The respective values in the weaning-success patients were 10.3 ± 1.5 and 11.2 ± 1.8 cm H_2O. No patient in either group exhibited a fall in twitch Pdi. The failure to develop fatigue was surprising because seven of the eight weaning-failure patients had a tension–time index above 0.15.

The most likely reason that patients did not develop fatigue is because physicians reinstituted mechanical ventilation before there was enough time for its development. The relationship between tension–time index and the length of time that a load can be sustained until task failure follows an inverse-power function. Bellemare and Grassino[37] expressed the relationship as: time to task failure = 0.1 (tension–time index).$^{-3.6}$ Figure 58-8 shows the increase in tension–time index over the course of the weaning trial[29] and predicted time to task failure.[37] At the point that the physician reinstituted mechanical ventilation, patients were predicted to

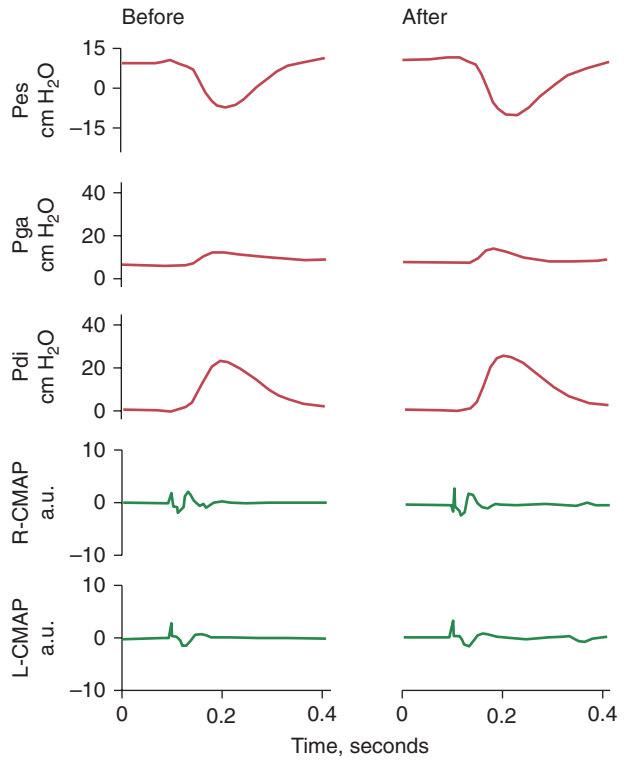

FIGURE 58-7 Esophageal pressure (*Pes*), gastric pressure (*Pga*), transdiaphragmatic pressure (*Pdi*), and compound motor action potentials (*CAMP*) of the right and left hemidiaphragms after phrenic nerve stimulation before (*left*) and after (*right*) a T-tube trial in a weaning-failure patient. The end-expiratory value of Pes and the amplitude of the right and left CAMPs were the same before and after the trial, indicating that the stimulations were delivered at the same lung volume and that the stimulations achieved the same extent of diaphragmatic recruitment. The amplitude of twitch Pdi elicited by phrenic nerve stimulation was the same before and after weaning. (Used, with permission, from Laghi et al.[29])

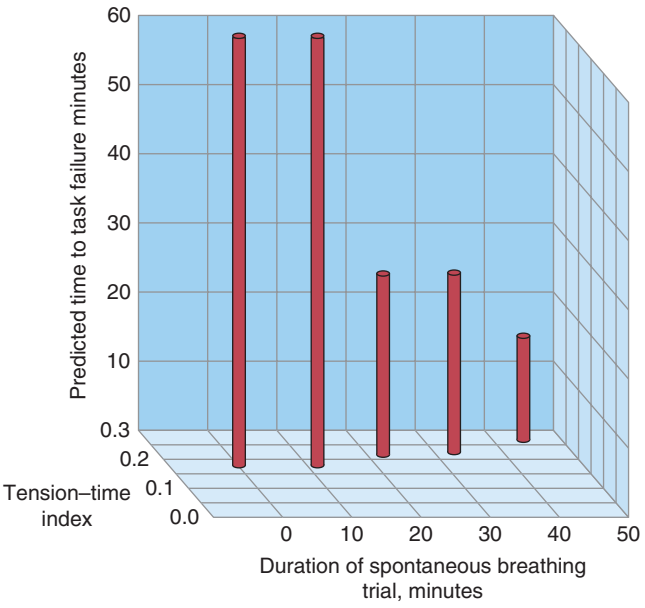

FIGURE 58-8 Interrelationship between the duration of a spontaneous breathing trial, tension–time index of the diaphragm, and predicted time to task failure in nine patients who failed a trial of weaning from mechanical ventilation. The patients breathed spontaneously for an average of 44 minutes before a physician terminated the trial. At the start of the trial, the tension–time index was 0.17, and the formula of Bellemare and Grassino[37] (see text for details) predicted that patients could sustain spontaneous breathing for another 59 minutes before developing task failure. As the trial progressed, the tension–time index increased and the predicted time to development of task failure decreased. At the end of the trial, the tension–time index reached 0.26. That patients were predicted to sustain spontaneous breathing for another 13 minutes before developing task failure clarifies why patients did not develop a decrease in diaphragmatic twitch pressure. In other words, physicians interrupted the trial on the basis of clinical manifestations of respiratory distress, before patients had sufficient time to develop contractile fatigue. (Used, with permission, from Laghi and Tobin.[27])

be able to sustain an additional 13 minutes of spontaneous breathing before developing task failure. In other words, clinical manifestations of severe respiratory distress were evident for a substantial time before the patients were predicted to develop fatigue. In an intensive care setting, these clinical signs will lead attendants to reinstitute mechanical ventilation before fatigue has time to develop.

In a study of nineteen patients being weaned from mechanical ventilation,[18] all but one of the eleven weaning-failure patients exhibited expiratory muscle activity (the exception being a patient with paraplegia). Expiratory muscle activity—as quantified by the expiratory rise in Pga—was absent in all but three of eight weaning-success patients, and its magnitude was trivial in the remainder (Fig. 58-9). At the onset of the trial, the expiratory rise in Pga was equivalent in the failure and success groups, 0.9 ± 0.5 and 0.1 ± 0.1 cm H_2O, respectively. At the end of the trial, the expiratory rise in Pga increased to 4.4 ± 1.1 cm H_2O in the failure group ($p = 0.0005$), whereas it did not change, 0.1 ± 0.1 cm H_2O, in the success group. Compared with the success group, the failure group exhibited larger increases in expiratory rise in Pga ($p = 0.004$). In the failure group, expiratory muscle activity accounted for 53 ± 4% of total PEEPi throughout the weaning trial.

In the study of Parthasarathy et al,[18] sternomastoid EMG activity, measured with fine-wire electrodes, was evident in 83 ± 9% of all the breaths in the weaning-failure group and in 19 ± 10% of all breaths in the weaning-success group ($p = 0.002$) (Fig. 58-10). Sternomastoid activity became evident within the first minute of the trial in eight of the eleven failure patients and in one of the eight success patients. By the end of the trial, sternomastoid activity was noted in all failure patients but in only three of the success patients, and this activity was modest. The immediate increase in sternomastoid activity in the failure patients probably results from increased respiratory motor output in response to a combination of decreased capacity of the respiratory muscles to generate pressure[29] and an increase in mechanical load that occurs early during the weaning trial. In addition to increased sternomastoid activity, weaning-failure patients

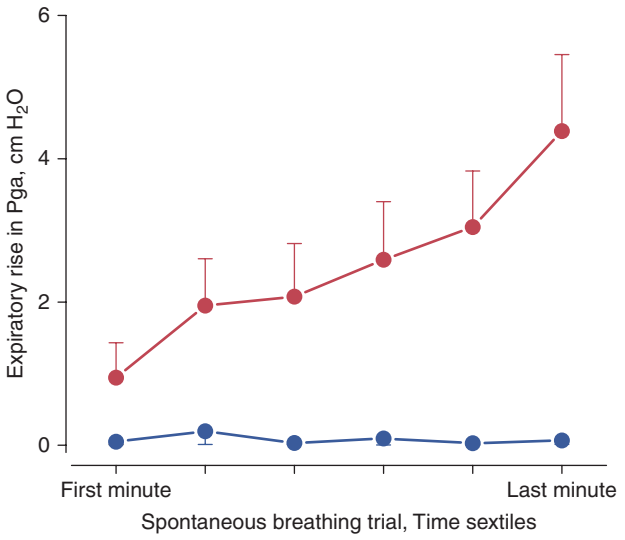

FIGURE 58-9 Expiratory rise in gastric pressure (*Pga*) during the course of a weaning trial in failure (•) and success patients (•). Between the onset and the end of the trial, failure patients developed an increase in the expiratory rise in Pga ($p = 0.0005$) whereas success patients did not. Over the course of the trial, failure patients had higher values of expiratory rise in Pga ($p = 0.004$) than did success patients. Bars represent ± standard error (SE). (Modified, with permission, from Parthasarathy et al.[18])

displayed greater inspiratory rib cage muscle contribution to tidal breathing throughout the trial than did the success patients (Fig. 58-11).

A striking feature of the weaning-failure patients is the timing at which different muscle groups become active.[18] The sequence begins with activity of the diaphragm and with greater activity of inspiratory rib cage muscles than is the case in the success patients; recruitment of sternomastoids and rib cage muscles is near maximum within 4 minutes of trial commencement, whereas the expiratory muscles are not recruited until quite late in the trial (at 17 to 20 minutes).[18] The existence of a hierarchy of respiratory muscle activation is supported by the known delayed activation of the sternomastoid muscles[38] and expiratory muscles in healthy volunteers[39,40] and in ambulatory patients with COPD.[41]

Cardiovascular Performance

Although the respiratory muscles do not develop fatigue, they perform a huge workload. Thus, they depend on an efficient transport of oxygen by the cardiovascular system. Aware of this fact, several researchers have examined cardiovascular performance during weaning. Lemaire et al[42]

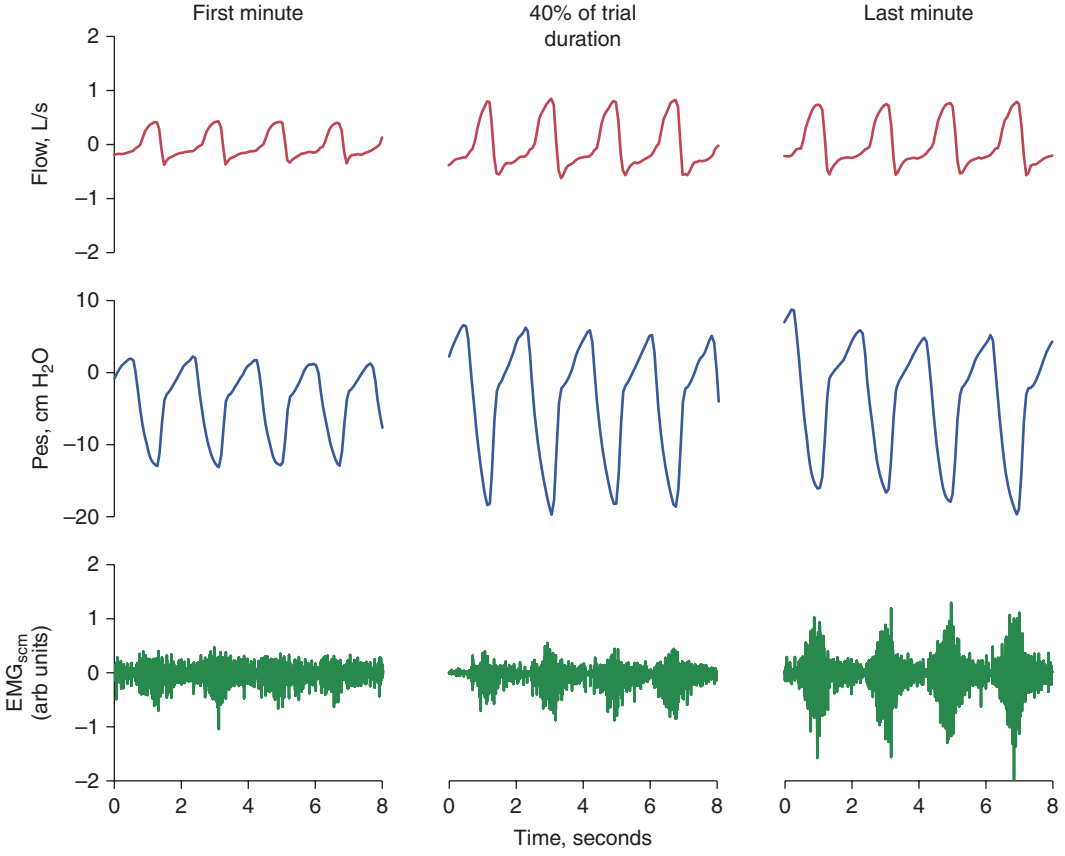

FIGURE 58-10 Representative tracings of flow, esophageal pressure (Pes), and electromyogram of the sternomastoids (EMG_{scm}) in a weaning-failure patient. Recordings were obtained during the first minute of the weaning trial, 40% of trial duration, and last minute of the trial. Phasic inspiratory activity of the sternomastoid muscle was evident within the first minute of the trial, and it increased progressively over the course of the trial. Note that phasic activity of the sternomastoids persists into expiration. (Used, with permission, from Parthasarathy et al.[18])

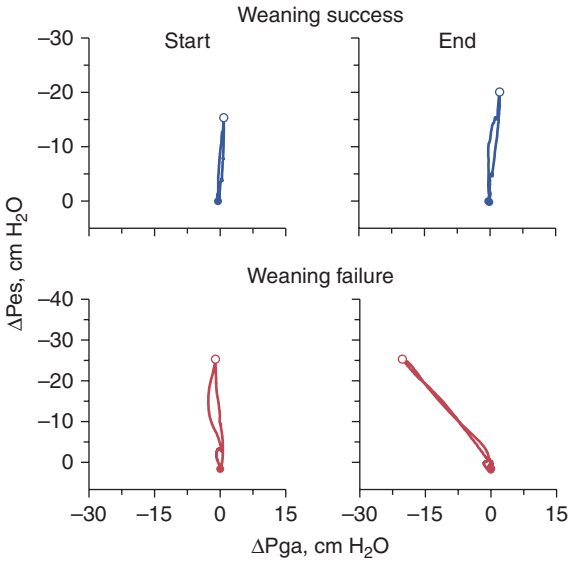

FIGURE 58-11 Plots of tidal changes in esophageal pressure (*ΔPes*) against tidal changes in gastric pressure (*ΔPga*) in a weaning-success patient and a weaning-failure patient. At the start of a weaning trial, the success patient (*top left panel*) exhibited swings in esophageal pressure that became markedly more negative between the onset (*closed symbol*) and the end of inspiration (*open symbol*); in contrast, gastric pressure increased only slightly. Therefore, the slope of the Pes–Pga plot at the onset of weaning (*top left panel*) was much greater than the slope recorded in healthy subjects during resting breathing, where the tidal change in gastric pressure is often greater than the tidal change in esophageal pressure. The steep Pes–Pga plot (*top left panel*) indicates a greater-than-usual contribution of the rib cage muscles to tidal breathing than that of the diaphragm. Between the onset (*top left panel*) and the end of weaning (*top right panel*), the slope of the Pes–Pga plot changed very little, indicating a constant contribution of the diaphragm and rib cage muscles to tidal breathing over the course of the weaning trial. In the case of the weaning-failure patient, the inspiratory swings in esophageal pressure and gastric pressure had a similar pattern at the start of the trial to that in the success patient (*bottom left panel*). At the end of the trial, the failure patient exhibited a markedly negative slope in the Pes–Pga plot, signifying a further increase in inspiratory rib cage muscle recruitment that was out of proportion to diaphragmatic recruitment.

studied fifteen patients with COPD, seven of whom had documented ischemic heart disease. After 10 minutes of breathing (through the ventilator without PEEP), the patients developed increases in transmural pulmonary artery occlusion pressure (PAOP) (8 to 25 mm Hg), cardiac index (3.2 to 4.3 L/min/m^2), left ventricular end-diastolic volume index (65 to 83 mL/m^2), and right ventricular end-diastolic volume index (83 to 103 mL/m^2). The investigators attributed the increase in left ventricular end-diastolic volume to augmentation of venous return (secondary to low pleural pressure during spontaneous breathing and central translocation of blood volume secondary to peripheral vasoconstriction) and increased left ventricular afterload (secondary to markedly negative pleural pressure swings and increased catecholamine release). Nine of the fifteen patients were weaned after 10 days of diuretic therapy, at which time PAOP had fallen to 9 mm Hg.

Although a particular PAOP has not been rigorously linked with the inevitable onset of cardiogenic pulmonary edema, an increase in PAOP above 18 mm Hg during a weaning trial is widely considered to indicate the onset of weaning-induced pulmonary edema.[43,44] Several research groups have reported increases in PAOP in patients as they failed a weaning trial, although these researchers did not detect a concomitant decrease in cardiac output.[42,45–47] As such, the cardiorespiratory stress posed by the resumption of spontaneous breathing after a period of mechanical ventilation resembles the challenges posed by whole-body exercise, which also results in increases in cardiac output and work of breathing.[48] Increases in adrenergic tone that accompany increased cardiorespiratory stress can produce increases in venous return, left-ventricular afterload, cardiac work, and myocardial oxygen demand—all of which may precipitate myocardial ischemia in predisposed patients.[42,43]

Richard et al[49] studied a group of twelve patients with COPD who did not have documented coronary artery disease. All of the patients tolerated at least two 30-minute T-tube trials. (This finding suggests that they were weaning-success patients, although it is not stated that they tolerated extubation.) Ejection fraction, measured by technetium^{99m} radionuclide angiography, was 54.5 ± 12.4% during mechanical ventilation. Spontaneous breathing resulted in a fall in ejection fraction to 47 ± 13%. The fall was homogenous and not accompanied by regional wall abnormalities that occur with myocardial ischemia. Moreover, thallium imaging performed 15 minutes after the weaning trial revealed normal myocardial perfusion. The investigators attributed the decrease in ejection fraction to increased left ventricular afterload.

The increases in oxygen consumption during a weaning trial means that patients who are unable to achieve sufficient increases in cardiac output are at risk of experiencing a decrease in oxygen transport. To investigate these considerations, Jubran et al[39] continuously recorded mixed venous oxygen saturation ($S\bar{v}_{O_2}$) in eight weaning-failure and eleven weaning-success patients over the course of T-tube trials that lasted about 40 minutes. Immediately before the trial, $S\bar{v}_{O_2}$ was equivalent in the two groups. On discontinuation of the ventilator, $S\bar{v}_{O_2}$ fell progressively in the failure patients (to 51.5 ± 7.9% at the end of the trial), whereas it did not change in the success patients (Fig. 58-12). Oxygen demand ($\dot{V}_{O_2}$) was similar in the two groups during the weaning trial, although it differed in the manner with which it was met.

The success patients demonstrated an increase in cardiac index between mechanical ventilation and the end of the trial, 3.07 to 3.51 L/m/m^2, which was accompanied by an increase in oxygen transport (Fig. 58-13). The failure group did not experience an increase in oxygen transport (partly because of elevations in right and left ventricular afterload); instead, they experienced an increase in oxygen extraction ratio, which, in turn, contributed to the fall in $S\bar{v}_{O_2}$. The failure patients also had more impaired pulmonary gas exchange ($\dot{Q}_{VA}/\dot{Q}_T$ was 0.32 at the start of the trial). The combination of greater venous admixture and low $S\bar{v}_{O_2}$

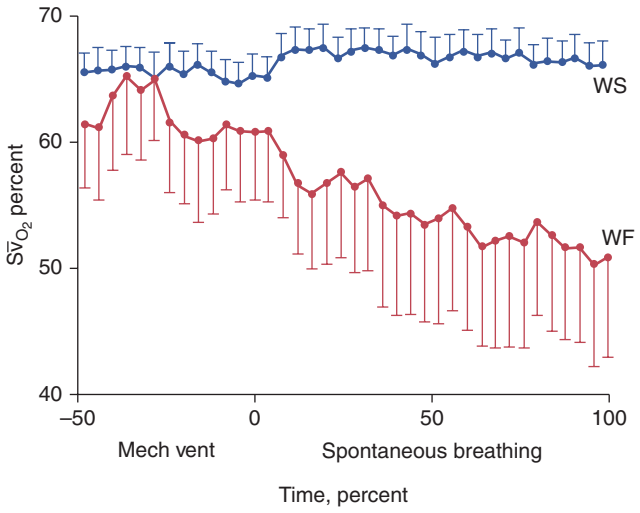

FIGURE 58-12 Ensemble averages of the interpolated values of mixed venous oxygen saturation ($S\bar{v}_{O_2}$) during mechanical ventilation (Mech Vent) and a trial of spontaneous breathing in weaning-success patients (*blue symbols*) and weaning-failure patients (*red symbols*). During mechanical ventilation, $S\bar{v}_{O_2}$ was similar in the two groups ($p = 0.28$). Between the onset and the end of the trial, $S\bar{v}_{O_2}$ decreased in the failure patients ($p < 0.01$), whereas it did not change in the success patients ($p = 0.48$). Over the course of the trial, $S\bar{v}_{O_2}$ was lower in the failure patients than in the success patients ($p < 0.02$). (Bars represent standard error [SE].) (Used, with permission, from Jubran et al.[45])

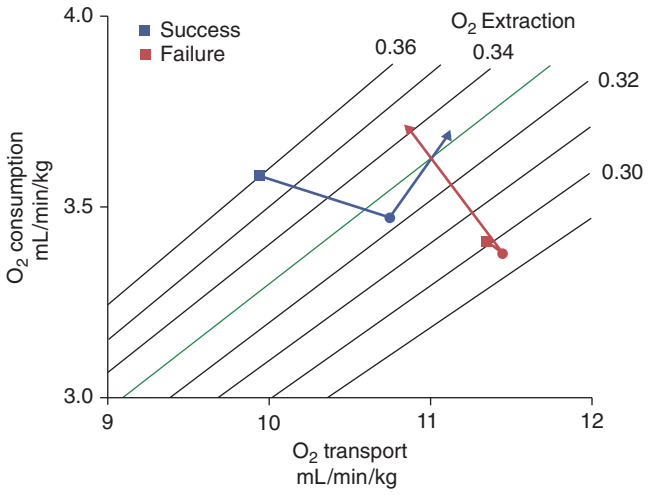

FIGURE 58-13 Oxygen transport, oxygen consumption, and isopleths of oxygen extraction ratio in weaning-success (*blue symbols*) and weaning-failure patients (*red symbols*) during mechanical ventilation (*squares*) and at the onset (*circles*) and end (*triangles*) of a T-tube trial. (Used, with permission, from Jubran et al.[45])

led to rapid arterial desaturation and a relative decrease in oxygen being supplied to the tissues.

Mean pulmonary artery pressure was higher in the failure patients than in the success patients during mechanical ventilation (Fig. 58-14). The pressure increased further over the course of the trial in the failure patients, whereas the success patients showed no change. Several factors account for the increase in pulmonary artery pressure. Hypoxemia and acidosis are potent vasoconstrictors. Pulmonary artery pressure can also be increased by alveolar vessel compression secondary to the increase in alveolar pressure that accompanies the dynamic hyperinflation and deterioration in pulmonary mechanics in weaning failure. During mechanical ventilation, the two groups had an equivalent mean arterial pressure, which increased in the failure patients by the end of the trial. The increase in mean arterial pressure combined with no change in cardiac index indicates an increase in left ventricular afterload.

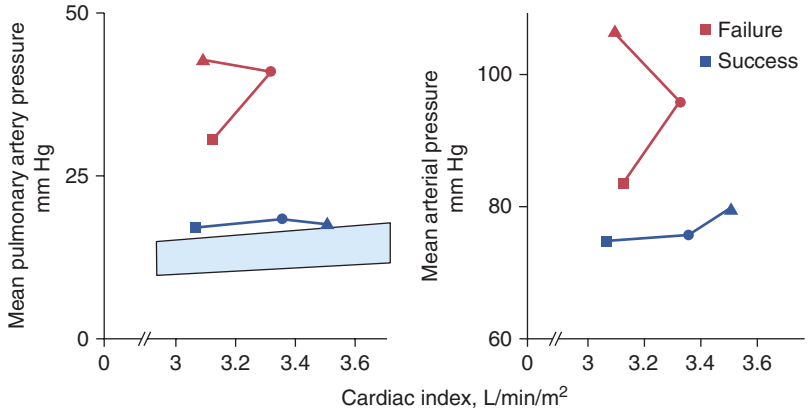

FIGURE 58-14 Mean pulmonary artery pressure and mean arterial pressure versus cardiac index during mechanical ventilation (*squares*) and at the onset (*circles*) and end (*triangles*) of a T-tube trial in weaning success (*blue symbols*) and weaning-failure patients (*red symbols*). The *blue shaded area* represents the normal range of increase in mean pulmonary artery pressure with cardiac index. In the success patients, cardiac index increased between mechanical ventilation and the end of the trial, mean pulmonary artery pressure remained slightly above the normal range, and mean arterial pressure did not change. Conversely, in the failure patients, cardiac index was similar during mechanical ventilation and at the end of the T-tube trial, but both mean pulmonary artery pressure and mean arterial pressure were higher by the end of the trial ($p < 0.025$ and $p < 0.05$, respectively). The increases in these vascular pressures, together with the lack of change in cardiac index, indicate increases in right and left ventricular afterload in the failure patients. (Used, with permission, from Jubran et al.[45])

In an investigation of similar design, Zakynthinos et al[31] studied twelve weaning-success and eighteen weaning-failure patients during a spontaneous breathing trial. Half of the failure patients increased their oxygen consumption and this increase was met mainly by an increase in oxygen extraction. The remaining half of the failure patients did not exhibit an increase in oxygen consumption; instead, increase in oxygen delivery was accompanied by a decrease in oxygen extraction. These studies[31,42,45] demonstrate variability in circulatory and global tissue oxygenation responses during weaning failure.

Gas Exchange

A primary goal of mechanical ventilation is to improve gas exchange, and accordingly one expects some deterioration in gas exchange with the resumption of spontaneous breathing. The most detailed study of gas exchange during weaning is that conducted by Beydon et al.[50] They studied eight patients with COPD who were considered ventilator dependent (although the patients were able to sustain at least 1- to 3-hour periods of spontaneous breathing). When switched from controlled ventilation, patients developed an increase in frequency, fall in V_T (without change in $\dot{V}_E$), and an increase in P_{CO_2} (41 to 49 mm Hg). Using the multiple inert gas technique, the investigators found that the distribution of ventilation to regions of ventilation–perfusion ($\dot{V}_A/\dot{Q}$) relationships above 100 (i.e., V_D/V_T) increased from 39 ± 8% during controlled ventilation to 46 ± 7% during spontaneous breathing. Perfusion of low $\dot{V}_A/\dot{Q}$ regions was higher during spontaneous breathing than during controlled ventilation (15 ± 11 vs. 6 ± 8%). The investigators also performed isotope scans, which revealed a decrease in $\dot{V}_A/\dot{Q}$ ratios between the apex and the base of the lungs. This observation indicated that the low $\dot{V}_A/\dot{Q}$ units identified by the inert gas technique were located at the lung bases. The major determinant of the $\dot{V}_A/\dot{Q}$ abnormalities was the size of V_T: It correlated with perfusion in the low $\dot{V}_A/\dot{Q}$ range, the decrease of $\dot{V}_A/\dot{Q}$ ratios in the bases, and widening of the isotopic craniocaudal gradient. The maldistribution of $\dot{V}_A/\dot{Q}$ ratios during spontaneous breathing were improved by controlled ventilation but not by pressure support of 10 cm H_2O.

Torres et al[51] used the multiple inert gas technique to study eight patients with COPD who were apparently successfully weaned. Measurements were first obtained during assist-control ventilation (V_T 700 mL, rate 12 breaths/min, and FI_{O_2} ≤0.40). On discontinuation of the ventilator, the patients developed rapid shallow breathing (relative to ventilator settings) and acute respiratory acidosis (increase in P_{CO_2} from 49 to 59 mm Hg, decrease in pH from 7.42 to 7.36). Spontaneous breathing caused an overall worsening of ventilation–perfusion inequality: The fraction of cardiac output distributed to low $\dot{V}_A/\dot{Q}$ (<0.1) areas increased from 9.4% to 19.6%, and the dispersion of ventilation distribution increased. Despite the deterioration in P_{CO_2} relationships, the expected fall in partial pressure of oxygen (P_{O_2}) was prevented by an increase in cardiac output (4.7 to 6.7 L/min) and increase in mixed venous P_{O_2} (37 to 42 mm Hg). A largely similar pattern of gas exchange was reported by Ferrer et al,[52] who studied seven patients with COPD who were not yet ready to tolerate complete discontinuation of mechanical ventilation.

PREDICTING OUTCOMES

General Principles of Medical Decision Analysis

When talking about weaning indices or weaning predictors, many clinicians overlook the fact that these measurements constitute a form of diagnostic testing. Accordingly, evaluation of the reliability of weaning-predictor tests must comply with the canons developed for evaluating diagnostic tests.[53–55] To understand the literature on medical diagnostic testing, the reader has to cope with a huge number of specialized terms, many of which have meanings that contradict the meaning of the same words in everyday speech. Specificity, for example, measures the fraction of patients who are correctly identified as not having the disease under consideration. In regular everyday speech, specificity means that something that "possesses properties that characterize a species" or that is "clearly defined and definite." These ideas are the opposite of the absence of a property (disease). The terms are also duplicative. Specificity is also known as true-negative rate and as 1 minus false-positive rate. All of the specialized expressions are simply different ways of combining true-positive, true-negative, false-positive, and false-negative results. Life would be easier if research on weaning predictors were solely communicated using these four test characteristics, and terms such as specificity were avoided. The reader, however, cannot adopt this minimalist approach and must instead grapple with the many terms because of their widespread use.

A second problem arises when a reader desires a more fundamental understanding and consults a textbook on medical decision analysis. Diagnostic test results are called "positive" (or abnormal) when they diagnose a "disease" (or undesirable condition), and "negative" when they indicate a normal or desirable condition.[45] When applying these concepts to weaning, the reader must think of "disease" as "weaning success" and a positive or abnormal test result as one that predicts weaning success. This orientation may seem counterintuitive. But too large a body of research already exists to make a fundamental change.

A third problem for the reader of a textbook on decision analysis is that the discussion is usually in generic terms, covering all possible disease states and all forms of diagnostic testing. This generic or abstract approach makes the discussion long-winded. The reader has to relate abstract concepts to the particular clinical situation that the reader is interested in. To ease discussion, we discuss the fundamental principles

of decision analysis in terms of a single diagnostic test. We select a test used for predicting weaning outcome, the f/V_T, because it has been subjected to the most investigation. And we focus on a single outcome: a patient's ability to tolerate a 30-minute T-tube trial without distress that is followed by extubation. This outcome is weaning success. Thus, a positive diagnostic test result is a recording that predicts actual successful weaning outcome without the need for reintubation. The development of distress during a T-tube trial that leads to the reinstitution of mechanical ventilation is weaning failure; extubation followed by reintubation is not a necessary requirement to satisfy the definition of weaning failure. Thus, a negative diagnostic test result is a reading that predicts either the development of distress during a T-tube trial (leading to the reinstitution of mechanical ventilation) or the need for reintubation after extubation. The reader can apply the same framework to other diagnostic tests (such as maximum inspiratory pressure) and to other outcomes (such as the prediction of reintubation in a patient who is extubated after a successful weaning trial).

The data generated by most diagnostic tests, including f/V_T, are reported as continuous variables. It is common, however, to focus on a threshold and view the data in dichotomous terms: An f/V_T value equal to or less than 100 (breaths/min/L) is referred to as a positive result (indicating a high likelihood of weaning success). All tests are inaccurate to varying degrees: No diagnostic test has a one-to-one correspondence with a disease state. The degree of error is assessed by comparing a test's performance against a reference test. For weaning predictors, the reference standard is a patient's ability to tolerate a weaning trial that leads to extubation. This reference standard gives rise to significant difficulties in interpreting research findings (see below). Its lack of concreteness (necessary if a disorder is to fit an ontologic model of disease) contrasts with more rigorous reference standards available for other diagnostic tests (histologic findings for evaluating a cancer marker).

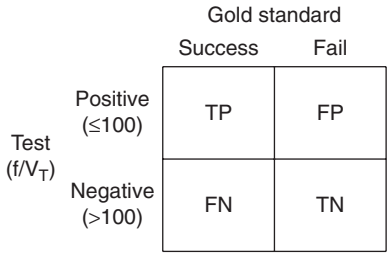
The characteristics of test results are most easily displayed by a fourfold table, often referred to as a "2 × 2" table (Fig. 58-15). For f/V_T, a true-positive result is a reading of equal to or less than 100 (the test predicts weaning success) in a patient who actually tolerates a T-tube trial that leads to extubation (weaning success). A true-negative result is an f/V_T reading greater than 100 (the test predicts weaning failure) in a patient who actually develops distress during a T-tube trial and requires the reinstitution of mechanical ventilation (weaning failure). A false-positive result is an f/V_T reading equal to or less than 100 (the test predicts weaning success) in a patient who actually fails a weaning trial. A false-negative result is an f/V_T reading equal to or less than 100 (the test predicts weaning failure) in a patient who actually tolerates a weaning trial and is extubated.

Each cell in Figure 58-15 represents one of the four unique characteristics of a test (true-positive, true-negative, false-positive, and false-negative results). When developing a new weaning predictor, researchers need to undertake the initial evaluation in roughly equal numbers of weaning-success and weaning-failure patients if the predictor is to prove reliable under future testing.[46] Once the four test characteristics have been determined in a broad spectrum of weaning-success and weaning-failure patients, the test characteristics are considered constant and the test can be applied to the evaluation of any given patient. There is, however, one major assumption, which is all too often ignored. The formulae assume that the prevalence of weaning success and weaning failure in the new groups in which the test is being applied is the same as in the sample from which the four test characteristics were originally developed.[53,56,57] If researchers are mindful of this fundamental requirement, much confusion can be avoided.

Sensitivity (also known by the more intuitive term, true-positive rate) answers the question: "In a weaning-success patient, what is the likelihood that the predictor test will be positive ($f/V_T \leq 100$)?" Thus, sensitivity measures the proportion of weaning-success patients in whom the predictive test is positive ($f/V_T \leq 100$). When clinicians are primarily interested in screening, they employ diagnostic tests that have a high sensitivity.[53] The purpose of a screening test is to pick up as many cases of a disease as possible out of the population being tested; screening can also be viewed as an exercise in ruling out disease, and a test for this purpose should have a low number of false-negative results (thus, a high sensitivity).[58] (Mnemonics have been proposed to remember these relationships. SnNout: If a test has a sufficiently high Sensitivity, a Negative result rules out the target disorder.) In the weaning context, this step is equivalent to using a predictor that will identify as many patients as possible who will actually pass a T-tube trial. Screening tests are typically performed in situations in which the pretest probability of the disease in question is low.[55] Because results are most often negative, the test should be easy to perform. As such, a test that takes 30 minutes or more to conduct, such as a T-tube trial, is not a satisfactory screening test.

Specificity (also known as true-negative rate) answers: "In a weaning-failure patient, what is the likelihood that the predictor test will be negative (f/V_T 100)?" Thus, specificity measures the proportion of weaning-failure patients in whom the predictive test is negative ($f/V_T > 100$). When clinicians are primarily interested in confirming (or ruling in) the presence of a disease, they employ diagnostic tests that have a low number of false-positive results and, thus, a high specificity.[53,58] (A mnemonic to remember this relationship is SpPin: If a test has a sufficiently high Specificity, a Positive result rules in the target disorder.) Because f/V_T has a relatively low specificity (0.64 in the original study,[59] it alone is not sufficient to confirm the presence of weaning failure. Instead, clinicians should undertake additional diagnostic testing, such as with a T-tube trial.

What are the characteristics of an ideal weaning-predictor test? Consider the following three diagnostic tests which differ in sensitivity and specificity. Test A has a sensitivity of 0.96 and specificity of 0.70; test B has a sensitivity of 0.70 and specificity of 0.96; and test C has a sensitivity of 0.83 and specificity of 0.83. Which test is best? The question cannot be answered until you are informed for what purpose



TP = Test predicts weaning success and patient actually succeeds

TN = Test predicts weaning failure and patient actually fails

FP = Test predicts weaning success and patient actually fails

FN = Test predicts weaning failure and patient actually succeeds

$$\text{Sensitivity} = \frac{TP}{TP + FN} = TPR = [1 - FNR]$$

$$\text{Specificity} = \frac{TN}{TN + FP} = TNR = [1 - FPR]$$

$$PPV = \frac{TP}{TP + FP}$$

$$NPV = \frac{TN}{TN + FN}$$

FN rate = 1 – sensitivity

FP rate = 1 – specificity

Likelihood ratio for a positive test = TPR / FPR = sensitivity / (1 – specificity)

Likelihood ratio for a negative test = FNR / TNR = (1 – sensitivity) / specificity

Prevalence = TP + FN / (TP + TN + FP + FN)

Diagnostic accuracy = [TP + TN] / [TP + TN + FP + FN]

FIGURE 58-15 A 2 × 2 tabular display of the characteristics of diagnostic tests. The vertical columns represent the results of the reference standard test. The horizontal rows represent the results of the index test. Readings of f/V_T equal to or less than 100 are classified as positive test results and readings greater than 100 are classified as negative test results. The relationship of these binary results to the outcome of a T-tube weaning trial forms a decision matrix that has four possible combinations.

the diagnostic test will be used. Many clinicians look on diagnostic testing from a monolithic perspective—a test is a test is a test. In reality, diagnostic testing is expected to fulfill two very different demands.[53–55] The first is screening, that is, to pick up cases of a condition at the earliest possible time. This demand requires a test with high sensitivity.[53–55] The second is confirmation of a condition for which there is already a strong suspicion. This demand requires a test with high specificity.[53–55] "A single test can seldom be excellent for the goals of both discovery [screening] and confirmation," Alvan Feinstein emphasized. "With rare exceptions, the same procedure cannot be sensitive enough to find all cases of the disease while simultaneously being specific enough to avoid false-positive identifications."[54] For example, chest radiography is reasonably sensitive (but nonspecific) in detecting lung cancer. Almost all patients with lung cancer will have an abnormal chest radiograph. (A normal chest radiograph is good in ruling out lung cancer.) But not everyone with an abnormal chest radiograph has lung cancer (high false-positive rate). Conversely, a positive histology result on bronchoscopic biopsy is a reasonably specific diagnostic method (false-positive results are uncommon). But it

is insensitive (often failing to capture cancers at inaccessible sites). For these reasons, clinicians commonly use diagnostic tests in combination.

A weaning-predictor test is used to spot the earliest point in time that a patient might tolerate a weaning trial. It serves solely as a screening test. On its own a positive predictor-test result is not used as justification for extubation. Before that step, a confirmatory test, such as with a T-tube trial, is undertaken. The ideal time to undertake a screening test is when the pretest probability of weaning success is 20% or less.[53] In contrast, weaning trials are commonly performed when the pretest probability of success is 75% or more.

The development of a reliable screening test hinges on avoiding false-negative results (a test predicting failure, but the patient actually succeeds).[53,54] Simultaneously the test needs to pick up every possible true-positive result—the mindset is to miss no patient who can breathe without the ventilator. To capture the maximum meaningful number of true-positive results, the threshold for defining a positive screening test may be set deliberately high.[53,54] This necessarily increases the number of false-positive results, producing a proportional decrease in specificity. Sensitivity captures exactly the components that define the reliability of a screening test because it contains only true-positive and false-negative rate. Likewise, specificity captures exactly the constituents of a reliable confirmatory test: avoidance of false-positive results (a test predicting success, but the patient actually fails) and maximizing true-negative rate.[53,54]

Sensitivity and specificity are often regarded as constant properties of a diagnostic test. The characteristics, however, for any diagnostic test are derived from data collected in a selected group of patients. Consequently, sensitivity and specificity of diagnostic tests vary across different parts of the clinical spectrum of the disease they are attempting to identify or exclude.[57,60] Both sensitivity and specificity also perform differently in populations with different distributions of disease severity. For example, the sensitivity and specificity of electrocardiographic stress testing differs between patients with triple-vessel coronary artery disease and patients with mild single-vessel disease.[61]

False-positive rate answers: "What is the likelihood that a weaning-failure patient will have a positive test result ($f/V_T \leq 100$)?" Thus, the false-positive rate measures the proportion of positive test results ($f/V_T \leq 100$) in all weaning-failure patients. In a weaning-failure patient, test results are only true-negatives or false-positives. Thus, false-positive rate is the complement of true-negative rate (false-positive rate = 1 minus true-negative rate).

False-negative rate answers: "What is the likelihood that a weaning-success patient will have a negative test result ($f/V_T > 100$)?" Thus, false-negative rate measures the proportion of negative test results ($f/V_T > 100$) in all weaning-success patients. In a weaning-success patient, test results are only true-positives or false-negatives. Thus, false-negative rate is the complement of true-positive rate (false-negative rate = 1 minus true-positive rate).

Sensitivity and specificity are calculated in patients in whom a diagnosis is already known. Clinicians, however, are faced with positive and negative results in patients whose diagnosis is not yet established. When contemplating a diagnosis, a clinician is not oriented down the vertical columns of the 2 × 2 table, but across the horizontal rows (see Fig. 58-15). Thus, clinicians think more in terms of positive-predictive and negative-predictive values than in terms of sensitivity and specificity.[52] Positive-predictive value answers: "What is the likelihood of weaning success in a patient who has an f/V_T equal to or less than 100?" Thus, positive-predictive value measures the fraction of patients with positive test results ($f/V_T \leq 100$) who are successfully weaned. Negative-predictive value answers: "What is the likelihood of weaning failure in a patient who has an f/V_T greater than 100?" Thus, negative-predictive value measures the fraction of patients with negative test results ($f/V_T > 100$) who fail a weaning trial. The positive- and negative-predictive values of a diagnostic test are particularly susceptible to variation in the prevalence of the condition under consideration (see below).

Likelihood ratio combines sensitivity and specificity into a single number. The likelihood ratio for a positive test relates the likelihood that a weaning-success patient will have a positive test result ($f/V_T \leq 100$) to the likelihood that a weaning-failure patient will have a positive test result. In other words, it is the probability of a positive test result ($f/V_T \leq 100$) in weaning-success patients divided by probability of the same test result in weaning-failure patients. It is calculated as true-positive rate/false-positive rate (or: sensitivity/[1 minus specificity]). The likelihood ratio for a negative test relates the likelihood that a weaning-success patient will have a negative test result ($f/V_T > 100$) to the likelihood that a weaning-failure patient will have a negative test result. In other words, it is the probability of a negative test result ($f/V_T > 100$) in weaning-success patients divided by probability of the same test result in weaning-failure patients. It is calculated as false-negative rate/true-negative rate (or: [1 minus sensitivity]/specificity).

Evidence-Based Medicine Task Force on Weaning

An Evidence-Based Medicine (EBM) Task Force of the American College of Chest Physicians[62,63] evaluated the usefulness of weaning-predictor tests. Employing a meta-analysis, the Task Force calculated pooled likelihood ratios for several predictors. They concluded that all weaning-predictor tests have low power, and recommended that clinicians should start the weaning process with a spontaneous breathing trial (a confirmatory test), and use the initial few minutes of the trial as a screening test.[62] This reverses the logic axiomatic to diagnostic testing. It is analogous to saying that when you suspect diabetes, start with a glucose-tolerance test and then, as the test gets underway, ask the patient for a urine sample in order to do a dipstick.[8]

The Task Force's meta-analysis contained more than fifteen methodologic errors, including several examples of the three main types of systematic error—selection bias (test-referral bias, spectrum bias), misclassification bias (categorizing reintubation as weaning failure), and confounding (considering pressure support to represent a form of unassisted breathing)—as well as several errors of interpretation.[64,65] Any one of the systematic errors would be sufficient to scupper the conclusions of the meta-analysis; yet when these flaws were subsequently identified and reported, the EBM Task Force did not contend a single one of them.[65–68] Instead, the Task Force viewed the errors as side issues that did not detract from their recommendations.[65,67] To ignore test-referral bias in the evaluation of a diagnostic test is analogous to a physiologist who claims that a partial pressure of arterial oxygen (Pa_{O_2}) of 80 mm Hg is always better than a Pa_{O_2} of 60 mm Hg, and the fact that the measurements were made at inspired oxygen concentrations of 50% and 21%, respectively, is an academic distraction best ignored.

Physicians recognize that writing an order for a T-tube trial constitutes a clinical decision. A corollary might be proffered that not writing an order means that no decision has been made. That interpretation would be wrong. Whenever a physician looks at a ventilated patient and does not order a T-tube trial (or weaning-predictor test), the physician is deciding that the patient is not weanable at this time (stage 2 of weaning; see Seven Stages of Weaning above). This subtle distinction is missed by the recommendation of the EBM Task Force to dispense with screening and commence the weaning process with a confirmatory test (a spontaneous breathing trial). They are thus encouraging physicians not to test for weanability until a patient looks ready for a T-tube trial. Their recommendation betrays a failure to comprehend the very purpose of weaning predictors. The sole purpose of a screening test (weaning predictors) is to alert a physician to consider doing a T-tube trial sooner than is the physician's custom—for the trial to occur earlier than would otherwise happen.[8] A positive result on a weaning-predictor test acts as a "physician alert," and aids in the cognitive process known as diagnostic triggering.[69]

The Bayes' Theorem

Before clinicians perform a diagnostic test, they formulate a pretest (or prior) probability of disease. In the context of weaning, clinicians form an initial gestalt of a patient's likelihood of passing a T-tube trial based on their previous experience of patients with similar clinical characteristics. After measuring a weaning predictor test, and knowing its test characteristics (sensitivity and specificity), the clinician formulates a new probability statement (of whether the patient is likely to pass the T-tube trial). The new statement is the posttest (or posterior) probability. The Bayes' theorem is an equation that describes the relationship between pretest probability and posttest probability. It is used to estimate how much the uncertainty of weaning outcome changes from before measurement of a predictor test (the pretest probability) to after obtaining the new information (the conditional probability). In particular, the Bayes' theorem is used to transform the information contained in sensitivity and specificity into a format that can be employed in diagnostic testing (calculation of posttest probability, in the format of positive-predictive and negative-predictive value).[54]

Conditional probability refers to the probability that a particular event will occur given that some other condition has been met.[57] In the weaning context, it addresses, "What is the probability of a positive f/V_T result (<100) conditional upon the patient's passing (or failing) a weaning trial?" A clinician can calculate the posttest probability of weaning success if the clinician has three pieces of information: (a) the pretest probability of weaning success (typically, the prevalence); (b) the probability of a positive f/V_T result (≤100) conditional upon the patient's passing a weaning trial (true-positive rate, or sensitivity); and (c) the probability of a positive f/V_T result (≤100) conditional upon the patient's failing a weaning trial (false-positive rate, or 1 minus specificity). A useful weaning predictor test has a high conditional probability (a high likelihood ratio), and thus markedly alters the posttest probability of weaning success. The Bayes' theorem is employed to convert the vertical indices in the 2×2 table (sensitivity and specificity) into the desired horizontal indices of disease prediction, which indicate posttest probability.[54] The posttest probability of weaning success after obtaining a positive test result (f/V_T ≤100) is the positive-predictive value. The posttest probability of weaning failure after obtaining a negative test result (f/V_T >100) is the negative-predictive value.

The Bayes' theorem operates on the assumption that the sensitivity and specificity of a test are constant irrespective of the pretest probability of disease. But "[i]n the few instances in which this assumption has been checked," notes Feinstein,[54] "it was found to be erroneous." In a study of exercise electrocardiography for the diagnosis of coronary artery disease, Hlatky et al[70] found sensitivity was 0.80 in patients with typical angina and 0.53 in patients with atypical chest pain; sensitivity was 0.85 in patients with triple-vessel disease and 0.48 in patients with single-vessel disease. Specificity was 0.85 when left-ventricular ejection fraction was equal to or greater than 50% and 0.73 when ejection fraction was 30% to 49%. In a study of patients being evaluated for urinary tract infection, Lachs et al[60] found that sensitivity of the dipstick test was 0.92 in patients with a high (>0.50) pretest probability of infection (patients with dysuria, urgency, and hematuria), and sensitivity was 0.56 in patients with a low pretest probability (≤0.50). Conversely, specificity was 0.42 in patients with a high pretest probability for infection, and 0.78 in patients with a low pretest probability. Indeed, for any condition, history and physical examination is likely to be more abnormal when a disease is extensive, and thus, the clinician will assign a high pretest probability.[71] In many studies of weaning predictors, researchers have assumed that reported values for sensitivity and specificity apply in all

circumstances. This assumption can give rise to errors when Bayes' theorem is applied.[54,57,72]

Pretest Probability of Successful Outcome

In evaluating the performance of weaning predictors, probably no aspect is ignored more often—and the source of greater confusion—than recognizing the fundamental importance of pretest probability (the anticipated prevalence of a disorder). The pretest probability is the fraction of weaning-success patients out of an entire weaning population (both success and failure patients). This pretest probability markedly affects the interpretation of new test information. In their book on medical decision analysis, Sox et al[55] state, "Perhaps the most important idea in this book is the following: The interpretation of a test result depends on the pretest probability of disease." That is, a clinician's interpretation of new diagnostic information depends on what the clinician believed before doing the test. As a clinician's estimate of pretest probability of weaning success increases, so also does the posttest probability of weaning success.

The pretest probability has an enormous influence over the ability of the results of any diagnostic test to alter the posttest probability of disease. When the pretest probability of weaning success is high, a positive test result ($f/V_T \leq 100$) has little effect. (The probability cannot increase much after a positive test because of a ceiling effect.) A negative test result ($f/V_T > 100$) will drop the probability considerably, but only into the large middle range of probability that is diagnostically inconclusive.[72] Conversely, when the pretest probability of weaning success is low, a negative test result ($f/V_T > 100$) has little effect. (The probability does not have anywhere to drop after a negative test. A positive test result [$f/V_T \leq 100$] has a large effect, but it only brings the clinician into the large middle range of probability.) Thus, when the pretest probability is already close to diagnostic certainty (high or low), a test that does not confirm the diagnostic suspicion can produce substantial changes in posttest probability. The above description is not unique to weaning predictors, but applies to all diagnostic tests in medicine. The only exception to this relationship between pretest probability and postprobability is an imaginary test with 100% sensitivity and 100% specificity.

A clinician gains the maximum increase in posttest probability for a positive test when pretest probability is 40%, and gains the maximum increase for a negative test when the pretest probability is 60%.[53] That is, physicians have most to gain from diagnostic testing when the pretest probability of a condition is close to 50%.[53] For a weaning predictor test to influence decision making, it needs to be measured early in a patient's course (expediting the transition between weaning stage 2 and stage 3). If a clinician observes that half or more of the clinician's measurements of weaning predictors generate positive results (indicating that a patient is ready for a weaning trial), that clinician is not measuring the predictor test early enough in his or her patient's course. A clinician who is measuring predictor tests early in a patient's course will obtain negative test results (indicating that a patient is not ready for a weaning trial) at least as often as positive results. Measuring weaning predictors in patients who have already passed a weaning trial is a futile undertaking. Unfortunately, most studies of weaning predictors have been conducted in patients who had a pretest probability of weaning success of 75% or higher (Table 58-1). Such a high pretest probability markedly decreases the apparent reliability of a weaning-predictor test (Fig. 58-16).

Sequential Diagnostic Testing

The implications of pretest probability are greater for weaning than for many clinical situations because weaning involves a sequence of three diagnostic tests: measurement of predictors, followed by a weaning trial, followed by an extubation trial. The Bayes' theorem assumes that the conditional probability of a test result is independent of pretest (prior) information—the assumption of conditional independence. The idea of independence is one of the most important concepts in probability theory.[73]

Two events are judged independent if the knowledge that one event has occurred tells you nothing about whether the second event will occur. The events "the patient has a skull fracture" and "the patient has cholecystitis" are independent. That is, conditioning on one event does not change

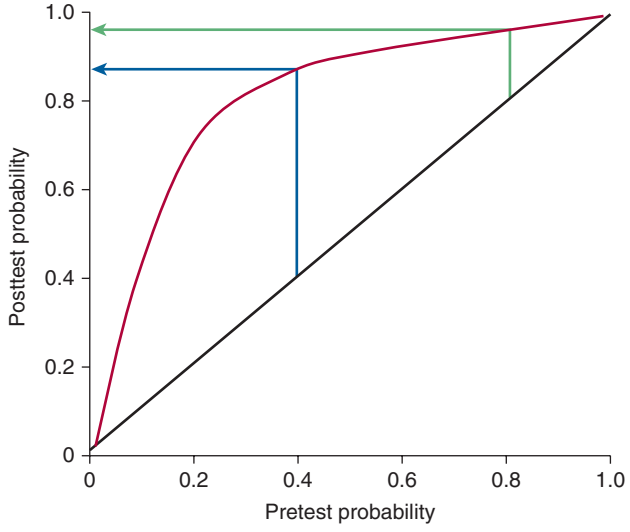


FIGURE 58-16 Relationship between pretest probability and posttest probability for a good weaning-predictor test, sensitivity of 0.9 and specificity of 0.9, is characterized by the red curve. If pretest probability of weaning success is 0.40, the Bayes' theorem dictates that a positive result on the weaning-predictor test will yield a posttest probability of 0.86. If pretest probability is 0.80, posttest probability will be 0.97. The increase between pretest and posttest probability in the second instance (21%, 0.17/0.80) is only a fraction of that in the first instance (115%, 0.46/0.40) despite the sensitivity and specificity being identical. Thus, a high pretest probability markedly decreases the apparent reliability of a weaning-predictor test.

Abbreviations: CCU, cardiac care unit; *EF,* extubation failure; *f/V_T,* frequency-to-tidal-volume ration; *IMV,* intermittent mandatory ventilation; *MICU,* medical intensive care unit (ICU); *M-SICU,* medical-surgical ICU; *Multidisc ICU,* multidisciplinary ICU; *NPV,* negative-predictive value; *NS,* nonstated location; *PICU,* pediatric ICU; *PPV,* positive-predictive value; *PS,* pressure support; *RICU,* respiratory ICU; *SICU,* surgical ICU; *WF,* weaning failure.

The listed studies are those that reported data on the accuracy of f/V_T as a predictor of weaning outcome. Four groups of investigators, Chatila et al, Jacob et al, Krieger et al, and Rivera and Weissman (studies 9, 16, 17, and 18 in the table), report data under two different conditions in their articles; both sets of data are presented. Pretest probability of success in a study is the fraction of patients with a successful outcome out of the total population (both success and failure patients) included in the study.

the probability of the other event. In contrast, the events "the patient has cholecystitis" and "the patient has abdominal pain" are not independent. The conditioning probability of abdominal pain, given cholecystitis, is much higher than the nonconditional probability of abdominal pain (the proportion of all patients in the world with abdominal pain). When both an exercise electrocardiogram and a radionuclide myocardial scan are performed before coronary arteriography, the false-positive rate of each test depends on the results of the other test.[55] That is, the assumption of conditional independence of the two tests is invalid. Likewise, the conditioning probability that a T-tube trial will be successful and lead to extubation is much higher given a positive f/V_T test result (≤100). The two events, a positive f/V_T test result (≤100) and a successful T-tube trial, are not conditionally independent.

Because the assumption of conditional independence has not been verified for most combinations of two or more tests, experts recommend that the posttest probability of the first test be used as the pretest probability of the second test.[55] Figure 58-17 shows typical changes in pretest probability of successful extubation and posttest probability of successful extubation with the sequential performance of f/V_T measurement, a T-tube trial, and a trial of extubation.

Spectrum Bias and Test-Referral Bias

The term *spectrum* denotes the range of disease presentation and severity found in patients used to challenge the sensitivity and specificity of a diagnostic test.[58] Spectrum bias occurs when a diagnostic test performs differently in different groups of patients, as occurs when the new study population contains more sick (or less sick) patients than the population in which the diagnostic test was originally developed.[60] Another form of bias, test-referral bias, occurs when the results of a test under evaluation (f/V_T) are used to select patients for the reference-standard test (T-tube trial).

To illustrate spectrum bias, we discuss the introduction of a hypothetical new weaning-predictor test. To make our account easy to understand, we use f/V_T as the previously unevaluated weaning-predictor test. To determine if the new test is reliable in predicting extubation outcome, the investigators study 100 patients. The average value of f/V_T in these patients is 111. Because the investigators do not know whether f/V_T is reliable or not, all patients proceed to a T-tube trial; and if they pass that, the patients continue to a trial of extubation. The investigators report that an f/V_T value of less than 100 is reliable in predicting a successful outcome. Subsequently, another group of investigators decide to reevaluate the usefulness of the weaning-predictor test. They also study 100 patients, and the average value of f/V_T is again 111. Of the study population, seventy patients have positive f/V_T results (values <100), and thirty have negative f/V_T results (values >100). The seventy patients with positive f/V_T results proceed to a T-tube trial. Because the initial study revealed that negative f/V_T results were reliable in predicting weaning failure, the clinicians refuse to undertake a T-tube trial in the thirty patients with negative f/V_T results. These are thus excluded in the second study. The exclusion of patients with negative results skews the study population toward less severely ill patients, an effect termed *spectrum bias*. The patients in the first study, who had an average f/V_T

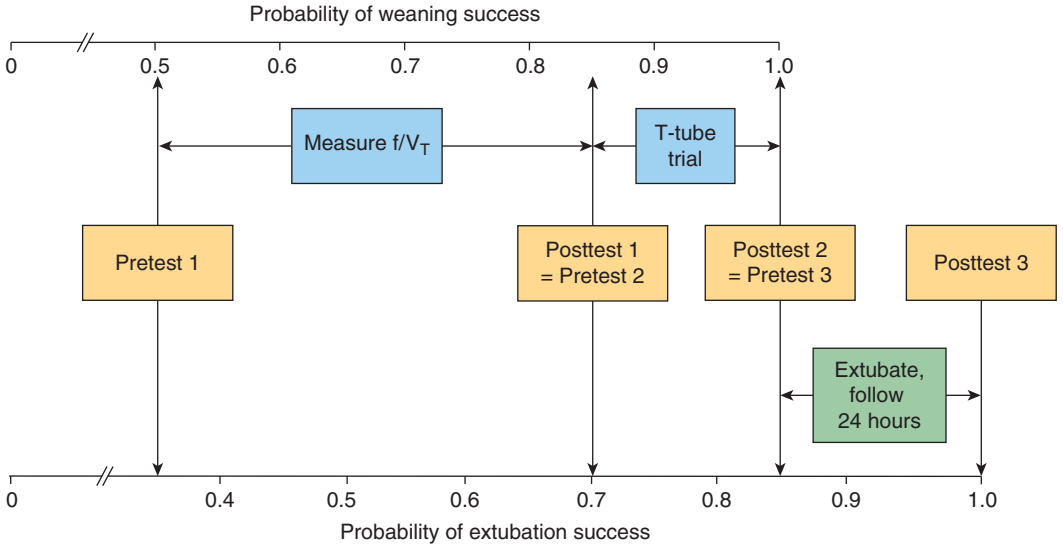

FIGURE 58-17 Interpreting the sequence of diagnostic testing in a patient who is weaned from mechanical ventilation and then extubated, with successful outcome defined as the ability to breathe spontaneously without ventilator assistance for 24 hours after extubation. Pretest 1 is the pretest probability of extubation success before measurement of f/V_T. The f/V_T reading constitutes the posttest results of the first diagnostic test, and also pretest probability of extubation success for the second diagnostic test, a T-tube trial. The outcome of the T-tube trial constitutes the posttest result of the second diagnostic test, and also the pretest probability of extubation success for the third diagnostic test, a trial of extubation. The outcome of the trial of extubation constitutes the posttest result of the third diagnostic test. In this hypothetical example, pretest probability of weaning success for the first diagnostic test is set arbitrarily at 0.50; the extent of the change for each subsequent step is based on average changes reported in published studies.

of 111, were more severely ill than the patients in the second study who had an average f/V_T of ninety. The selection of less severely ill patients in the second study produces an increase in the pretest probability of success; it also alters the sensitivity and specificity of the test.[54,55]

A second form of bias, test-referral bias, occurs when the results of a test under evaluation are used to select patients for the reference-standard test.[54,55] Consider a weaning-predictor test where its reliability is evaluated in terms of its ability to predict the successful toleration of extubation. If patients are required to pass a weaning trial before extubation, this study-entry requirement necessarily excludes all patients who fail. This step has three effects on the study population: first, fewer patients with negative results (of the weaning-predictor test) are included; second, relatively more patients with positive results are included; third, pretest probability of success is increased.[54,55] The first consequence produces a decrease in the specificity of the weaning-predictor test in this population compared with the population in which the test was originally developed. The second consequence increases the sensitivity of the test. Figure 58-18 provides a hypothetical example of how test-referral bias leads to changes in pretest probability, sensitivity, and specificity. The risk for the occurrence of test-referral bias is enormous when three diagnostic tests are undertaken in a sequential manner, as is the case with weaning and extubation.

Spectrum bias and test-referral bias accounts for much confusion in the interpretation of studies of weaning predictor tests. A skilled clinician who measures f/V_T will obtain on average at least as many (if not more) negative test results as positive test results (if the clinician is trying to move the transition between stage 2 and stage 3 of weaning [see Fig. 58-1] to an earlier time in a patient's course). Thus, pretest probability of weaning success is 50% or lower. Clinicians commonly use the f/V_T result to decide which patients will progress that day to a weaning trial. They subsequently use the results of the weaning trial to decide which patients will undergo a trial of extubation. If tolerance of extubation is used as the reference gold standard for evaluating the accuracy of f/V_T, the requirement to pass a weaning trial before extubation (as a criterion for entry into a study) will lead to fewer patients with negative test results (f/V_T >100) and relatively more patients with positive test results (f/V_T ≤100) in the study population (test-referral bias). Thus, the patients in the new study population will have a lower f/V_T on average than the population in which the weaning predictor was originally developed (spectrum bias). Test-referral bias leads to an increase in both true-positive rate and false-positive rate.

Several studies of weaning predictors suffer from the flaws of spectrum bias and test-referral bias.[15,74–82] The misinformation that has resulted from failure to take into account test-referral and other forms of bias brings to mind the comment of the late Alvan Feinstein, the founding father of clinical epidemiology:[56] "The most important issues in biostatistics are not expressed with statistical procedures. The issues are inherently scientific, rather than purely statistical, and relate to the architectural design of research, not to the numbers with which the data are cited and interpreted."

The extreme case of test-referral bias is the situation in which investigators require a positive f/V_T result (value ≤100) before subjecting a patient to a T-tube trial. By design, no patient with a negative f/V_T result (value >100) would undergo a T-tube trial. In that instance, all failed T-tube trials

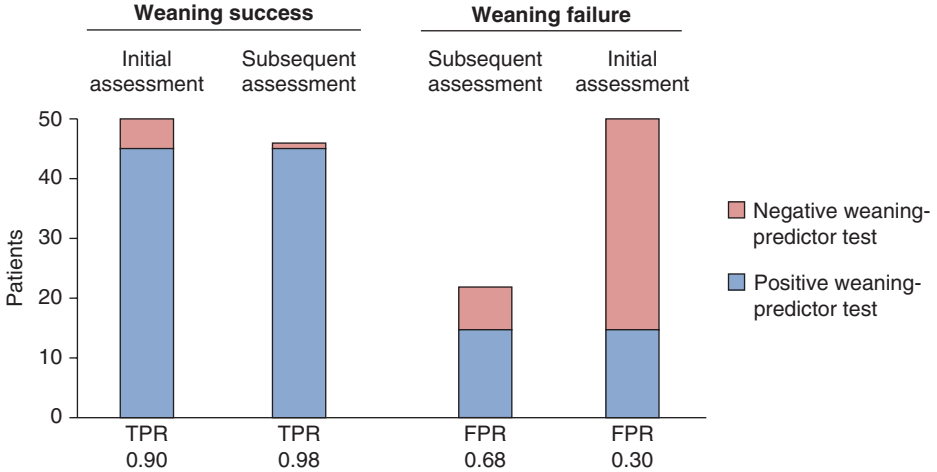

FIGURE 58-18 Test-referral bias. An initial study population (*outer two columns*) for the development of a new weaning predictor consists of fifty weaning-success patients and fifty weaning-failure patients. Of the fifty success patients, forty-five have a positive-test result (true-positive rate [*TPR*] or sensitivity of 0.90) (*first column*). Of the fifty failure patients, thirty-five have a negative-test result (false-positive rate [*FPR*] of 0.30 or specificity of 0.70) (*fourth column*). In a subsequent study (*second and third columns*), clinicians decide not to refer 80% of patients with negative test results (that predict weaning failure) for a T-tube trial. The 80% decrease in negative-test results in the success arm causes a decrease in false-negative results (true-positive results do not change); thus, the true-positive rate (sensitivity) increases to 0.98 (*second column*). The 80% decrease in negative-test results (twenty-eight fewer patients with negative-test results) in the failure arm causes a decrease in true-negative results (false-positive results do not change); thus, the false-positive rate increases to 0.68 (specificity decreases to 0.32) (*third column*).

would be in patients who had positive f/V_T results. Thus, the false-positive rate of f/V_T equal to or less than 100 would tend toward 1.0, and specificity toward 0. Investigators who have evaluated the accuracy of f/V_T have not required an f/V_T equal to or less than 100 per se before referring patients for a weaning trial (the reference gold standard test). Vallverdu et al[77]and Fernandez et al,[82] however, did require patients to have a frequency equal to or less than 35 breaths/min and V_T equal to or greater than 5 mL/kg; for an average 70-kg patient, these criteria result in f/V_T less than 100. Khamiees et al[79] required f/V_T less than 125 for entry. Not surprisingly, these three groups reported very low specificities for f/V_T (see Table 58-1). (Specificity in the study of Fernandez et al[82] is inflated through use of an f/V_T threshold of 50.)

Bayesian Analysis of Reported Performance of f/V_T

Motivated by the meta-analysis undertaken by the EBM Task Force[62,63] and cognizant of the group's failure to employ Bayesian principles in their pooled calculation, Tobin and Jubran[32] examined whether variation in reported reliability of f/V_T in predicting weaning success might be explained by spectrum and test-referral bias, as reflected by variation in pretest probability of success. They took data from the twenty studies included in the EBM Task Force's meta-analysis and nine additional studies published after the meta-analysis. Table 58-1 lists the evaluated studies.

Pretest probability of successful outcome varied from 0.45 to 0.98; reported sensitivity ranged from 0.35 to 1.00, with a mean of 0.87 ± 0.14; and specificity ranged from 0.00 to 0.89 (Table 58-1). The data were entered into a Bayesian model with pretest probability (prevalence of success) as the operating point. A weighted Pearson correlation analysis, which adjusts for the number of patients contained in a study, was used to compare the relationship between pretest probability and the reported values of positive- and negative-predictive value.

Figures 58-19 and 58-20 show that most of the positive-predictive and negative-predictive values in the studies fall close to or above the lower 95% confidence interval (CI) of the values predicted by the Bayes' theorem for pretest probability, using the sensitivity and specificity originally reported by Yang and Tobin.[59] Figure 58-21 shows that reported positive-predictive values were significantly correlated with the values of positive-predictive values predicted on the basis of the sensitivity and specificity originally reported by Yang and Tobin: $r = 0.86$, $p < 0.0001$. The correlation between reported and predicted negative-predictive values was $r = 0.82$, $p < 0.0001$. These correlations provide de facto confirmation of the sensitivity and specificity reported in the original 1991 study.

Also evident in Table 58-1 is the high rate of successful outcome, 75% or higher in more than half the studies. The high success rate reflects occurrence of spectrum bias, and the lower value of f/V_T in subsequent studies than in the original report (77.4 vs. 89.1) provides further evidence of spectrum bias. The high occurrence of test-referral bias is suggested by the high success rate together with the lower specificity of f/V_T in subsequent studies than in the original report (0.52 vs. 0.64). These analyses indicate that the low values of likelihood ratio for f/V_T reported by the Task Force are largely explained by their failure to correct for the occurrence of spectrum bias and test-referral bias.

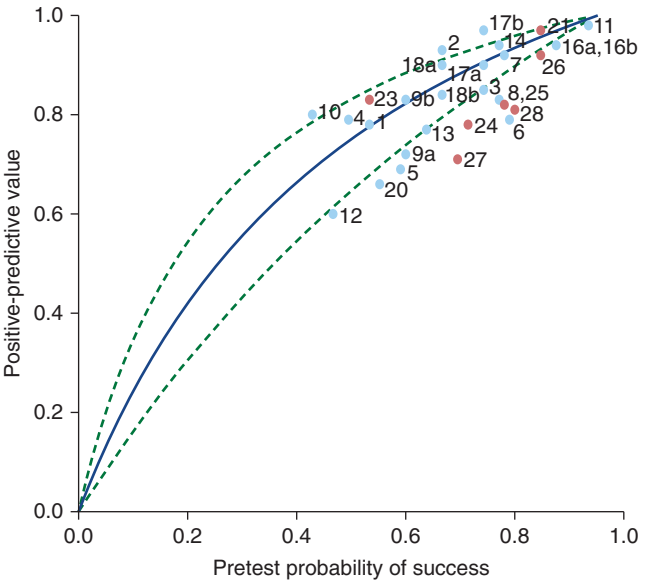

FIGURE 58-19 Positive-predictive value (posttest probability of successful outcome) for f/V_T plotted against pretest probability of successful outcome. Studies included in EBM Task Force meta-analysis are indicated by *blue symbols*; additional studies are indicated by *red symbols*. The curve is based on the sensitivity and specificity originally reported by Yang and Tobin[59] and the Bayes' formula for 0.01-unit increments in pretest probability between 0.00 and 1.00.[55] The lines represent the upper and lower 95% CIs for the predicted relationship of the positive-predictive values against pretest probability. The observed positive-predictive value in a study is plotted against the pretest probability of weaning success. The numbering of a study corresponds to its numbering in Table 58-1, and not to the numbering of the references. (Used, with permission, from Tobin and Jubran.[32])

A key requirement in establishing a scientific fact is to test a hypothesis under various settings and see if a finding is reproducible. The data from the twenty-nine studies in Table 58-1 are aggregated data from thousands of patients, in various settings, collected by investigator groups who varied widely in research skills. When these data were entered into a Bayesian model with pretest probability as the operating point, the observed posttest probabilities were closely correlated with the values predicted by the original study on f/V_T ($p < 0.0001$).

A further limitation in the Task Force's analysis was their failure to focus on the goal of a weaning-predictor test: to screen for weanability. Their use of likelihood ratio represents conflation of screening and confirmation. Likelihood ratio is not precisely suited to the evaluation of a screening test because it includes test components vital for screening (true-positive and false-negative rates) but

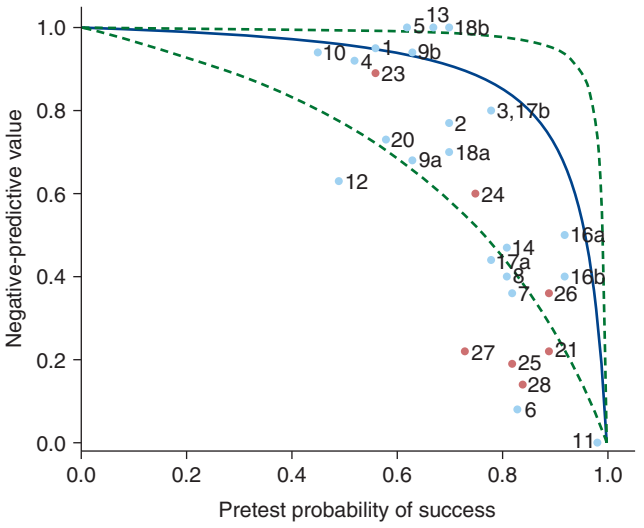

FIGURE 58-20 Negative-predictive value (posttest probability of unsuccessful outcome) for f/V_T. Studies included in EBM Task Force metaanalysis are indicated by *blue symbols*; additional studies are indicated by *red symbols*. The curve, its 95% CIs, and placement of a study on the plot are described in the legend to Figure 58-19. The observed negative-predictive value in a study is plotted against the pretest probability of weaning success (prevalence of successful outcome). The numbering of a study corresponds to its numbering in Table 58-1, and not to the numbering of the references. (Used, with permission, from Tobin and Jubran.[32])

also components not directly focused on screening (true-negative and false-positive rates); the latter cloud the contribution of the vital components.[54] In contrast, sensitivity captures exactly the components that define the reliability of a screening test because it contains only true-positive and false-negative rate. The average reported sensitivity of f/V_T was 0.87 (Table 58-1). Thus, contrary to the conclusion reached by the EBM Task Force, the facts included in the aggregated studies show that f/V_T is a reliable predictor of weaning success.

Tailoring a Predictor to Patient Needs

The threshold value of a test (the single value that separates positive from negative results) is determined by conducting research in a large number of patients. When applying the test to an individual patient, however, clinicians may decide to raise or lower the threshold value, taking into account unique aspects of a particular patient's condition.

Consider a severely immunocompromised patient in whom the physician believes that the risk of complications with continued ventilation far outweigh the risk of weaning failure or reintubation. With that mindset, the physician wants a weaning predictor test that has a very low rate of false-negative results. (A false-negative result is a test that predicts failure, f/V_T >100, but the patient succeeds.) False-negative results are reflected in sensitivity (for f/V_T, 0.97)[59] and negative-predictive value (for f/V_T, 0.95.)[59] To minimize the likelihood of a false-negative result in this patient, the physician may decide to undertake a T-tube trial even when f/V_T is higher than the usual threshold of 100 (say, 115 or 125). Use of a higher threshold moves borderline patients away from being kept on the ventilator and pushes them toward a weaning attempt. The clinician must recognize that a lower false-negative likelihood can only be achieved by also accepting a higher false-positive likelihood for the test result.

The second example relates to a patient with a neck deformity who the physician is leaning toward keeping on the ventilator for an additional day or longer rather than taking a risk of weaning failure and reintubation. The physician wants a weaning predictor test that has a very low rate of false-positive results. (A false-positive is a test that predicts

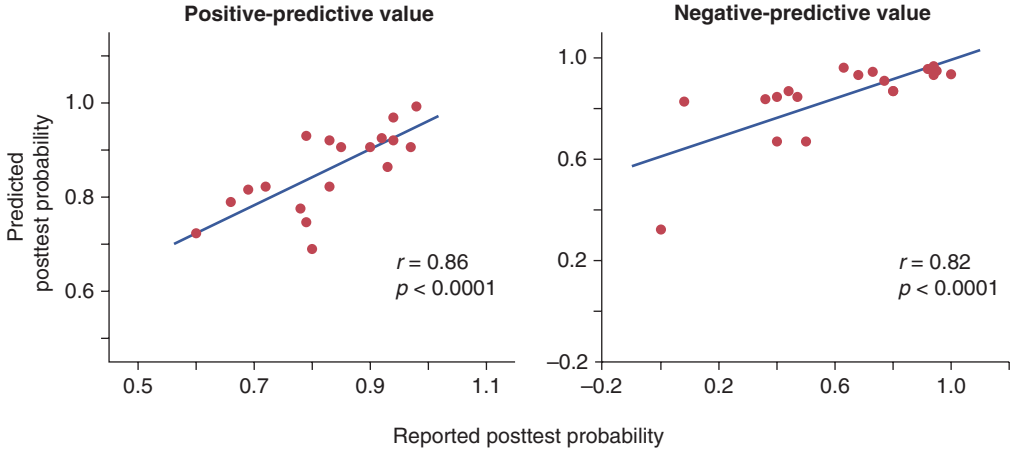

FIGURE 58-21 The relationship between the reported posttest probabilities for f/V_T (among the studies included in the EBM Task Force's meta-analysis) and the values predicted by observed pretest probability together with the sensitivity and specificity originally reported by Yang and Tobin.[59] The weighted Pearson correlation for positive-predictive value was $r = 0.86$, $p < 0.0001$ (*left panel*), and for negative-predictive value the correlation was $r = 0.82$, $p < 0.0001$ (*right panel*). (Used, with permission, from Tobin and Jubran.[32])

success, f/V_T <100, but the patient will fail a weaning trial.) False-positive results are reflected in specificity (for f/V_T, 0.64)[59] and positive-predictive value (for f/V_T, 0.78).[59] To minimize the likelihood of a false-positive result in this patient, the physician may decide to undertake a T-tube trial only if the f/V_T threshold is lower than the usual 100 (say, 90 or 80). But, again, the lower false-positive likelihood can be achieved only by accepting a higher false-negative likelihood for the test result.

If the particular group of patients that a clinician manages usually have a high likelihood of weaning success (high prevalence, or pretest probability, of success), the clinician should use an f/V_T threshold higher than 105, and thus accept a higher false-positive rate so as to maintain a high true-positive rate.[83] This new threshold will result in a higher sensitivity and lower specificity.

How much to adjust thresholds in an attempt to minimize false-negative results and false-positive results is an area of active decision-analysis research. In population studies, the threshold of a test is set such that the burden of false-positive results multiplied by the number of false-positive results balances the burden of false-negative results multiplied by the number of false-negative results. When adjusting the threshold value for an individual patient, the clinician needs to do an analogous computation. Reducing the occurrence of one undesirable test result can only be achieved by simultaneously increasing the occurrence of the other undesirable result. In the language of game theory, this balancing action is a zero-sum game (one goal is achieved at the expense of another).

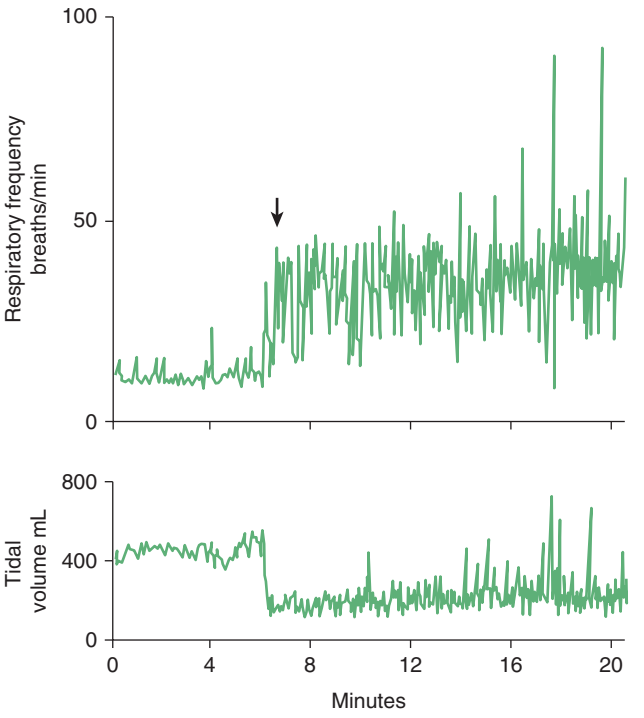

FIGURE 58-22 A time-series, breath-by-breath plot of respiratory frequency and tidal volume in a patient who failed a weaning trial. The *arrow* indicates the point of resuming spontaneous breathing. Rapid, shallow breathing developed almost immediately after discontinuation of the ventilator. (Used, with permission, from Tobin et al.[10])

PREDICTION OF WEANING OUTCOME

Frequency-to-Tidal-Volume Ratio

TECHNICAL DETAILS

The introduction of f/V_T as a weaning predictor stemmed from research into the pathophysiology of weaning failure. In 1986, Tobin et al[10] showed that patients who failed a T-tube trial exhibited an increase in frequency and a fall in V_T in the first few minutes after removal of ventilator support (Fig. 58-22).[10] In 1991, Yang and Tobin[59] reported that f/V_T was superior to nine other weaning predictors. In that study, sensitivity was 0.97, specificity 0.64, positive-predictive value 0.78, and negative-predictive value 0.95. Since the initial study, f/V_T has been employed in hundreds of studies, not all of them related to weaning. The manner of making the measurement and the use of f/V_T in decision making has varied considerably. The key steps that should be followed in order to obtain a reliable measurement of f/V_T are discussed in the following paragraphs.

The measurement should be performed relatively early in the patient's course. In the original study, Yang and Tobin[59] pointed out that the measurement was aimed at detecting "the earliest time that a patient might resume spontaneous breathing." That is, f/V_T functions solely as a screening test. The intent is to move the transition between stage 2 and stage 3 of weaning (see Fig. 58-1) to an earlier time in a patient's course. It makes no sense to make the measurement after the performance of a trial of spontaneous breathing, as many researchers have done.[15,84]

In the original study, the measurement of f/V_T was made with a handheld spirometer after disconnecting the patient's endotracheal tube from the ventilator circuit. That is, the measurement was made while the patient breathed room air, as that was the custom when obtaining weaning predictors in the 1980s. This is the approach we still employ (Fig. 58-23). (Some patients exhibit oxygen desaturation during the measurement, which indicates that they are not ready to proceed to a weaning trial.)

To measure f/V_T, some researchers use the pneumotachograph within the ventilator, taking care to place the patient in the "flow-by" mode and ensure that pressure support (PS) and continuous positive airway pressure (CPAP) are both set at zero. Patel et al[85] recently reported that such use of the pneumotachograph within an Evita ventilator (Evita 4 or Evita XL, Dräger, Telford, PA) yielded equivalent values of f/V_T to those obtained manually with a Wright spirometer.[85]

The measurement should be obtained over a full minute of unassisted breathing. Some clinicians employ a shorter duration, but this is unreliable because of variability in breathing. It is also important that the patient's breathing

FIGURE 58-23 Measurement of f/V_T. The patient's endotracheal tube is disconnected from the ventilator circuit and from supplemental oxygen, and the patient breathes room air. A handheld spirometer (with a filter) is attached to the end of the endotracheal tube. After the patient has established a regular respiratory rhythm (which may take about 1 minute), cumulative ventilation is measured for exactly 1 minute while respiratory frequency is simultaneously counted. The average tidal volume is calculated as minute ventilation divided by respiratory frequency. f/V_T is calculated as respiratory frequency divided by the average tidal volume.

pattern achieves equilibrium before starting the measurement. Mechanical ventilation can depress respiratory motor output through several mechanisms,[86] and shallow breaths and apneic pauses are common during the first minute after disconnecting a patient from the ventilator. We wait until we see that the patient has established a regular respiratory rhythm, which generally occurs by the end of the first minute of unassisted breathing. We then make the measurement of f/V_T over the subsequent minute (see Fig. 58-23).

A common mistake is to measure f/V_T while the patient is receiving ventilator assistance, either in the form of PS or CPAP. The goal of recording a patient's respiratory frequency and tidal volume is to forecast the values of these variables following removal of the endotracheal tube—when a patient will be breathing without PS or CPAP. Thus, it is irrational to measure f/V_T while the patient is receiving ventilator assistance. Moreover, the numbers themselves are drastically different. Values of f/V_T during unassisted breathing are 23% to 52% higher than during PS of 5 cm H_2O; values during unassisted breathing are 46% to 82% higher than during PS of 10 cm H_2O(Fig. 58-24).[87–90] Some clinicians assert that a PS of 5 to 10 cm H_2O simply overcomes the resistance posed by an endotracheal tube. This claim ignores the inflammation and edema that develops in the upper airways after an endotracheal tube has been in place for some time. After the endotracheal tube has been removed, the mucosal swelling produces an increase in upper airway resistance. Straus et al[91] demonstrated experimentally that the respiratory work dissipated against the supraglottic airway after extubation is almost identical to the work dissipated against the endotracheal tube before extubation (see Techniques of Weaning below).

The measurement of f/V_T while a patient is receiving CPAP also suffers from flawed thinking. In healthy subjects, CPAP 5 cm H_2O caused f/V_T to decrease by 38% as compared with unassisted breathing.[92] In thirty-three patients recovering from coronary bypass surgery, f/V_T was 49% lower when measured in the presence of CPAP 5 cm H_2O than during unassisted breathing: f/V_T 36 ± 14 and 71 ± 23 (standard deviation [SD]), respectively (see Fig. 58-24).[93] In sixty ventilated patients, f/V_T was 21% lower when measured in the presence of CPAP 5 cm H_2O (delivered through the ventilator circuit) than when patients breathed through a T-piece circuit without CPAP: median values of 71 (IQR: 52 to 88) and 90 (IQR: 59 to 137), respectively (p <0.001).[85] In the latter study, 89% of patients satisfied the threshold f/V_T for weaning success, equal to or less than 105, while receiving CPAP 5 cm H_2O, but only 65% satisfied it while breathing through a T-piece circuit. The ability of CPAP to alter the distribution of patients on each side of the threshold is sufficient to account for much of the variation in performance of f/V_T in research studies.

Some authors claim that use of CPAP 5 cm H_2O simply replaces the loss of "physiologic PEEP," which results from the presence of an endotracheal tube.[63] Physiologic PEEP, however, is a myth. Static recoil pressure of the respiratory system is zero at end-expiration. The addition of external PEEP while a patient is still intubated confounds clinicians in their ability to assess the challenges the patient will have to face following extubation.

In the original study on f/V_T, the value that best discriminated weaning-success patients from weaning-failure patients was equal to or less than 105.[59] This threshold is commonly rounded to 100 because sensitivity was the same for both f/V_T equal to or less than105 and f/V_T equal to or less than 100. Although it is crucial for investigators to adhere meticulously to a threshold of 105 (or 100) when conducting a research study, clinicians should not feel tethered to such a threshold in every patient (see "Tailoring a Predictor to Patient Needs" above). Dichotomizing the readings of a diagnostic test on the basis of a single cutoff value inevitably means that much information is discarded; an f/V_T reading of 106 does not carry the same clinical significance as an f/V_T of 136 (despite being handled identically in a research study). Physicians should use their judgment in making decisions based on the actual

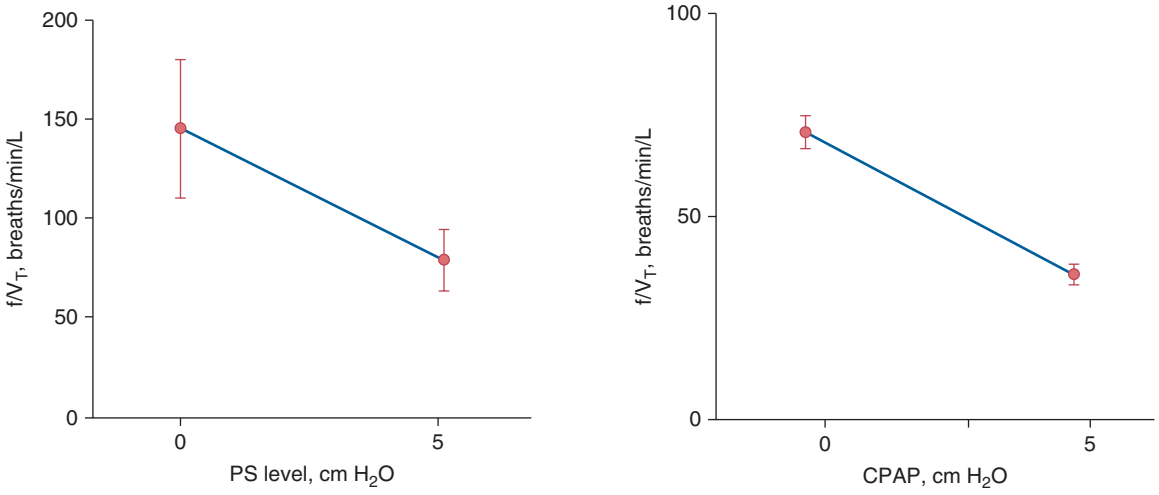

FIGURE 58-24 Effect of pressure support (*PS*) and continuous positive airway pressure (*CPAP*) on frequency-to-tidal volume ratio (f/V_T). *Left panel:* In twelve patients with COPD, f/V_T was 145 ± 121 (standard deviation [SD]) while patients received no ventilator assistance; the addition of PS 5 cm H_2O caused f/V_T to decrease to 79 ± 53 (45% decrease).[90,138,139] *Right panel:* In thirty-three postoperative patients, f/V_T was 71 ± 23 (SD) during unassisted breathing; the addition of CPAP 5 cm H_2O caused f/V_T to decrease to 36 ± 14 (49% decrease).[93]

reading of f/V_T and the characteristics of the patients rather than feeling constrained by a single cutoff value.

COMPARISON OF FREQUENCY-TO-TIDAL-VOLUME RATIO WITH OTHER DIAGNOSTIC TESTS

A detailed evaluation of a diagnostic test, when confined to that test alone, leaves a reader with an incomplete understanding of its usefulness. It is helpful for a reader to compare the performance of the test against other tests in common use. Table 58-2 provides a listing of true-positive rate (sensitivity), false-positive rate (1 minus specificity), and likelihood ratios for f/V_T as a weaning predictor and a number of other tests in common use, as reported by Sox et al.[55]

RANDOMIZED, CONTROLLED TRIAL

Tanios et al[94] undertook a randomized, controlled trial (RCT) to determine whether the inclusion of f/V_T in a weaning protocol influenced weaning time. They studied 304 patients: 153 in the f/V_T-protocol group and 151 in the nonprotocol group. Patients in the f/V_T-protocol group could proceed to a weaning trial (CPAP 5 cm H_2O and PS 7 cm H_2O or less) if—and only if—they had an f/V_T of less than 106. In the second study arm, clinicians did not follow the protocolized approach to weaning. The rate of extubation was the same in both groups: 82%. The duration of weaning was longer in the f/V_T-protocol group than in the nonprotocol group: median 3 (IQR: 1, 5) versus 2 (2, 6) days ($p = 0.04$). The authors concluded that including a weaning predictor (f/V_T) in a protocol prolonged weaning time.

The study has three major problems. The first arises with clinical management of patients in the control group. It is assumed that physicians managing patients in this group did not calculate f/V_T. Physicians are highly aware that respiratory frequency and tidal volume are key variables in deciding whether a patient will tolerate weaning and extubation. Once this knowledge has crept into a physician's brain, it cannot be surgically extirpated at the point of commencing an RCT. To ensure that physicians did not employ breathing pattern in their decision making, Tanios et al[94] would have had to have taken steps to hide or occlude the display of frequency and tidal volume on the bedside monitor and ventilator screen. Alternatively, Tanios et al[94] would have had to compare their usual care group with matched patients weaned in their unit before the late 1980s—before research studies began emphasizing the importance of respiratory frequency and tidal volume in clinical decision making on weaning.[10,59,95]

A second problem is the pretest probability of weaning/extubation success, 82%, in the patients of Tanios et al.[94] At a pretest probability of weaning success of 82%, the posttest probability for a positive f/V_T result, as calculated by the Bayes' theorem, is 93%. The benefit that accrues from such a small increment (from 82% to 93%) is extremely difficult to detect by means of an RCT.

The third problem is that f/V_T was one of several components in a weaning protocol. It is important to make a distinction between the use of a protocol in conducting a research study and its use in everyday clinical practice. In the research protocol of Tanios et al,[94] patients who had an f/V_T of 105 or less progressed to a weaning trial whereas patients with an f/V_T of 106 or higher were returned to the ventilator. When conducting research, this is exactly how a protocol must be specified and followed. No flexibility was permitted. A competent clinician, however, would think it daft to slavishly comply with a protocol that decided an entire day of ventilator management on a one-unit difference in a single measurement of f/V_T. Rather, intelligent physicians customize knowledge to the particulars of each

TABLE 58-2: TEST CHARACTERISTICS OF SOME COMMON DIAGNOSTIC TESTS

Test	TPR	FPR	Positive LR	Negative LR
f/V_T ≤105	0.97	0.36	2.72	0.04
f/V_T 100	0.97	0.32	3.03	0.04
f/V_T 80	0.81	0.11	7.52	0.22
Acid phosphatase for prostatic metastases	0.83	0.01–.003	42	0.17
Angiography in abdominal aortic aneurysm	0.70	0.05	14	0.32
Chest X-ray in lung cancer	0.60	0.04	15	0.42
CPK-MB in acute myocardial infarction	0.94	0.10	9.4	0.07
Ventilation–perfusion scan (segmental/larger) in PE	0.76	0.20	3.8	0.30
Pa_{O_2} <90 mm Hg in pulmonary embolism	0.95	0.50	1.9	0.10
FEV_1 <80% for COPD				
Young, minimal symptoms, nonsmoker	0.07	0.05	1.4	0.98
Middle age, moderate symptoms, smoker	0.27	0.10	2.7	0.81
Stress ECG for coronary artery disease	0.60	0.17	3.5	0.45
Theophylline >20 mcg/mL for toxicity	0.60	0.10	6.0	0.44
Ultrasound for endocarditis	0.37	0.04	9.3	0.66
WBC indium scan for abdominal abscess	0.86	0.05	17.2	0.15

Abbreviations: COPD, chronic obstructive pulmonary disease; *CPK-MB,* creatine phosphokinase-myocardial band; *ECG,* electrocardiogram; *FEV_1,* forced expiratory volume in 1 second; FPR, false-positive rate (1 – specificity); *f/V_T,* frequency-to-tidal-volume ratio; *LR,* likelihood ratio; *Pa_{O_2},* partial arterial oxygen pressure; *PE,* pulmonary embolism; *TPR,* true-positive rate; *WBC,* white blood cell count.

LR >10 or <0.1 = generates large and often conclusive changes in pretest to posttest probability;
LR 5 to 10 or 0.1 to 0.2 = generates moderate and usually useful shift in pretest to posttest probability;
LR 2 to 5 or 0.5 to 0.2 = generates a small and sometimes important change in pretest probability;
LR 1 to 2 or 0.5 to 1.0 = generates a small and rarely important change in pretest probability.

patient and are expected to outperform the inflexible application of a protocol—as has been shown in numerous studies of weaning protocols (see Weaning by Protocol versus Usual Care below).

Tanios et al[94] concluded that the inclusion of f/V_T in a protocol results in prolonged weaning time, and also that "f/V_T should not be used routinely in weaning decision making." The latter, however, is a non sequitur. The authors are conflating the use of f/V_T as one component of an inflexible protocol and its use in clinical decision making. The authors' experimental design did not test the use of f/V_T in decision making per se; rather, the design tested whether the use of a protocol that keeps a patient ventilated for an additional day when f/V_T is 106 as opposed to 105 increases the time required for weaning.

Arterial Blood-Gas Values

Other than in the course of withdrawing life support, mechanical ventilation is virtually never discontinued in a patient who has severe hypoxemia, such as a Pa_{O_2} less than 55 mm Hg with fractional inspired oxygen concentration (FI_{O_2}) greater than 0.40. Computations such as the Pa_{O_2}/FI_{O_2} ratio or alveolar-arterial P_{O_2} gradient are often used to quantify gas-exchange function. The relationship of these variables to more direct measurements of ventilation–perfusion relationships and shunt is based on many assumptions, and the relationship is variably affected by changes in the concentration of inhaled oxygen.[96] Few of these measurements have been rigorously evaluated as predictors of weaning outcome.

Krieger et al[97] found that a Pa_{O_2}/FI_{O_2} ratio of 238 (equivalent to a Pa_{O_2} of 50 with an FI_{O_2} of 0.21) had a positive-predictive value of 90% and a negative-predictive value of 10%. Yang and Tobin[59] found that a Pa_{O_2}-to-alveolar partial pressure of oxygen (PA_{O_2}) ratio of 0.35 provided the best separation between weaning-success and weaning-failure patients in an initial training data set. When that threshold was evaluated in a subsequent validation data set, the positive-predictive value was 0.59 and negative-predictive value was 0.53. These poor test performances do not mean that measurement of gas exchange is of no value in predicting weaning outcome. All such studies suffer from test-referral bias and patients with severe hypoxia were excluded from the study population. Although threshold values of the efficiency of gas exchange cannot be recommended for weaning prediction, weaning attempts are not recommended in patients with borderline hypoxemia.

Minute Ventilation

Normal minute ventilation ($\dot{V}_E$) is approximately 6 L/min.[98,99] Based on an initial report of Sahn and Lakshminarayan,[100] $\dot{V}_E$ of less than 10 L/min became one of the standard weaning predictors. Table 58-3 summarizes the subsequent studies with accessible data on the accuracy

TABLE 58-3: ACCURACY OF MINUTE VENTILATION IN PREDICTING WEANING OUTCOME

of $\dot{V}_E$ as a predictor of weaning outcome. When interpreting these data, it is essential to recognize the influence of test-referral bias, because clinicians are reluctant to initiate weaning attempts in patients with a high $\dot{V}_E$.

Maximum Inspiratory Pressure

The airway pressure during a maximum inspiratory effort, maximum inspiratory pressure ($P_I$max), provides a global measure of inspiratory muscle strength. The measurement is usually made at the opening of the endotracheal tube with an aneroid manometer while the patient makes a maximum effort against a closed airway.[101] The use of $P_I$max as a weaning predictor stems from a study by Sahn and Lakshminarayan.[100] They found that all patients with a $P_I$max value more negative than −30 cm H_2O were successfully weaned, whereas all patients with a $P_I$max less negative than −20 cm H_2O failed a weaning trial. Table 58-4 summarizes subsequent studies with accessible data on the accuracy of $P_I$max as a predictor of weaning outcome.

Vital Capacity

The normal vital capacity is usually between 65 and 75 mL/kg, and a value of 10 mL/kg or more has been suggested to predict a successful weaning outcome. Many investigators have found that vital capacity is often

unreliable. For example, Milbern et al[102] found vital capacity of 15 mL/kg to be falsely positive in 15% and falsely negative in 63% of patients. In a study of ten patients with Guillain-Barré syndrome, Chevrolet and Deleamont[103] reported that vital capacity was helpful in guiding the weaning process. Patients with a vital capacity of less than 7 mL/kg were unable to tolerate as few as 15 minutes of spontaneous breathing. As vital capacity increased to greater than 15 mL/kg with recovery from the illness, patients were safely extubated. Apart from unique circumstances, such as patients with Guillain-Barré syndrome, vital capacity is rarely used as a weaning predictor.

Airway Occlusion Pressure

The pressure generated during the first 0.1 second of an airway occlusion ($P_{0.1}$) is widely used as an index of respiratory center motor output.[104,105] During resting breathing in normal subjects, $P_{0.1}$ is approximately 0.5 to 1.5 cm H_2O. Several investigators have evaluated the usefulness of $P_{0.1}$ as a predictor of weaning outcome (Table 58-5). In these studies, the threshold value of $P_{0.1}$ discriminating between weaning success and weaning failure ranged from 3.4 to 6.0 cm H_2O.

Reproducibility of Standard Weaning Predictors

As with any diagnostic test, it is important to have precise details of the instrumentation used for the measurement, the conditions of the measurement, key steps in making the measurement, and reproducibility of the values. Reproducibility should be assessed in terms of variation in measurements made by one individual on several occasions, and variations in measurements made by several individuals at one point in time. The reproducibility of weaning predictor tests has been assessed to varying extents.

Before worrying about reproducibility, the first requirement for measuring a physiologic variable is to ensure that the patient has achieved a steady state (before the recording is commenced). This requirement can be difficult to satisfy when measuring weaning predictors: The switch between assisted ventilation and autonomous breathing means that there will be some intervening period when a steady state will not be present. For example, if measurement of frequency and V_T commences immediately after disconnecting a patient from the ventilator (say, within 10 seconds of the last ventilator breath and continued over the next 60 seconds), the patient may initially experience apneas (consequent to ventilator-induced neuromechanical inhibition).[106,107] The recorded values of frequency and V_T will be different than if the investigators had waited a minute or so to first ensure that the patient had begun to breathe in a steady manner. Chatila et al[108] reported that measurements of f/V_T at 30 minutes into a weaning trial more accurately predict outcome than measurements in the first minute.[109] Although it is true that including data of the first 30 seconds or so may be unrepresentative, this does not mean that it takes 30 minutes to establish a steady state.

Jubran et al[22] studied the time required for f/V_T to reach a point of equilibration in thirty-five weaning-failure and twenty-five weaning-success patients. The median time to reach ±10% of the final value of f/V_T was 2 (IQR: 1 to 2) minutes in both the weaning-success and weaning-failure patients (see Fig. 58-6). Within 2 minutes of the onset of the T-tube trial, 77% of the failure patients and 73% of the success patients had reached ±10% of the final value of f/V_T. The rapid equilibration of f/V_T contrasts with the slower equilibration of swings in esophageal pressure. The median time to reach ±10% of the final value of swings in esophageal pressure was 7.5 (4.2 to 14.75) minutes in the failure

patients and 5 (2 to 8.5) minutes in the success patients. Based on these data, it is reasonable to usually commence measurement of f/V_T at 60 seconds after removal of the ventilator and then continue the measurement for another 60 seconds.

Yang and Tobin[59] investigated the methods used for measuring $\dot{V}_E$ and its subsets. In a survey of twenty-five hospitals, the most common condition for the measurement was unassisted breathing while receiving room air (thirteen hospitals). Ten hospitals made the measurement during assisted breathing while receiving oxygen supplied by three different methods. Two hospitals measured $\dot{V}_E$ during ventilator support. The latter error seemed laughable in 1991, but today it is even more widely made.

Yang and Tobin[110] measured $\dot{V}_E$ and its subsets in thirty-three patients, who were clinically stable and considered ready to undergo a trial of weaning. $\dot{V}_E$ was 11.9 ± 0.8 L/min while patients spontaneously breathed oxygen through the ventilator circuit (the same FI_{O_2} as patients had received during ventilator support; achieved Pa_{O_2} 89 ± 4 mm Hg). When the patients were switched to room air, $\dot{V}_E$ increased to 13.5 ± 1.1 L/min; frequency also increased from 30.1 ± 11.8 to 33.9 ± 2.2 breaths/min, whereas V_T did not change. Fifteen patients satisfied the $\dot{V}_E$ threshold to progress to a weaning trial ($\dot{V}_E$ <10 L/min) while they breathed oxygen, but seven of them (47%) no longer satisfied this threshold when switched to room air. The study illustrates a wide range of conditions under which $\dot{V}_E$ is measured, and emphasizes the need to control the conditions of the measurement.

Yang[111] examined the reproducibility of predictor measurements in thirty patients about to undergo a weaning trial. Repeat measurements were obtained by a single individual on three trials over 15 minutes. The coefficients of variation for the repeated measurements (during 1 minute of room air breathing) were 10.8 ± 2.1% for $\dot{V}_E$, 6.7 ± 1.2% for frequency, 7.6 ± 1.2% for V_T, and 9.5 ± 1.1% for f/V_T. The coefficient of variation for measurements of $P_I$max (measured with a one-way valve, ensuring a lung volume below functional residual capacity) was 10.6 ± 1.5%. Repeat measurements of vital capacity were the least reproducible, with a coefficient of variation of 19.6 ± 2.8%.

Multz et al[112] undertook a more detailed study of the reproducibility of $P_I$max (measured with an aneroid manometer) in fourteen ventilator-dependent patients. Triplicate measurements were obtained by five experienced investigators who encouraged the patients to make vigorous inspiratory efforts. Measurements of $P_I$max at a single sitting by a single investigator showed good reproducibility: coefficient of variation of 12 ± 1%. Much greater variation was observed when $P_I$max was measured in the same patient on the same day by different investigators: coefficient of variation 32 ± 4%.

Measurements of $P_{0.1}$ exhibit the greatest variability, perhaps because the pressures recorded are very small (normal: 0.5 to 1.5 cm H_2O) and the timing (0.1 second) must be precise. The coefficient of variation within individual subjects is approximately 50%.[113,114] The interindividual coefficient of variation is approximately 20% to 33% during a single set of measurements,[114,115] but on repeated measurements (during CO_2 rebreathing trials) it is approximately 60%.[116]

Gastric Tonometry

The reliability of gastric tonometry in predicting weaning outcome was discussed in considerable depth in the second edition of this book. The rationale for its use is that the gastrointestinal mucosa becomes ischemic early with the development of either hemodynamic compromise or a redistribution of blood flow.[78,117–121] New studies supporting the use of this technique for weaning prediction have not been published during the interval between the second edition and this edition. We are not aware of any research or clinical group that advocates the use of gastric tonometry as a weaning predictor and the topic will not be discussed.

B-Type Natriuretic Peptides

Pro-brain natriuretic peptide (BNP), a prohormone, is synthesized by cardiomyocytes in response to mechanical stretch as occurs with increased atrial or ventricular pressure, volume overload or both.[122] Once secreted, pro-BNP is immediately cleaved into the biologically active 32-amino acid carboxyl-terminal peptide (BNP) and its inactive 76-amino acid amino terminal (N-terminal) fragment (NT-proBNP).[123] Both systolic and diastolic dysfunction of the left ventricle can result in high levels of BNP and NT-proBNP in the bloodstream, and these biomarkers are widely used as screening tools in patients with suspected cardiac disorders. Several investigators have evaluated the accuracy of BNP and NT-proBNP in identifying the likelihood and presence of cardiac causes of weaning failure.

In 102 patients about to undergo a 1-hour weaning trial, Mekontso-Dessap et al[124] measured plasma BNP and repeated the measurement in the first sixty patients at the end of the trial. Forty-two patients (41.2%) were classified as outcome failures: thirty-seven patients failed the weaning trial and five patients failed extubation. Plasma BNP was higher in patients with an unsuccessful outcome. The area under the receiver operating characteristic (ROC) curve for plasma BNP that predicted an unsuccessful outcome was 0.89 ± 0.04; a cutoff value of 275 pg/mL provided the greatest diagnostic accuracy (86%). The higher value of BNP, however, before the weaning trial in the outcome failures does not necessarily mean that cardiac dysfunction was responsible for the failed weaning attempt. Plasma BNP can be elevated for reasons other than left-heart dysfunction, such as advanced age, female gender, renal dysfunction, sepsis, pulmonary hypertension, vigorous fluid management, and extensive use of agents such as diuretics, angiotensin-converting enzyme inhibitors, and β-blockers.[43,125] Moreover, the level of BNP did not significantly change

between the beginning and the end of the weaning attempt. Nine patients who failed the initial weaning attempt were successfully weaned after diuretic therapy, which was associated with a significant decrease in BNP from 517 to 226 pg/mL ($p = 0.01$).[124]

Grasso et al[125] measured plasma levels of NT-proBNP in nineteen patients with COPD before and at the end of a weaning trial. Eight patients (42%) were classified as having acute cardiac dysfunction at the end of the trial. Baseline NT-proBNP levels were significantly higher (median: 5000; IQR: 4218 pg/mL) in these patients than in patients without evidence of acute cardiac dysfunction (median: 1705; IQR: 3491 pg/mL). Plasma levels of NT-proBNP increased significantly at the end of the weaning trial only in patients with acute cardiac dysfunction (median: 12,733; IQR: 16,456 pg/mL; $p < 0.05$). The increase in NT-proBNP over the course of the weaning trial, but not baseline NT-proBNP, provided a good prediction of weaning-induced cardiac dysfunction: area under ROC curve, 0.909 (95% CI, 0.69 to 0.98; $p < 0.0001$, cutoff = 184.7 pg/mL). The response pattern is the opposite of that reported by Mekontso-Dessap et al,[124] who found that the baseline value of plasma BNP, but not the change in BNP over the course of a weaning trial, predicted weaning failure.

The relative accuracy of BNP and NT-proBNP for predicting and identifying cardiac dysfunction as the cause of weaning failure was investigated by Zapata et al[126] in a group of 100 patients who had received mechanical ventilation for more than 48 hours. Thirty-two patients failed the weaning trial, and twelve of these were classified as resulting from cardiac failure, diagnosed on the basis of PAOP greater than 18 mm Hg or echocardiographic features of elevated filling pressures. Before the weaning trial, BNP and NT-proBNP were higher in patients who went on to fail because of cardiac causes than in the remaining patients: Threshold values based on ROC curve analyses were 263 ng/L for BNP ($p < 0.001$) and 1343 ng/L for NT-proBNP ($p = 0.08$). The threshold value of BNP that most accurately predicted weaning-induced cardiac failure was lower than the value reported by Mekontso-Dessap et al,[124] plasma BNP of 263 and 275 ng/L, respectively, and the level of diagnostic accuracy was also lower, 68% and 85%, respectively. Both BNP and NT-proBNP increased significantly over the course of the weaning trial in patients who developed cardiac failure. BNP was superior to NT-proBNP both in predicting and making a diagnosis of cardiac failure. Zapata et al[126] attributed the superior performance of BNP to its shorter circulating half-life (20 minutes). The longer half-life of NT-proBNP (120 minutes) promotes increased accumulation of the peptide after secretion, and thus produces a wider range of plasma concentrations.

At this juncture, there is considerable divergence among the results of studies evaluating the ability of natriuretic peptides to predict weaning outcome. Some investigators report that baseline values have the greatest predictive power,[124] whereas others report that the change in a peptide over the course of a weaning trial is more reliable;[125] some investigators report that NT-proBNP is more reliable than BNP,[125] whereas others report the opposite;[126] and the threshold value that discriminate between weaning-success and weaning-failure patients differs considerably among the studies.

TECHNIQUES OF WEANING

Researchers who developed weaning predictors never recommended that patients be immediately extubated if a patient passed the predictor test. A one-step approach would be reasonable if the risks associated with the development of postextubation distress and the need for reintubation were trivial. Instead, clinicians decide whether to extubate a patient after performing two diagnostic tests in sequence (measurement of predictors followed by a weaning trial). The importance of this two-step approach is illustrated by the study of Zeggwagh et al.[127] They studied 101 patients, ventilated for more than 48 hours (mean: 10 ± 10 days; range: 2 to 60 days), who were considered ready for weaning by the unit team. The unit team then extubated the patients without first undertaking any formal weaning trial. (The extubation decision was based on relatively crude variables, and not the results of more sophisticated weaning predictor tests.) Of the 101 patients, thirty-seven required reintubation. This rate is double (or more) the rate reported in most other studies. These data of Zeggwagh et al[127] emphasize the need for a formal weaning trial before extubation.

The two-step strategy long employed by clinicians is consistent with the theoretical reasoning of the ideal approach to diagnostic testing. Clinicians first contemplate the possibility of a condition (typically a disease, but here it is the possibility of weaning success). At this stage they need a test with very high sensitivity. When the test results are negative (normal), the condition can be confidently ruled out.[53] If the test results are positive (abnormal), the clinician ideally follows the now stronger suspicion (based on the initial very sensitive test) with a second diagnostic test that is very specific. When the result of a very specific test is positive (abnormal), it essentially rules in a disease.[47] Studies of f/V_T have shown it to have a much higher sensitivity than specificity; several investigators have reported sensitivities of 0.90 or higher[1,77,81,118,128–131] or 0.97 or higher.[14,59,108,109,132,133]

For the second diagnostic test, a T-tube or some other weaning trial, clinicians operate on the assumption that it has a high specificity, although this assumption has never been formally tested. A test with high specificity has a low rate of false-positive results (patients who pass a T-tube trial, are extubated, but require reintubation). The usual rate of reintubation after passing a T-tube trial is 15% to 20%, although some investigators have reported reintubation rates as high as 29%.[78,80,118,129,134] The true-negative rate is also needed for calculation of specificity. Determination of the true-negative

rate for a T-tube trial would require the extubation of all patients who fail the trial and counting how many require reintubation, an experiment that is unethical.

A second rationale for the use of weaning techniques is that they somehow improve the patient's likelihood of tolerating extubation. That is, weaning techniques have some therapeutic action beyond their diagnostic role. This rationale is generally couched in terms of improved reconditioning of the respiratory muscles.

A weaning task force[62,63] has suggested that measuring predictors may inhibit expeditious weaning, and they advocated the bypassing of this step and starting weaning evaluation with a trial of spontaneous breathing. Yet in a study used to support this viewpoint, Ely et al[135] found that physicians refused to order a spontaneous breathing trial in 64% to 89% of patients who had already demonstrated satisfactory respiratory function on their weaning predictors. Respiratory therapists had demonstrated greater than 95% compliance in measuring f/V_T. It is difficult to understand how the demonstration of good physiologic performance on weaning predictors could have resulted in the failure to undertake a trial of spontaneous breathing in up to 90% of patients.

The major techniques that are used include T-tube trial, PS, intermittent mandatory ventilation (IMV), or some combination of these three.

Intermittent Mandatory Ventilation

Chapter 7 discusses IMV in detail. With IMV, the patient receives periodic positive-pressure breaths from the ventilator at a preset volume and rate. In addition, the patient can take spontaneous breaths between these mandatory breaths.

When IMV is used for weaning, the mandatory rate from the ventilator is reduced in steps of 1 to 3 breaths/min, and an arterial blood gas is obtained about 30 minutes after each change. Unfortunately, adjusting the number of ventilator breaths in accordance with the results of blood gases can lead to a false sense of security. As little as 2 to 3 positive-pressure breaths per minute can achieve acceptable blood gases, but these values provide no information about a patient's work of breathing, which may be excessive.

IMV was originally seen as the ideal mode for weaning: The ventilator breaths were expected to provide respiratory muscle rest, and the intervening spontaneous breaths to facilitate reconditioning. Accordingly, it was thought that respiratory muscle rest would be proportional to the number of positive-pressure breaths. Subsequent studies revealed that patients have difficulty in adapting to the intermittent nature of the assistance.[136,137] Studies revealed that inspiratory effort is equivalent for the assisted and unassisted breaths. At IMV rates of 14 breaths/min or less, tension–time index for both the assisted and unassisted breaths is above the threshold associated with respiratory muscle fatigue. At a moderate level of ventilator assistance (where the ventilator accounts for 20% to 50% of the total ventilation), electromyographic recordings reveal that activity of the diaphragm and sternomastoid muscles during assisted breaths is no lower than that during unassisted breaths.[137] These findings suggest that respiratory center output is preprogrammed and unable to adapt to breath-by-breath changes in load as occur with IMV. Consequently, IMV may contribute to the development of respiratory muscle fatigue or prevent recovery from it.

Pressure Support

Chapter 8 discusses pressure support (PS) in detail. Like IMV, PS provides graded assistance, but differs from IMV in that the clinician sets the level of pressure (rather than the volume) to augment every spontaneous respiratory effort. The level of pressure is usually adjusted in accordance with the patient's frequency. The frequency, however, that signals a satisfactory level of respiratory muscle rest has never been well defined, and recommendations range from 16 to 30 breaths/min.[90,138,139]

When PS is used for weaning, the level of pressure is reduced gradually, in decrements of 3 to 6 cm H_2O, titrated to the patient's frequency. PS is commonly used to counteract the work imposed by breathing through the endotracheal tube and ventilator circuit. Consequently, the notion arose that if a patient was able to sustain ventilation at this "compensatory level" of PS, the patient should be able to breathe without difficulty after extubation. Investigators have estimated this compensatory level of PS to range from 3 to 13 cm H_2O. No method has ever been shown to reliably estimate the compensatory level of PS required by an individual patient.

Individuals who recommended the addition of PS for overcoming resistance of the endotracheal tube failed to recognize that the upper airways become inflamed and edematous after an endotracheal tube has been in place for some time. When the endotracheal tube is removed, the resistance of the upper airway is higher than normal. This subject was investigated rigorously by Straus et al.[91] They studied fourteen patients who tolerated a 2-hour T-tube trial and were then extubated. Work of breathing did not change between the start and end of the trial, 20.0 ± 9.1 and 22.1 ± 10.6 J/min, respectively. Importantly, work did not decrease after extubation, 22.6 ± 9.7 J/min. The work dissipated against the supraglottic airway after extubation was almost identical to the work dissipated against the endotracheal tube before extubation (approximately 11% of total work of breathing). These data indicate that the addition of any level of PS will lead to underestimation of a patient's work of breathing after extubation—the very goal that is being attempted by a weaning trial that uses a low level of PS. Mehta et al[140] measured work of breathing in twenty-two patients before and 15 minutes after extubation. The work of breathing at PS 5 cm H_2O before extubation underestimated the work of breathing performed after extubation by 36%; work of breathing at CPAP 5 cm H_2O underestimated the work of breathing performed after extubation by 23%.

Most investigators have focused on the effect of PS on inspiratory muscle effort. The switch between inspiration and expiration can give rise to problems, particularly in

patients with COPD. With PS, ventilator assistance ceases when the patient's inspiratory flow falls to a preset amount (such as 25% of the peak flow). Air flow changes more slowly in patients with COPD, and these patients often begin to exhale while the ventilator is still pumping gas into their chests. In a study of patients with COPD who were receiving PS 20 cm H_2O, almost half recruited their expiratory muscles before the ventilator had completed mechanical inflation.[90]

T-Tube Trials

The oldest weaning technique is to undertake trials of spontaneous breathing through a T-tube circuit. In the past, these trials started with a duration of approximately 3 to 5 minutes, and were repeated every 30 minutes.[141] The duration of spontaneous breathing was progressively increased according to patient tolerance, as decided by physical examination and arterial blood-gas measurements. Patients were not extubated until they tolerated the T-tube trial for several hours: up to 8 hours in the classic study of Sahn and Lakshminarayan,[100] up to 16 hours in a study from the late 1980s,[97] and 12 hours in a study from the mid-1990s.[142] The need for frequent changes to the ventilator circuit (every hour or more often) placed enormous demands on the intensive care staff, and the approach became extremely unpopular. By the late 1980s, T-tube trials had been largely supplanted by IMV.[143]

Today, it is usual to limit a T-tube trial to 2 hours or less. We typically extubate a patient who does not develop distress during a 30-minute T-tube trial. If a patient fails a T-tube trial, we wait 24 hours before we undertake a subsequent trial. Our reasoning is based on the knowledge that most patients who fail a T-tube trial experience considerable stress on the respiratory muscles secondary to marked increases in their work of breathing. The respiratory muscles take 24 hours or longer to recover from this stress (Fig. 58-25).[144] Accordingly, we reinstitute full assistance with assist-control ventilation for at least 24 hours before reassessing the patient for another T-tube trial.

Optimal plumbing of the T-tube circuit is necessary to avoid imposing respiratory work. Humidified gas is commonly provided in the form of a heated or cool aerosol of water from a large-volume nebulizer. This system can provoke bronchospasm in patients with reactive airways disease. Such patients can be managed with a non–aerosol-generating system, such as a heated passover humidifier.

A T-tube trial serves as a diagnostic test. It is primarily a means of evaluating a patient's ability to sustain spontaneous ventilation. Patients are judged to have failed a T-tube trial when they develop severe tachypnea, increased accessory muscle activity, diaphoresis, facial signs of respiratory distress, oxygen desaturation, tachycardia, arrhythmias, or hypotension. The degree of change in these variables, however, varies from report to report.

A standardized approach to patient monitoring during a T-tube trial does not exist. Indeed, there is no agreement as to whether the monitoring of any variable helps in deciding whether to continue a T-tube trial for an initially planned duration, prolong it, or curtail it. We monitor all such patients with a pulse oximeter. In a report on more than 1000 spontaneous breathing trials, Ely et al[135] observed only one transient episode of desaturation—a rate so staggeringly low as to beggar belief. In a study of seventeen patients with COPD who failed a T-tube trial, Jubran and Tobin[17] found that severe hypoxemia (P_{O_2} ≤46 mm Hg) was the primary cause of failure in two patients. In a study of 100 spontaneous breathing trials in eighty-three patients, Salam et al[145] observed seven instances in which the results of arterial blood gases caused physicians to defer extubation in patients judged otherwise to have passed the trial. Recent data indicate that patients who fail a T-tube trial do not develop low-frequency fatigue.[29] These data, however, do not exclude the possibility of high-frequency fatigue.[27] Moreover, weaning-failure patients (on average) experience more than four times the normal level of inspiratory effort (at the end of a T-tube trial), and some patients experience more than six times the normal value.[17] Given the magnitude of these changes, we do not recommend the undertaking of a T-tube trial in a cavalier manner. Such large increases in respiratory effort cause severe dyspnea, and, apart from humanitarian considerations, we do not know what imprint severe dyspnea leaves on a patient's psyche.

Jubran et al[22] investigated whether repeated measurements of esophageal pressure throughout a trial of spontaneous breathing might provide additional guidance over a single measurement obtained during the first minute of the trial. They quantified the change in esophageal pressure over

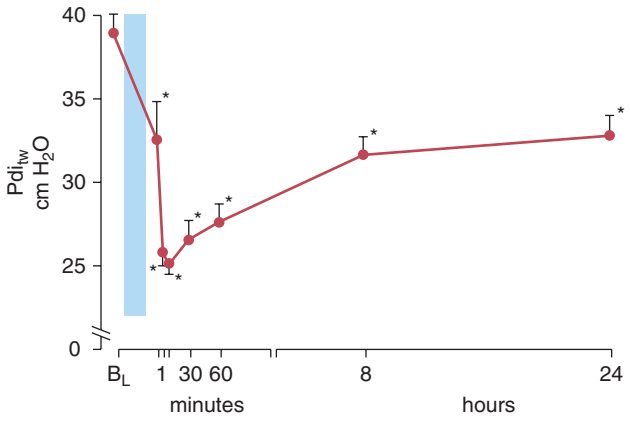

FIGURE 58-25 Induction of diaphragmatic fatigue (*stippled bar*) produced a significant fall in transdiaphragmatic pressure (Pdi) elicited by twitch stimulation of both phrenic nerves. Significant recovery of twitch pressure was noted in the first 8 hours after completion of the fatigue protocol; no further change was observed between 8 and 24 hours, and the 24-hour value was significantly lower than baseline. The delay in reaching the nadir of Pdi_{tw} probably results from twitch potentiation, induced by repeated contractions, which was present at the end of the protocol. Values are mean ± standard error (SE). *, significant difference compared with baseline value, p <0.01. (Used, with permission, from Laghi et al.[144])

the first 9 minutes of the trial using a multivariate adaptive regression spline procedure. In a study of sixty patients, an esophageal pressure–trend index had a sensitivity of 0.91 and specificity of 0.89. Specifically, an esophageal pressure–trend index reading of equal to or less than 0.44 was 8.2 times more likely to occur in weaning failure than in weaning-success patients. These data suggest that the continuous monitoring of esophageal pressure swings during a T-tube trial may provide additional guidance in patient management over tests used for deciding when to initiate weaning.

An implied goal of techniques that involve a gradual reduction in ventilator assistance—whether with IMV, PS, or T-tube trials of increasing duration—is to recondition the respiratory muscles, which may have been weakened during the period of mechanical ventilation. Theoretically, a once-daily trial of spontaneous breathing and a prolonged period of rest may be the most effective method of eliciting adaptive changes.[146,147] That approach meets the three principal requirements of a conditioning program: overload, particularity, and reversibility.[146] During a T-tube trial, patients breathe against an elevated intrinsic load, thus satisfying the overload requirement. Particularity is also satisfied, in that the trial is an endurance stimulus and the desired objective is enhanced endurance. Finally, the use of a daily trial prevents regression of the adaptive changes. This reasoning, however, is solely based on indirect evidence. The effect of different weaning techniques on respiratory muscle reconditioning has not been investigated.

Spontaneous Breathing Trials

During a T-tube trial, a patient is not connected to the ventilator. To convey the lack of assistance, T-tube trials were also described as trials of spontaneous breathing. The two labels were considered synonymous, and used interchangeably. Subsequently, the term "spontaneous breathing trial" was also used to describe patients who were breathing through the ventilator but not receiving any positive-pressure inspiratory assistance as occurs with use of "flow-by." Flow-by avoided the substantial respiratory work imposed by the demand valves in older ventilators, and became a popular alternative to a T-tube circuit for conducting a trial of spontaneous breathing.

Authors, unfortunately, now use the term "spontaneous breathing trial" to describe weaning trials conducted with a fixed level of PS, ranging from 5 to 10 cm H_2O. It is an oxymoron to label PS as spontaneous breathing. The word "support" is an antonym of "unassisted." The problem is not simply semantic. It is unscientific to regard positive-pressure assistance (of 5 to 10 cm H_2O) with every inspiratory effort as unassisted breathing. This unscientific thinking has led authors to believe that measurements of breathing pattern at PS of 5 to 10 cm H_2O is no different than measuring breathing pattern while a patient is disconnected from the ventilator. The argument that PS of 5 to 10 cm H_2O does no more than compensate for the work imposed by an endotracheal tube is now known to be invalid (see Pressure Support above).

The weaning of a patient from the ventilator boils down to making clinical judgments as to whether a patient will be able to sustain ventilation on his or her own, and if not, how much ventilator assistance is required. It is unfortunate that the same term—"spontaneous breathing"—is now used to describe both breathing without any ventilator assistance and breathing with the delivery of positive-pressure assistance with every inspiratory effort. An expression that formerly facilitated meaningful communication has been corrupted such that it misleads not only readers but also the authors themselves.

The sloppiness of communication has reached its apogee in the trials of noninvasive ventilation for management of postextubation distress. Before extubation, patients undergo a trial of "spontaneous breathing" at PS 5 to 8 cm H_2O. After extubation, the major intervention is the delivery of PS (perhaps at a lower level) by face mask. The nonchalant representation of PS 7 cm H_2O as "spontaneous breathing" signifies a fundamental misunderstanding of physiology.

Addition of Positive End-Expiratory Pressure to Replace "Physiologic Positive End-Expiratory Pressure"

Some clinicians recommend that all patients with an endotracheal tube should receive PEEP of 5 cm H_2O, claiming that this level of PEEP is replacing a loss of physiologic PEEP produced by intermittent narrowing of the vocal cords. These claims do not square with long-standing knowledge of pulmonary physiology. Lung volume at end-expiration generally approximates the relaxation volume of the respiratory system (i.e., the lung volume determined by the static balance between the opposing elastic recoil of the lung and chest wall).[148,149] The static recoil pressure of the respiratory system is thus zero at end-expiration in a healthy person.

The addition of PEEP of 5 cm H_2O is not without consequence. In ten ventilated patients who had PEEPi of 6.2 ± 1.0 cm H_2O, Smith and Marini[150] found that that the addition of external PEEP of 5 cm H_2O decreased work of inspiration by 19%. The addition of PEEP can also substantially increase cardiac output in patients with left-ventricular failure. In either circumstance, the rapid removal of PEEP may lead to rapid decompensation at the time of extubation. Thus, the generic order of "5 of PEEP" may cause physicians to underestimate the likely challenges that a patient will face after extubation.

Head-to-Head Comparisons

The first RCT of the three major weaning techniques was conducted by Brochard et al.[3] They randomized 109 difficult-to-wean patients (defined as failure to tolerate their first

2-hour T-tube trial) to three study arms. At 21 days, there were fewer weaning-failure patients among the PS group (2/26, 8%) than among the patients weaned by T-tube trials (10/30, 33%) or IMV (16/41, 39%). Also, less time was taken to wean with PS (5.7 ± 3.7 days) than with T-tube trials (8.5 ± 8.3 days) or IMV (9.9 ± 8.2 days). Statistically, however, the only difference was a shorter weaning time for PS patients (5.7 ± 3.7 days) than for the combined T-tube and IMV patients (9.3 ± 8.2 days; $p < 0.05$).

Esteban et al[4] undertook an RCT that had a similar design to that of Brochard et al. They randomized 130 difficult-to-wean patients (again defined as failure to tolerate their first 2-hour T-tube trial) to four study arms: IMV, PS, once daily T-tube trials, and intermittent spontaneous breathing trials (this terminology was used because six patients breathed through a circuit providing CPAP 5 cm H_2O; the remaining twenty-seven had T-tube trials; the trials were of gradually increasing duration, at least twice daily, with ≥1 hour of assist-control ventilation between each trial). At 14 days, mechanical ventilation was still required by 17% of IMV patients, 11% of PS patients, 3% of once-daily T-tube patients, and 3% of patients weaned by intermittent T-tube or CPAP trials. The time taken to wean was a median of 5 days for IMV (IQR: 3 to 11), 4 days (IQR: 2 to 12) for PS, 3 days (IQR: 1 to 6) for once-daily T-tube trials, and 3 days (IQR: 2 to 6) for intermittent T-tube/CPAP trials. The rate of successful weaning with once-daily T-tube trials was about three times faster than with IMV and two times faster than with PS; there was no difference between the speed of weaning with once-daily T-tube trials versus intermittent T-tube/CPAP trials.

These two studies concur in finding that IMV was the least-effective method for weaning a difficult patient. The steps taken in setting the IMV rate were largely the same in the two studies: The initial IMV rate was half the respiratory frequency seen during assist-control ventilation (IMV of about 10 breaths/min in both studies). Then, IMV rate was decreased by 2 to 4 breaths/min twice a day if the patient tolerated it. The point for extubation differed between the studies. In the study of Brochard et al, patients were extubated when they tolerated an IMV of 4 breaths/min for 24 hours. In the study of Esteban et al, patients were extubated when they tolerated an IMV of 5 breaths/min for 2 hours. This difference probably accounts for the shorter weaning time with IMV in the study of Esteban et al[4] versus that of Brochard et al[3]: 5 days versus 10 days.

The data appear to differ in the relative efficacy of PS and T-tube trials. The reason for the difference can again be understood by examining the two protocols. The initial level of PS was largely similar in the two studies: pressure titrated to respiratory frequency (20 to 30 breaths/min[3]; <25 breaths/min[4]). This resulted in a PS of 18 cm H_2O in both studies. PS was decreased by 2 to 4 cm H_2O twice a day in the study of Brochard et al, and by that amount or more in the study of Esteban et al. The point for extubation differed between the studies. In the study of Brochard et al, patients were extubated when they tolerated PS of 8 cm H_2O for 24 hours. In the study of Esteban et al, patients were extubated when they tolerated PS of 5 cm H_2O for 2 hours. This difference probably accounts for the shorter weaning time with PS in the study of Esteban et al than in the study of Brochard et al: 4 days versus 6 days. The approach to T-tube trials also differed. Brochard et al performed trials of increasing duration twice a day. Esteban et al used two approaches to T-tube trials: One arm consisted of T-tube trials once a day, and the second arm consisted of intermittent spontaneous breathing trials. The point for extubation differed between the studies. In the study of Brochard et al, extubation was contemplated when patients tolerated a 2-hour T-tube trial, but there could be as many as three separate 2-hour trials. In the study of Esteban et al, patients were extubated when they first tolerated a 2-hour trial.

The investigators of the two preceding studies[3,4] set the duration of T-tube trials at 2 hours. In a subsequent study, conducted in 526 patients who had received more than 48 hours of ventilation, Esteban et al[151] found that the rate of weaning failure was equivalent for trials lasting 30 and 120 minutes: 12% (33/270) and 16% (40/256), respectively. The rates of reintubation were virtually identical (13%); approximately 74% of patients in the two arms were successfully extubated. This study consisted of patients undergoing a first weaning attempt, unlike the two earlier trials that were limited to patients with demonstrable difficulty in being weaned. The findings, however, suggest that most patients can be weaned after a 30-minute trial, which simplifies management by freeing staff time for other patient care tasks. With a similar goal, Perren et al[152] found that the rate of weaning failure was equivalent when ninety-eight patients were randomized to breathe with PS of 7 cm H_2O for 30 or 120 minutes: 6.5% (3/46) and 11.5% (6/52). The rates of reintubation did not differ significantly (7% and 4%, respectively).

Koh et al[153] investigated whether adding a 1-hour T-tube trial would alter outcome in patients who had already undergone progressive decreases in PS (3 to 5 cm H_2O every hour) to a level estimated to offset imposed respiratory work (by the endotracheal tube and ventilator circuit: mean: 7.6 ± 0.4 cm H_2O [SE]; range: 4 to 13 cm H_2O). The rate of weaning failure was not significantly different in patients who were extubated after the additional T-tube trial and those extubated directly, 45% (10/22) and 30% (6/20), respectively, nor did the rates of reintubation differ, 18% (4/22) and 20% (4/20), respectively.

Matic and Majeric-Kogler[154] studied 260 patients who had received mechanical ventilation for more than 48 hours and who had who satisfied several criteria of readiness for weaning (such as frequency <35 breaths/min, V_T >5 mL/kg, f/V_T <100, and P_{O_2} >60 mm Hg on FI_{O_2} <0.40). Patients were randomized to a 2-hour T-tube trial or a 2-hour trial of PS 8 cm H_2O. Of the 150 patients in the PS trial group, 120 (80.0%) passed the trial and were extubated. Of the 110 patients in the T-tube trial group, eighty (72.7%) passed the trial and were extubated ($p = 0.06$). The remaining patients who failed the initial weaning trial were returned to assist-control

ventilation, and the previously assigned weaning technique was again attempted after 24 hours (or when the patient's condition permitted). The rate of weaning success was higher in the PS group than in the T-tube trial group: twenty-six of thirty (86.7%) versus twenty-one of thirty (70%). In addition, the time for weaning was shorter for the PS group, 54 (IQR: 47 to 88) versus 94 (IQR: 79 to 132) hours, as was total time for mechanical ventilation, 215 hours (IQR: 187 to 259) versus 262 hours (IQR: 216 to 328). The rate of reintubation was equivalent for the PS and T-tube trial groups: one (3.5%) versus two (6.7%) patients.

Vitacca et al[155] studied seventy-five patients with COPD who had been transferred to a long-term weaning unit. The patients had required more than 15 days of mechanical ventilation, and all had a tracheostomy. Of the seventy-five patients, twenty-three (31%) tolerated a T-tube trial for 48 hours and were studied no further. The remaining fifty-two patients failed the T-tube trial after 290 ± 452 minutes, and were randomly assigned to weaning by PS or T-tube trials. Weaning was deemed successful when patients tolerated spontaneous breathing for 48 hours or longer. Clinical outcomes were equivalent in the PS and T-tube trial groups: weaning success rate 73% (19/26) versus 77% (20/26); mortality 11.5% (3/26) versus 7.6% (2/26); ventilator duration 181 ± 161 versus 130 ± 106 hours; weaning unit stay 33 ± 12 versus 35 ± 15 days; and hospital stay 49 ± 27 versus 50 ± 32 days. The investigators also retrospectively compared fifty-five patients managed by the protocols of this study with sixty-two control patients managed in the same institution during the 2 years preceding the study. The study patients exhibited better outcomes than the historical control group: 30-day weaning success rate 87% versus 70%; ventilator duration 103 ± 144 versus 170 ± 127 hours; weaning unit stay 27 ± 12 versus 38 ± 18 days; and hospital stay 38 ± 17 versus 47 ± 18 days.

Weaning by Protocol versus Usual Care

Several investigators have examined whether formalizing weaning steps into a systematic protocol might alter weaning outcome. Many of these studies were motivated by the results of a 1996 study by Ely et al,[156] who combined two steps from previous studies—measurement of f/V_T (and other predictors) and a 2-hour T-tube trial—into an algorithm. They randomized 300 patients into an intervention arm and a usual-care arm. Patients in the intervention arm were screened in the early morning. To pass the screen, patients had to meet all of the following five criteria: f/V_T less than 105; Pa_{O_2}/FI_{O_2} greater than 200; PEEP equal to or less than 5 cm H_2O; adequate cough during suctioning; and no infusions of vasopressors or sedatives (with the exception of dopamine ≤5 mcg/kg/min and intermittent sedative boluses). Patients who passed the screen automatically underwent a trial of spontaneous breathing (a T-tube trial or flow-by and CPAP 5 cm H_2O) later that morning (without requiring an order from the primary physician). If the patient tolerated the trial, the primary physician was informed both orally and by a note in the chart.

The time taken to wean (from the point of satisfying the predictor criteria until the discontinuation of mechanical ventilation) was shorter in the intervention group than in the usual-care group: median 1 day (IQR: 0 to 2) versus 3 days (IQR: 2 to 7). The duration of ventilation was also shorter: 4.5 days (IQR: 2 to 9) versus 6 days (IQR: 3 to 11). Reintubation was less common in the intervention group than in the usual-care group: 4% versus 10%. This study demonstrates that a two-step approach—systematic measurement of predictors followed by a single daily T-tube (or flow-by/CPAP) trial—was superior to usual care.

A closer inspection of the data illustrates some important points about weaning. Among the 149 patients in the intervention group, 113 (76%) met the predictor criteria. Of these 113 patients, eighty-eight (78%) passed the spontaneous breathing trial. Yet, extubation was not attempted that day in 45% (40/88) of the patients who passed the trial. In a subsequent analysis of the data, Ely et al[157] noted that eighty-four of the 300 patients never satisfied the weaning predictor thresholds. Of these eighty-four patients, fifty-nine (70.2%) were never extubated. The remaining twenty-five patients (25/300; 8.3% of the overall study group) were successfully extubated despite never satisfying the predictor thresholds. Of these twenty-five patients, fifteen (15/300) had Pa_{O_2}/FI_{O_2} ratios less than 200 (5% of the overall study group) and ten (10/300) (3.3% of the overall study group) had f/V_T readings higher than 105. These data highlight that (a) the major source of delay in weaning of patients in the intervention group resulted from the failure of physicians to take action in patients who passed a spontaneous breathing trial (extubation was delayed in 45% of these patients), (b) almost 80% of patients who meet predictor thresholds will tolerate an immediate spontaneous breathing trial, and (c) f/V_T (105) falsely identifies approximately 3% of patients who can be extubated.

Ely and members of the Evidence-Based Medicine Task Force on weaning[62,158] subsequently argued that the data from the 1996 study provided evidence in support of the use of formalized protocols in weaning management. To claim that use of a protocol per se improves patient outcome, the weaning approach must be the same in both the protocol arm and nonprotocol arm of a research study. In the 1996 study,[156] however, 76% of patients in the usual-care arm were managed with IMV, whereas no patient in the intervention arm was weaned using IMV. Several studies had already shown that IMV impeded weaning. Such a study design lacks internal validity and cannot be used as the basis for claims that use of a weaning protocol per se expedites weaning.[159]

The next study to test the benefit of protocolized management of weaning was undertaken by Kollef et al.[2] They randomized 179 patients to a protocol group and 178 patients to usual care. The study was conducted in four intensive care units (ICUs), and weaning techniques were a mixture of PS, CPAP, and IMV. Overall, the duration of mechanical ventilation was shorter for the protocol group than for the

usual-care group: median 35 hours (IQR: 15 to 114) versus 44 hours (IQR: 21 to 209). The difference, however, was significant in only one of the four ICUs. Moreover, interpretation of the data for this ICU is not straightforward. Patients in the usual-care group were significantly sicker than were the patients in the protocol group: Acute Physiology, and Chronic Health Evaluation (APACHE) II scores were 15.4 versus 13.6. In separate analysis, the investigators found that APACHE II score was at least as important as protocol management as a determinant of the duration of mechanical ventilation. In the other three ICUs, there was no difference in duration of mechanical ventilation between the protocol and usual-care groups; in one ICU, the trend was in the opposite direction.

Marelich et al[160] undertook a randomized comparison of weaning by protocol versus usual care in 335 patients, about half of whom were in the medical ICU and half in the surgical ICU. They randomized 186 patients to a protocol arm and 189 patients to a usual-care arm. The duration of mechanical ventilation was shorter for the protocol arm than for the usual-care arm: 68 hours (IQR: 33 to 164) versus 124 hours (IQR: 54 to 334) ($p = 0.001$).[160] Benefit, however, was confined to the medical ICU. Protocol management achieved no advantage in the surgical ICU.

Namen and members of the Ely research group[161] investigated the benefit of protocolized weaning in a neurosurgical ICU. There were forty-nine patients in the protocol arm and fifty-one patients in the usual-care arm. Implementation of protocolized weaning had no beneficial effects on any patient outcome, such as number of days of mechanical ventilation, costs, morbidity, or mortality.

Randolph et al[162] randomized 182 children who had failed to satisfy criteria for extubation (and had been ventilated for >24 hours) to three arms: PS protocol, volume-support ventilation protocol, usual care. The rate of weaning failure was equivalent for PS, volume-support ventilation, and usual care, 15%, 24%, and 17%, respectively, as was the median duration of weaning, 1.6, 1.8, and 2.0 days, respectively. The authors concluded that protocols did not shorten the duration of weaning.

Krishnan et al[163] did an RCT in 154 patients assigned to weaning by protocol and 145 patients weaned according to usual care. The duration of mechanical ventilation was equivalent for protocol weaning and usual care, 60.4 versus 68.0 hours, as was the rate of successful weaning, 74.7% versus 75.2%.

Of the six RCTs that have tested the benefits of weaning protocols, three research groups have reported that protocolized weaning is superior to usual care. Two of these studies, those by Ely et al[156] and Kollef et al,[2] have internal-validity problems of such magnitude that the data cannot be accepted as valid evidence on which to base a claim that protocols per se expedite weaning. The third study, that by Marelich et al,[160] revealed no benefit in one of the two ICUs in the study. The trials conducted by Namen et al,[161] Randolph et al,[162] and Krishnan et al[163] revealed no benefit for protocolized weaning. Thus, only half of a study (out of six studies) revealed valid support for protocolized weaning, with the remainder providing no evidence of benefit.

In addition to these studies of weaning protocols in ICU patients, Vitacca et al[155] investigated the benefits of protocolized management of patients admitted to a long-term weaning facility. The investigators concluded that protocolized weaning significantly decreased the duration mechanical ventilation as compared with usual care: 103 ± 144 versus 170 ± 127 hours (Fig. 58-26). Inspection of the Kaplan-Meier curve, however, reveals that the plots differ only at time zero; thereafter, the two plots superimpose on one another. On first evaluation, more than 30% of patients classified as "difficult-to-wean" were immediately weaned. That is, benefit was not derived from use of a protocol, but from the presence of a "thinking" doctor at the bedside.

There is a deeper reason why protocolized management does not lead to improvements in weaning outcome. This relates to a fallacy in historiography (the methodology employed by historians) known as the Whig-interpretation-of-history fallacy: the tendency among historians to write their account on the side of the winners, to praise military strategists and revolutionaries provided they have been successful.[164] The fallacy can be best appreciated by first considering an example, and then reflecting on the implications for clinicians and researchers.

Numerous computer versions of the Battle of Gettysburg exist on the market. These reproduce with great accuracy the terrain, corps involved, and serial chronology of events in the battle. A moderately good player taking the Confederate side can beat the Union side.[165] Yet, Robert E. Lee, universally regarded as the best strategist and tactician on either side, lost. How could a moderately accomplished player outperform Lee? The player today knows from the outset what Lee did not know. Lee did not know that the battle was going to take place at the specific location of Gettysburg. Lee did not know precisely which units would be involved and where, the time scale of preliminary stages of the battle, the constraints imposed by the terrain, and all the trivial contingencies that powerfully influenced the final outcome of the battle. The determinate shape of the battle was conferred only retrospectively by its outcome. There are no conclusive reasons that the series of events turned out the way they did—each could have turned out otherwise. It is impossible to incorporate all possible contingencies into a battle plan. Simply, the computer version does not reproduce the situation that Lee faced; instead, it is what historians call a Whig illusion.

The error committed by Whig historians is that endings seem inevitable—but only after the fact. Nothing, however, could ever happen if reality did not kill all the other potentialities originally inherent in any given situation.[166] From a historical perspective, every sequence of events appears as though it could not have happened otherwise. This produces an existential illusion. Weaning researchers who expect protocols to improve clinical outcome are committing the Whig fallacy. At the outset of a weaning attempt, there is not a set of determinate, enumerable factors, the totality of which

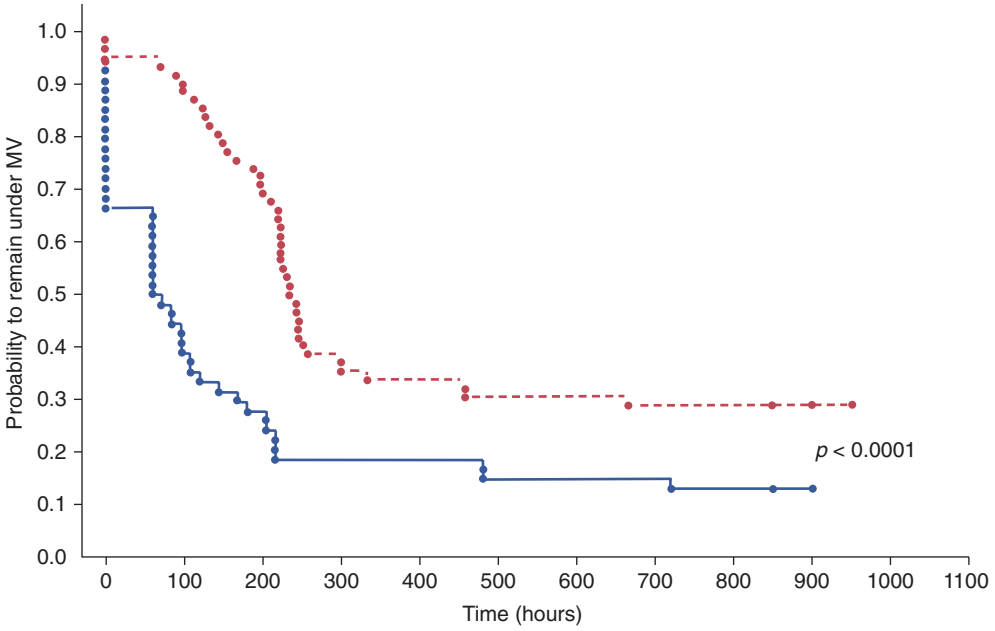

FIGURE 58-26 Kaplan-Meier curves of probability of continued mechanical ventilation (MV) in patients managed by a weaning protocol versus usual care. The time of continued mechanical ventilation was significantly shorter with protocolized weaning as compared with usual care: 103 ± 144 versus 170 ± 127 hours (p <0.0001). (Used, with permission, from Vitacca et al.[155])

comprises the situation—like the set of steps used to provide the proof for a theorem in Euclidean geometry. To suppose otherwise is to confuse an a posteriori (retrospective) perspective with an a priori (prospective) perspective. This is the fallacy committed by protocol advocates, Whig historians, and malpractice attorneys.

Computerized Approaches to Weaning

Investigators have attempted to apply various forms of artificial intelligence to mechanical ventilation.[129,167,168] These approaches have been most fruitful in the management of weaning. A specially constructed ventilator based on these efforts was compared against usual care in a multicenter RCT conducted by Lellouche et al.[169] The computerized system was embedded in an Evita 4 ventilator (Dräger, Lübeck, Germany). The modified ventilator continuously monitored respiratory frequency, tidal volume, and end-tidal CO_2 tension, and repeatedly altered the level of delivered PS based on iterative changes in these three variables. Depending on a patient's response, the computerized system periodically and automatically decreased the level of PS by 2 to 4 cm H_2O. Importantly, the algorithm accepted transient instabilities, such as a brief increase in respiratory frequency, without making changes in a patient's classification. The pace of pressure reduction was tailored according to the needs and performance of each individual patient. Once a predesignated minimal level of PS was reached, the ventilator automatically subjected the patient to a weaning trial, conducted at a low level of PS. If the patient performed satisfactorily, a message was displayed on the screen recommending the removal of the ventilator. Lellouche et al[169] enrolled 144 patients from five medical–surgical ICUs into the study. The patients had received at least 24 hours of ventilator assistance, and were enrolled at an early stage of their course, at a point when weaning predictor tests did not signal readiness to wean. In four of the five ICUs, usual care involved the use of paper-based weaning protocols. Compared with usual care, the computerized system decreased weaning duration from a median of 5 to 3 days ($p = 0.01$) and decreased total duration of mechanical ventilation from 12 to 7.5 days ($p = 0.003$).

This study provides support for the use of computerized ventilators as a method to expedite weaning. The study also carries lessons for the better management of weaning using conventional ventilators. Of the seven stages of weaning, stage 2, the period of diagnostic triggering—the time when a physician begins to think that the patient just might be ready come off the ventilator—is the most critical (see Fig. 58-1). RCTs on weaning techniques have revealed that 60% to 80% of patients ventilated for a week or more were successfully disconnected from the ventilator successfully on the first day they were evaluated for weaning.[3,4] If weaning-predictor tests had been performed in these patients at an earlier time, it is highly likely that many of them could have been removed from their ventilator a day, or several days, sooner than was the case.

With the artificial-intelligence-operated ventilator,[169] screening tests were performed repeatedly and automatically, and thus the delay inherent in diagnostic triggering (stage 2) was bypassed. Moreover, once a predesignated readiness threshold was reached, a confirmatory test—a weaning trial that advises on the appropriateness of extubation—was

automatically performed, without requiring any action (or decision making) on the part of the staff. For patients in the usual-care arm of the trial, Lellouche et al[169] calculated that the number of T-tube trials performed according to patient readiness was only 51%. The delay in human decision making and action was further emphasized by the lapse of more than 14 hours (0.6 ± 2.65 days) between the time that a message first indicated that a patient had passed a weaning trial until removal of the endotracheal tube. Indeed, only 42% of the patients were extubated on the day that the message was first displayed.

Rose et al[170] undertook an RCT of the ventilator employed by Lellouche et al,[169] which now goes by the name SmartCare. A total of 102 patients in an Australian ICU were equally divided between the computerized ventilator and usual care. The median time from the first identified point of suitability for weaning commencement until the display of a message indicating that a patient had passed a weaning trial was 20 hours (IQR: 2 to 40) for the computerized ventilator versus 8 hours (IQR: 2 to 43) for usual care ($p = 0.3$). The adjusted probability of reaching separation potential was estimated to be 31% lower with the computerized ventilator as compared to usual care (95% CI, 5l% lower to 9% greater). At least two factors are likely to have contributed to the markedly different outcome in the two studies. First, 68% of enrollees in the study of Lellouche et al[169] were medical patients, whereas 78% of enrollees in the Australian study[170] were surgical patients, which are typically less challenging to wean. Second, the nurse-to-patient ratio in the Australian ICU was 1:1.

A third RCT of computerized weaning versus usual care was undertaken by Taniguchi et al.[171] These Brazilian researchers employed a different computerized system, termed *mandatory rate ventilation,* from that used in the studies of Lellouche et al[169] and Rose et al.[170] An algorithm, embedded in a Taema-Horus ventilator, automatically adjusted the level of PS according to a target respiratory rate. If the patient's respiratory rate (averaged over four respiratory cycles) exceeded the target by more than 3 breaths/min, the level of PS was increased by 1 cm H_2O, and vice versa. Taniguchi et al[171] found no difference in weaning duration with the two approaches. The level of PS was lower with usual care than with the computerized ventilator (over at least the first three hours of the study). Similar to the study of Rose et al,[170] enrollees in the study of Taniguchi et al[171] consisted solely of postoperative patients. Another important factor that contrasts with the research team of Lellouche et al[169] is that both the Brazilian and Australian clinicians knew they were competing against a machine that they did not help to create.

Respiratory Muscle Training

Over the past 25 years, researchers have emphasized that respiratory muscle fatigue is likely to be more important than respiratory muscle weakness in causing weaning failure (see Pathophysiology of Weaning Failure: Respiratory Muscles above). There is growing recognition that this attribution is misplaced. Recordings of twitch pressures with the use of phrenic-nerve stimulation have revealed that many weaning-failure patients have very severe respiratory muscle weakness.[172,173] A renewed focus on respiratory muscle strength has gathered impetus from a recent RCT, which revealed that deliberate measures aimed at improving respiratory muscle strength resulted in a significant increase in the weanability of patients.

Martin et al[174] enrolled sixty-nine patients in a single-blind RCT designed to determine whether inspiratory muscle-strength training would improve weaning outcome. The patients had received mechanical ventilation for approximately 40 to 50 days before entry into the study. Thirty-five patients were randomized to strength training and thirty-four patients to sham therapy.

Strength training was achieved with the use of a commercial threshold inspiratory muscle trainer (Threshold PEP; Respironics Inc., Murrysville, PA), which required patients to generate inspiratory pressures of −4 to −20 cm H_2O at the onset of an inspiration. During a training session, a patient was removed from the ventilator and the threshold device connected to the tracheostomy tube (keeping the cuff inflated). The patient was then required to perform four sets of six to ten threshold-loaded inspirations; between each set, the patient was returned to the ventilator for 2 minutes. The setting on the threshold device was adjusted to the highest pressure setting that the patient could consistently open during each inspiration (airway pressures at the tracheostomy tube were monitored). Over the course of the study, the pressure setting on the device was increased according to patient tolerance. Patients in the sham arm inspired through an inspiratory muscle training device that contained a large hole, with the result that little pressure was required to generate airflow. Sessions were performed 5 days a week (Monday to Friday).

In addition to the inspiratory muscle-strength training sessions, all patients were subjected to weaning trials of progressively longer duration. These trials involved the use of automatic tube compensation, CPAP, or low levels of PS. Weaning trials were conducted 7 days a week according to a predesignated scheme.

Upon completion of the study, twenty-five of the thirty-five (71%) patients in the strength-training arm were weaned as compared with sixteen of thirty-four (47%) patients in the sham arm ($p = 0.039$). Over the course of the study, the inspiratory pressure setting on the threshold device became more negative: −9.54 ± 3.70 (SD) versus −14.52 ± 4.59 cm H_2O ($p = 0.0004$). Corresponding pressures in the sham arm were −3.10 ± 1.54 and −3.36 ± 2.08 cm H_2O ($p = 0.86$). Over the course of the trial, patients in the strength-training arm exhibited an increase in $P_I$max from 44.4 ± 18.4 to 54.1 ± 17.8 cm H_2O ($p < 0.0001$); corresponding values of $P_I$max in the sham arm were 43.5 ± 17.8 and 45.1 ± 19.5 cm H_2O.

The results of this study suggest that use of a simple device (a threshold loader) can markedly increase the

weanability of patients. The challenge now is to reproduce these findings and find out whether further adjustments to the training regimen might achieve an even greater level of success. The positive outcome highlights the importance of respiratory muscle strength as a determinant of weanability. The results also suggest that other methods of increasing respiratory muscle strength, such as the use of transcutaneous neuromuscular electrical stimulation or novel biologic or pharmacologic compounds, may also expedite weaning.

Physical and Occupational Therapy to Aid Weaning

The use of techniques aimed at whole-body rehabilitation, including formal physical and occupational therapy, shortly after the initiation of mechanical ventilation, holds considerable promise for improving long-term functional performance after discharge from the ICU, but it may also expedite weaning. Preliminary research in this area had shown promise,[175] but interest was heightened by a recent RCT.[176]

Schweickert et al[176] sought to determine whether early implementation of a program of formal physical and occupational therapy would lead to improvements in functional outcomes in ventilated patients. At two university hospitals, investigators enrolled patients who had received less than 72 hours of mechanical ventilation, which was expected to continue for at least another 24 hours; enrollees were also required to have exhibited functional independence 2 weeks before admission. From an initial screening of 1161 patients, 104 were enrolled: Forty-nine were randomized to early exercise and mobilization (physical and occupational therapy), starting on the day of enrollment, and fifty-five to usual care. (Usual care at the two study sites did not include routine physical therapy for ventilated patients.)

Each day, infusions of sedative agents were interrupted in both groups; by the end of the study, no differences in sedation and analgesia practices were observed in the two groups. In the intervention arm, patients also underwent passive range of motion exercises for all limbs, delivered by a physical and occupational therapist, every morning. Once patient interaction was achieved, sessions began with active assisted exercises in the supine position. If these exercises were tolerated, treatment was advanced to bed mobility activities, including transferring to upright sitting, followed by participation in activities of daily living. Such therapy took place on 87% of days of the study in the intervention group. During mechanical ventilation, the median duration of physical and occupational therapy differed between the groups: median 0.32 hours a day (IQR: 0.17 to 0.48) in the intervention arm and 0 hours a day in the control arm. Therapy commenced at a median of 1.5 days (IQR: 1.0 to 2.1) after intubation in the intervention group versus 7.4 days (IQR: 6.0 to 10.9) in the control group.

The primary end point, the number of patients returning to independent functional status at hospital discharge, was reached by twenty-nine (59%) patients in the intervention group and nineteen (35%) patients in the control group ($p = 0.02$): odds ratio 2.7 (95% CI 1.2 to 6.1). Over the first 28 days of the study, patients in the intervention arm had a higher number of ventilator-free days, 23.5 (IQR:7.4 to 25.6), than did patients in the control group, 21.1 days (IQR:0.0 to 23.8; $p = 0.05$); overall duration of mechanical ventilation was also shorter in the intervention group, 3.4 days (IQR:2.3 to 7.3) versus 6.1 days (IQR:4.0 to 9.6; $p = 0.02$). Use of formal physical and occupational therapy resulted in a higher number of independent activities of daily living and greater unassisted walking distance at hospital discharge than achieved in the control group.

Although efforts to mobilize ventilator-supported patients, including attempts to help them walk while receiving ventilator assistance, have been employed for decades as an aid to weaning,[141] the impressive results achieved by Schweickert et al[176] crystalizes the components of physical and occupational therapy that are crucial to achieve success.

Role of Sedation in Weaning

Pharmacologic agents that produce sedation are almost invariably used in patients receiving mechanical ventilation with the goals of decreasing anxiety and agitation, enhancing patient–ventilator synchronization, and facilitating patient care. Commonly, sedative drugs are administered by means of continuous intravenous infusions. Sedative agents accumulate in the body far beyond the treatment period, especially in critically ill patients, as a result of impaired renal or hepatic function. Sedative agents also hinder the assessment of mental function, leading physicians to suspect organic brain disorders when none exist. To determine whether the accumulation of sedative agents hinders ventilator management, Kress et al[177] undertook an RCT in 128 adult patients receiving mechanical ventilation in a medical ICU. In the intervention arm, an investigator interrupted the infusion of midazolam, propofol, or morphine on a daily basis until the patients were awake and could follow instructions or until they became uncomfortable or agitated. A patient was considered "awake" if the patient was able to perform at least three of the following four actions: open the eyes in response to a voice, use the eyes to follow the investigator, squeeze a hand, and stick out the tongue on request. In the control group, sedative infusions were interrupted only at the discretion of the intensivist.

Daily awakenings resulted in a shorter duration of mechanical ventilation, median of 4.9 days versus 7.3 days in the control group ($p = 0.004$), and shorter ICU stay, 6.4 days versus 9.9 days ($p = 0.02$). Interruption of sedation also reduced the number of diagnostic tests (brain scan, lumbar puncture) ordered to assess changes in mental status, six versus sixteen in the control group ($p = 0.02$).

Girard et al[178] extended these findings by combining daily interruption of sedation with spontaneous breathing trials.

The investigators randomized 336 ventilated patients to an intervention arm, consisting of paired use of sedative interruption and systematic use of spontaneous breathing trials versus a control arm, consisting of spontaneous breathing trials and the administration sedative agents at the discretion of the intensivist. The paired intervention resulted in more days breathing without ventilator assistance (3.1 days in the 28-day study, 95% CI 0.7 to 5.6), and earlier discharge from both the ICU and hospital. In an accompanying editorial, Brochard[179] pointed out several problems with the experimental design of the study—the absence of a requirement to stop sedatives in the control group before a spontaneous breathing trial, the timing of weaning onset, and markedly increased rate of failed weaning trials in the control arm—that render the interpretation of this study highly problematic.

Strøm et al[180] went a step further than previous investigators and sought to determine whether total withholding of sedative agents would prove superior to daily interruption of sedation. Patients in the control arm received propofol for the first 48 hours and midazolam thereafter, titrated to reach a Ramsay score of 3 to 4; sedation was interrupted every day until patients were awake. Patients in the intervention arm received bolus doses of morphine (2.5 or 5 mg), as did patients in the control arm, but did not receive intravenous infusions of sedatives or analgesics. No sedation was associated with significantly more days without ventilator assistance (mean: 4.2 days, 95% CI 0.3 to 8.1 days), and earlier discharge from both the ICU and hospital. Agitated delirium was more frequent in the intervention group than in the control group (20% vs. 7%; $p = 0.04$), and the use of haloperidol was also more frequent (35% vs. 14%). Moreover, an extra person was needed at the bedside for 2.5 days to comfort and reassure patients more often in the intervention group than in the control group (20% vs. 5%). Follow-up data have not been published on these patients to determine whether they are more or less prone to posttraumatic stress disorder or other psychological problems.

CONCLUSION

The hazards of mechanical ventilation make it imperative to wean patients at the earliest possible time in their clinical course. Premature weaning attempts, however, cause considerable respiratory distress that may set back a patient's course. Premature extubation is also hazardous. To minimize both delayed weaning and premature extubation, a two-step diagnostic strategy is recommended: measurement of weaning predictors followed by a weaning trial. Because each step constitutes a diagnostic test, clinicians must be mindful of the scientific principles of clinical decision making when interpreting the information generated by each step.

The critical step is for the physician to contemplate the possibility that a patient just might be able to tolerate weaning. Such diagnostic triggering is facilitated through use of a screening test, which is the rationale for measurement of weaning predictor tests. It is important not to postpone this first step by waiting for a more complex diagnostic test, such as a T-tube trial. A positive result on a screening test (weaning predictor test) is followed by a confirmatory test (weaning trial), to increase the likelihood that a patient will tolerate extubation.

Many complex facets of pulmonary pathophysiology impinge on weaning management. Thus, weaning requires individualized care at a high level of sophistication. Few other activities undertaken by physicians in the ICU require a greater intellectual input and carry greater potential for improving patient outcome than the application of physiologic principles in the weaning of patients.

EXTUBATION

Martin J. Tobin
Franco Laghi

It is easy to merge decisions about extubation with decisions about weaning in everyday practice. Indeed, much patient mismanagement is caused by conflating these two subjects. But the conflation is not confined to clinicians. Many researchers have also merged the two subjects, such as using weaning predictors to predict reintubation in a patient who has already tolerated a weaning trial. The result is scientific confusion.

When a patient tolerates a weaning trial without distress, a clinician feels reasonably confident that the patient will be able to sustain spontaneous ventilation after extubation. But this is not the only consideration. The clinician also has to consider whether the patient will be able to maintain a patent upper airway after extubation.

Removal of an endotracheal tube is typically performed under controlled conditions. The patient has satisfactorily tolerated a weaning trial. Enteral feeding is temporally withheld for approximately 4 hours. The patient is usually positioned in a sitting posture. The endotracheal tube, mouth, and upper airway are suctioned, paying attention to the collection of secretions above an inflated cuff. Some clinicians recommend keeping a suction catheter in place (aiming for the catheter to barely protrude from the distal end of the endotracheal tube) as the cuff is deflated; this step is taken in an attempt to capture any secretions sitting on top of an inflated cuff, which might fall into the airway after deflating the cuff. Some clinicians forcefully inflate the lungs with an Ambu Bag immediately before pulling out the endotracheal tube, hoping that the larger than usual ensuing exhalation will push secretions upward and outward. After removal of the endotracheal tube, the patient is given supplemental oxygen, titrated to oxygen saturation (S_{O_2}), being particularly cautious with a patient who is at risk of carbon dioxide retention. Patients may have impaired airway protection reflexes immediately after extubation. If speech is impaired for more than 24 hours, indirect laryngoscopy should be undertaken to assess vocal cord function. Oral intake should be delayed in patients who have been intubated for a prolonged period.

In the hours following extubation, patients are carefully monitored for ability to protect the upper airway and sustain ventilation. Most patients will display progressive improvement, allowing the discontinuation of supplemental oxygen and ultimate discharge from the intensive care unit (ICU).

POSTEXTUBATION DISTRESS

Between 2%[1,2] and 30%[3–6] of patients experience respiratory distress in the postextubation period (Table 59-1). Many, but not all, require reinsertion of the endotracheal tube and mechanical ventilation. These patients are commonly classified as *extubation failures*, a term popularized by Demling et al.[7] These investigators defined extubation failure as the need for reintubation within 7 days. Unfortunately, the

meaning of extubation failure varies among authors, leading to scientific confusion. Even when authors employ it as a synonym for reintubation, the period under study varies—within 24, 48, or 72 hours, or as long as 7 days.

Extubation failure is most often defined as the need for reintubation. The corollary of this definition is that all patients who do not require reintubation should be classified as extubation successes no matter how much difficulty they experience. A number of patients develop stridor after extubation, which resolves with inhalation of racemic epinephrine or other therapy without requiring reintubation. If extubation failure is defined as reintubation, such patients should be excluded. But if researchers are investigating the development of respiratory distress after extubation, all patients with significant postextubation stridor should be included. Much confusion could be avoided if researchers used the term *reintubation* when that is their sole criterion for extubation failure. If researchers use the term *extubation failure*, it seems logical to assume that their study population includes some patients with postextubation distress who did not require reintubation. In many reports, however, researchers do not make it clear which approach they are adopting—whether (or not) their category of extubation failure included some patients who developed distress after extubation but who did not require reintubation.

Investigators have variably classified patients who required noninvasive ventilation (NIV) after extubation as satisfying or not satisfying the definition of extubation failure. De Lassence et al[8] specified that they excluded patients who were managed by NIV in a cohort of extubation failure patients. Maldonado et al[5] included patients managed by NIV among their group of extubation failures, as did Haberthur

et al[9] and Jiang et al.[10] Moreover, Haberthur et al[9] extended the term *extubation failure* to include patients experiencing unjustified delay in extubation with one particular weaning technique if that patient tolerated extubation after being switched to an alternative weaning technique.

If patients die from a cardiorespiratory cause without being reintubated, it seems unscientific to classify them as extubation successes. Some authors[11] have specified that their definition of extubation failure included both the need for reintubation or unexpected death within 72 hours. Most authors, however, do not address this issue. Some extubated patients refuse reintubation (as part of a decision for withdrawal of life support) and die. How should these patients be classified? Demling et al[7] classified fatal outcomes as extubation failures, Epstein et al[12] excluded such patients from their group of extubation failures, and Namen et al[13] classified such patients (who died) as extubation successes.

How should patients who experience unplanned extubation followed by reintubation be classified? In a group of forty-two extubation failures, Epstein et al[12] included four unplanned extubations (who required reintubation within 72 hours) because these occurred while a weaning trial was in progress, but excluded sixteen other unplanned extubations (requiring immediate extubation) because these did not occur during weaning trials. If patients are extubated because of a defective endotracheal tube and then reintubated, how should they be classified? Epstein and Ciubotaru[14] excluded such patients, but many authors do not state clearly how such patients are classified.

Some patients may be inappropriately reintubated because of poor clinical judgment. What criteria should be set for judging a reintubation as appropriate? Epstein and Ciubotaru[14] listed the following criteria: increase in arterial carbon dioxide tension (P_{CO_2}) greater than 10 mm Hg and decrease in pH of 0.10; arterial oxygen tension (P_{O_2}) less than 60 mm Hg or less than 90% with an inspired oxygen concentration (FI_{O_2}) greater than 0.50; signs of increased work of breathing (high respiratory rate, accessory muscle use, or paradoxical breathing); and inability to protect the airway (secondary to upper airway obstruction or excess secretions). Many of these criteria are similar to those used for defining weaning failure, but it is more difficult to ensure their rigorous and consistent application as criteria for reintubation. Weaning failure typically occurs under controlled conditions, usually within 1 hour of starting a weaning trial. Reintubation for postextubation distress may not occur until many hours after extubation, and the listing of satisfied criteria may not be entered on a data form until hours after the event.

CAUSES AND PATHOPHYSIOLOGY OF POSTEXTUBATION DISTRESS

The listed indications for reintubation vary considerably from study to study. Of these, postextubation stridor has attracted the most attention.

FIGURE 59-1 Mild postextubation laryngeal edema as seen with a rigid laryngoscope. (Used, with permission, from Antonaglia et al.[102])

Postextubation Upper Airway Obstruction

A number of investigators have reported that upper airway obstruction accounts for approximately 15% of patients requiring reintubation (15% in the study of Epstein and Ciubotaru;[14] 14.7% in that of Esteban et al;[15] and 15.4% in that of Smina et al[16]). These investigators, however, did not report what proportion of patients who developed clinical manifestations of upper airway obstruction did not require reintubation. Upper airway obstruction may result from edema of the subglottic area or the vocal cords, reflex closure of the vocal cords (laryngospasm), or compromise of the tracheal lumen (tracheomalacia or compression by a hematoma) (Figs. 59-1 and 59-2). The laryngeal edema that occurs in intubated

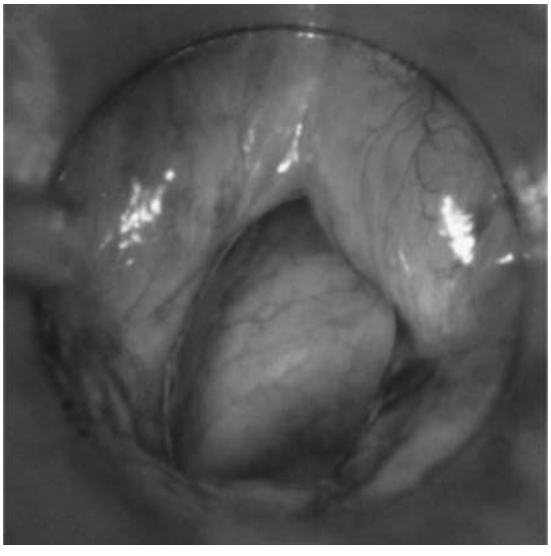

FIGURE 59-2 Moderately severe postextubation laryngeal edema as seen with a rigid laryngoscope. (Used, with permission, from Antonaglia et al.[102])

patients is believed to arise from direct mechanical trauma to the larynx by the endotracheal tube. Almost every patient intubated for 4 days or more develops laryngeal edema and mucosal ulcerations, usually located posterior to the level of the vocal cords, where the tube exerts the highest pressure.[17] Laryngeal edema is usually transient and self-limiting, and most of the lesions resolve within 1 month.[18]

Upper airway obstruction causes stridor only if the patient is capable of generating sufficient airflow; if airflow is insufficient, obstruction may cause hypercapnia, hypoxemia, or paradoxical breathing. Of 110 extubated patients, Sandhu et al[19] observed that thirteen (11.8%) developed stridor, but less than half of the patients with stridor (6/13) required reintubation (no patient required reintubation for any reason other than stridor in this series). Jaber et al[20] observed stridor in thirteen of 112 (11.6%) extubated patients, and nine of the thirteen required reintubation (only 2% [2/99] of patients without stridor required reintubation). Francois et al[21] undertook a randomized controlled trial of the effect of steroids on postextubation laryngeal edema in 761 critically ill patients requiring at least 36 hours of mechanical ventilation. Of the 343 patients in the placebo arm, seventy-six (22%) exhibited features of postextubation laryngeal edema. Twenty-six of the 343 extubated patients (8%) required reintubation, and the reintubation was linked to laryngeal edema in fourteen (54%[14/26]) of these patients. Forty-six percent of the patients with postextubation stridor or endoscopic laryngeal edema did not require reintubation, indicating that the development of stridor is not a particularly strong predictor of the need for reintubation.[17]

In the above studies, upper airway obstruction was typically diagnosed on the basis of clinical manifestations. De Bast et al[22] undertook fiber-optic examination before reintubation or directly inspected the glottis during reintubation to confirm the presence of laryngeal edema. Of seventy-six patients who had been intubated for at least 12 hours, fourteen required reintubation within 24 hours of extubation (reintubation rate, 18.4%). Of these fourteen patients, eight (57.1%) had laryngeal edema.

When upper airway obstruction occurs, it is typically manifested soon after extubation. Of the seventy-six patients who developed features of laryngeal edema in the study of Francois et al,[21] 47% (36/76) developed it within 5 minutes of extubation, 34% (26/76) developed it between 6 and 30 minutes after extubation, and 18% (14/76) developed it 30 minutes or longer after extubation.

Although laryngeal edema can develop as early as 6 hours after intubation,[22] many, but not all,[23] investigators have noted that the rate of postextubation stridor increases in proportion to the duration of ventilation. Jaber et al[20] observed that duration of intubation was longer in thirteen patients with stridor than in ninety-nine patients without stridor: 10.9 versus 5.5 days. Sandhu et al[19] likewise observed a longer duration of intubation in six patients who developed postextubation stridor than in ninety-seven patients who did not: 6.5 ± 1.9 versus 2.6 ± 2.6 days. Darmon et al[24] observed that stridor was more common among patients intubated for longer than 36 hours than among patients intubated for a shorter time: 7.2% (25/346) versus 0.9% (3/317).

Women are more susceptible to postextubation stridor than men, and the rate may vary with ethnicity. In a series from France, Darmon et al[24] observed stridor in 7.4% (20/284) of women and 2.1% (8/379) of men. In a series from Taiwan, Ho et al[23] observed stridor in 39% (7/18) of women and 17% (10/59) of men.

Other risk factors associated with the development of laryngeal edema include traumatic intubation, excessive tube size, excessive tube mobility secondary to insufficient fixation, a patient fighting against the tube or trying to speak, excessive pressure in the cuff, too frequent or too aggressive tracheal suctioning, occurrence of infections or hypotension, and the presence of a nasogastric tube that predisposes to gastroesophageal reflux.[22] It is also possible that a biochemical reaction between the tube material and the airway mucosa may cause laryngeal edema.[22] Compared with the ninety-nine patients without stridor, the thirteen patients who developed stridor in the series of Jaber et al[20] were more likely to have the following: a traumatic and/or difficult intubation (54% vs. 7%), a history of self-extubation (38% vs. 4%), a higher balloon cuff pressure (83 vs. 40 cm H_2O), a higher simplified acute physiology score (SAPS) II score (50 vs. 38), and a medical rather than a surgical reason for admission (46% vs. 18%).

Other Causes of Postextubation Distress

Conditions other than upper airway obstruction that cause postextubation distress vary from study to study. In a report on reasons for reintubation, Epstein and Ciubotaru[14] noted upper airway obstruction in 15%; other reasons for reintubation included respiratory failure (28%), congestive heart failure (23%), aspiration or excessive secretions (16%), encephalopathy (9%), and other conditions (8%). The frequency of a particular reason differs among studies. For example, cardiac failure accounted for 23% of the cases of Epstein and Ciubotaru[14] and 6.6% (4/61) of the cases of Esteban et al,[15] but none of the cases of Smina et al[16] or De Bast et al.[22] Because of the limited rigor of these studies, there is little point in attempting a more detailed analysis of the relative incidence of other causes of reintubation.

Pathophysiology

None of the studies of reasons for postextubation cardiorespiratory distress can be considered as studies of pathophysiologic mechanisms in the same sense as are studies of the pathophysiology of weaning failure. For studies of postextubation distress, investigators filled out case report forms. These forms constitute post hoc incident reports completed after some event. In many cases, investigators are making a best guess as to what might explain a patient's deterioration.

In contrast, research into the pathophysiology of weaning failure is based on the simultaneous recording of several signals, starting before a weaning trial and continuing until after its completion. In this way, it is possible to understand the relative roles of control of breathing, respiratory muscle activity, derangements of lung and chest wall mechanics, gas exchange, and cardiovascular performance in weaning failure. Conducting similar types of studies to delineate the mechanisms of postextubation cardiorespiratory distress will be challenging.

The first challenge is instrumentation. The recording of swings in intrathoracic pressure, as reflected by esophageal pressure, is relatively easy. But on its own, esophageal pressure is of limited value. Derivation of most indices, such as airway resistance, compliance, and intrinsic positive end-expiratory pressure, require a simultaneous measurement of airflow. It is extremely difficult to obtain a meaningful measure of airflow or tidal volume in a recently extubated patient.[25] The use of a mouthpiece or face mask causes marked distortion of the breathing pattern. Inductive plethysmography provides a means for overcoming this problem. For example, Tobin et al[26] used this technique to study changes in breathing pattern in ten patients at the point of extubation (Fig. 59-3). During the first 15 minutes after extubation, both minute ventilation and mean inspiratory flow (a measure of respiratory motor output) increased, accompanied by a decrease in the degree of abdominal paradox. By the end of the first hour after extubation, respiratory drive and minute ventilation had returned to preextubation levels. No further change in breathing pattern was observed over the subsequent 24 hours. The investigators did not study any patients who developed postextubation distress. When inductive plethysmography is combined with esophageal pressure recordings, great care is required to ensure that the two signals are perfectly aligned. The smallest misalignment will cause major errors in estimates of intrinsic positive end-expiratory pressure and other measures of lung mechanics. A requirement not faced by researchers studying the pathophysiology of weaning failure is the need to record the development of laryngeal obstruction. As such, additional research instrumentation includes fiber-optic endoscopy.

Perhaps an even greater challenge than the instrumentation is the timing. Weaning failure almost invariably occurs within the first hour of attempted spontaneous breathing. The time course for the development of postextubation cardiorespiratory distress extends over a longer span. In the study of Epstein and Ciubotaru,[14] for example, only 33% of reintubations occurred within the first 12 hours after extubation, and 42% occurred after 24 hours.

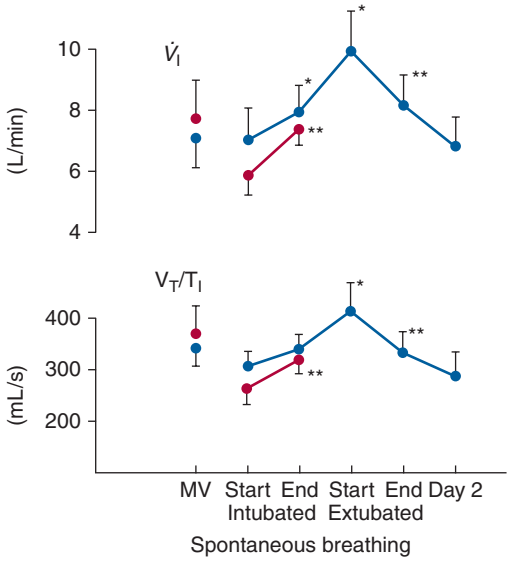

FIGURE 59-3 Recordings of minute ventilation ($\dot{V}_I$) and mean inspiratory flow (V_T/T_I), a measure of respiratory motor output, during mechanical ventilation (*MV*), at the start and end of a T-tube trial, the first 15 minutes after extubation, 45 to 60 minutes after extubation, and 24 hours after extubation. Ten patients who tolerated the T-tube trial and were extubated are shown in *blue* and seven patients who failed the T-tube trial and were reconnected to the ventilator are shown in *red*. Bars represent ±1 standard error (SE); *, $p < 0.05$; **, $p < .01$ compared with the value during the immediately preceding time-block of spontaneous breathing. (Used, with permission, from Tobin et al.[26])

CONSEQUENCES OF POSTEXTUBATION DISTRESS

Many, but not all,[27] investigators have reported that mortality is many times higher in patients who require reintubation than in patients who tolerate extubation (Table 59-2). Three explanations have been offered to account for the increased mortality: complications associated with the act of reintubation itself; development of a new problem in the interval between extubation and reintubation; and the need for reintubation is simply serving as a marker for a poor prognosis.

Endotracheal intubation is typically performed under elective and controlled conditions. It is more challenging to perform intubation in a patient developing acute distress in the period after extubation. Complications have been reported to occur at the time of reintubation in 15%,[28] 18%,[15] and 28% of patients.[14] In a study of forty consecutive

TABLE 59-2: ASSOCIATION BETWEEN REINTUBATION AND MORTALITY

Reference	Mortality in Reintubated Patients	Mortality in Patients Tolerating Extubation
Daley et al[27]	8%	6.5%
Epstein et al[12]	43%	9.1%
Esteban et al[28]	27%	2.6%
Esteban et al[15]	33%	4.6%
Perren et al[88]	33%	3.6%
Thille et al[31]	50%	4.9%

patients requiring reintubation (for any reason), Torres et al[29] reported that 47% (19/40) developed nosocomial pneumonia after reintubation, as compared with 10% of matched control patients (odds ratio [OR]: 5.9). In a study of 297 intubations performed under emergency conditions (in 238 adults), Schwartz et al[30] reported seven deaths (mortality: 2.4%) at the time of or within 30 minutes after intubation; five of the deaths were associated with a systolic blood pressure less than 90 mm Hg. In contrast to the experience of Torres et al,[29] only 4% of patients developed a radiographic infiltrate compatible with a new aspiration pneumonia.[30] In a study by Esteban et al,[15] mortality was no greater among the eleven patients who developed complications at the time of reintubation than in the remaining fifty patients (45.4% and 30.0%, respectively; $p = 0.53$). Based on the above considerations, it seems unlikely that the higher mortality in reintubated patients is a direct consequence of complications associated with the act of reintubation itself.

A second explanation is the development of a new problem during the interval between extubation and reintubation. In support of this possibility is the observation of Epstein and Cibotaru[14] that mortality increases in proportion to the time between extubation and reintubation: mortality of 69% in patients reintubated between 49 and 72 hours after extubation (17% of the group), 24% in patients reintubated in the first 12 hours after extubation (33% of the group), and 39% in patients reintubated between 13 and 24 hours after extubation (25% of the group).

The third explanation for higher mortality in reintubated patients is that reintubation is simply serving as a marker for a poor prognosis. Sicker patients are more likely to undergo reintubation. Epstein and Ciubotaru[14] have argued against this explanation. They note that reintubation continues to have a strong independent effect on mortality even after controlling for generalized severity of illness at weaning onset, comorbidity, age, and need for acute dialysis. It is, however, possible that the need for reintubation is measuring some additional aspect of disease severity not captured by the above variables.

Thille et al[31] have argued that reintubation has a direct and specific effect on patient outcome because it is frequently followed by marked clinical deterioration. They studied twenty-six patients who failed extubation and required reintubation within the subsequent 72 hours; 50% of the reintubated patients died in the ICU. At the time of extubation, the Sequential Organ Function Assessment (SOFA) score was not significantly different between the twenty-six patients who subsequently required reintubation and 142 patients who tolerated extubation. In the first 24 hours after extubation, the SOFA score increased significantly from 3.4 ± 2.9 to 4.7 ± 3.4 in the failed extubation group, mainly as a result of hemodynamic and respiratory deterioration. Patients who tolerated extubation showed an improvement in their SOFA score over the same interval, essentially because of removal of the ventilator. These data suggest that reintubation leads to adverse consequences, and it is not simply a marker for a poor prognosis.

PREDICTORS OF POSTEXTUBATION DISTRESS

Because reintubation causes serious complications in some patients, attempts are made to predict its likely occurrence. A number of physiologic variables have been evaluated for their ability to predict this likelihood. For some patients, the likelihood of reintubation is considered so high that a clinician may proceed to tracheotomy without first attempting extubation.

Ability to Sustain Spontaneous Ventilation

It is extremely uncommon to undertake planned extubation without first assessing a patient's ability to sustain spontaneous ventilation. This assessment typically consists of observing a patient breathing through a T-tube circuit or while assisted by a low level of pressure support or intermittent mandatory ventilation. A weaning trial serves primarily as an additional diagnostic test, with the aim of predicting whether a patient will develop distress after extubation and need reintubation. The predictive accuracy of a weaning trial as a diagnostic test has never been evaluated in a rigorous scientific manner.

A true-positive result of a T-tube trial is defined as a patient who tolerates the trial without distress, is then extubated, and does not require reintubation. The usual rate of reintubation is 15% to 20% (sometimes lower), but higher reintubation rates have been reported by some investigators: 23.5%,[29] 25%,[32] 26.7%,[5] 28.6%,[4] and 29.4%.[3] These false-positive test results mean that the positive-predictive value and specificity of passing a T-tube trial in predicting that a patient will not require reintubation is much less than 100%. To measure the false-negative rate would require extubating patients who fail a T-tube trial, and counting how many do not require reintubation. For obvious ethical reasons, we do not know this number. Given the natural caution of physicians, we can confidently assume that it is higher than 0%. As such, sensitivity and negative-predictive value will be less than 100%. It is no surprise that the ability of a T-tube trial to predict reintubation has a sensitivity and specificity of less than 100%; no diagnostic test is perfect. But a weaning trial is not solely used as a diagnostic test for predicting the likelihood of reintubation. The outcome of a weaning trial is also used as a reference standard against which the accuracy of weaning predictor tests are measured.

Weaning Predictor Tests

Several investigators have investigated the ability of weaning predictor tests to predict the development of distress after extubation. The question posed is along these lines: "Does frequency-to-tidal-volume ratio (f/V_T), or some other predictor test, measured before a T-tube trial, predict the likelihood of reintubation?" To answer this question with

scientific validity, it is imperative that the investigators take clearly defined steps to ensure that clinicians are *not* taking the results of the T-tube trial into account when deciding whether to extubate the study patients. (In other words, a decision to extubate the patient must be taken before the T-tube trial, and must proceed even if the patient exhibits significant distress during the trial.) If researchers allow clinicians to use results of a T-tube trial (done after measurement of the weaning predictor test) when deciding whether or not to proceed with extubation, the researchers need a different experimental design because they are asking a different research question. The question is now, "In what instances do weaning predictor tests override the results of a subsequently undertaken T-tube trial?"

Before we discuss the findings of studies on the use of tests to predict the likelihood of postextubation distress, we ask the reader to undertake a simple thought experiment. You, as the patient's clinician, record f/V_T, and obtain a reading of 60. You then proceed to a T-tube trial. If the patient develops severe distress during the trial, would you extubate the patient? (Please exclude circumstances in which you believe that the internal diameter of the endotracheal tube is the main cause of distress.) We believe that most experienced clinicians will answer"no." Consider another scenario: A resident measures f/V_T in your patient, obtains a value of 120, and proceeds to a T-tube trial. If the patient tolerates the trial without significant distress, would you defer extubation? We believe most experienced clinicians would again answer "no," although they might monitor the postextubation period more closely than if the patient had an f/V_T reading of 90 before the trial.

For both of the preceding scenarios, we believe that few if any experienced clinicians would allow a measurement of f/V_T (made before a T-tube trial) to override a judgment based on how well a patient tolerates a T-tube trial. Given the results of the thought experiments, it makes little sense to undertake research studies of the accuracy of weaning predictor tests (measured before a weaning trial) to forecast a patient's likely need for reintubation (in a patient who passes a weaning trial). It makes even less sense when one considers that a clinician's action based on the patient's performance during the weaning trial will have inevitably muddied the experimental waters. Let us consider a patient in whom a weaning predictor test predicts a high likelihood of respiratory distress. A weaning trial is nevertheless undertaken. The patient develops distress, and so is not extubated. By excluding such patients from a study, the investigators are markedly underestimating the true-negative rate of the test for predicting distress after extubation (where the test predicts distress and the patient actually develops distress).

It is difficult to understand why so many investigators have undertaken this type of research. We suspect they have been seduced by affirmative answers to two subsidiary questions. "Do patients with satisfactory weaning predictors usually tolerate a spontaneous breathing trial?" Yes. "Do patients who tolerate a spontaneous breathing trial usually avoid reintubation?" Yes. It might seem logical to conflate these two issues, and ask:"Do patients with satisfactory weaning predictors usually avoid reintubation?" The only way to address this question in a scientific manner is to measure weaning predictors and extubate the patient without an intervening weaning trial. Zeggwagh et al[33] are the only group of investigators to undertake such a study.

The investigators prospectively studied 101 patients (ventilated for 10.4 ± 10.3 days) at the point that their ICU physicians contemplated weaning. They measured a series of physiologic measurements during 2 minutes of spontaneous breathing; the results of these measurements were not communicated to the primary team. The team then extubated the patients without first undertaking any form of weaning trial. The extubation decision was made by the ICU team, based on the following criteria: improvement or resolution of the condition precipitating the need for mechanical ventilation; good level of consciousness with cessation of all sedative agents; temperature less than 38°C (100.4°F); respiratory frequency less than 35 breaths/min; S_{O_2} greater than 90% on FI_{O_2} equal to or less than 0.40; hemodynamic stability; and the absence of electrolyte disorders, acid–base disturbance, or hemoglobin less than 10 g/dL. Reintubation was necessary in 37% of the patients. Several variables predicted the need for reintubation with a reasonable degree of accuracy. For example, f/V_T had a sensitivity of 0.77 and a specificity of 0.79, with an area under a receiver operating curve (ROC) curve of 0.81 ± 0.06; maximum expiratory pressure had a sensitivity of 0.52 and a specificity of 0.92, with an area under an ROC curve of 0.73 ± 0.07. The investigators developed a model based on three variables: f/V_T, maximum expiratory pressure, and vital capacity. The area under the ROC curve for the model was 0.91 ± 0.04 for a development data series and 0.86 ± 0.06 for a validation data series.

This study by Zeggwagh et al[33] suggests that undertaking a weaning trial before extubation is useful because their rate of reintubation is about double that reported in studies in which weaning trials precede extubation. The clinicians in the study by Zeggwagh et al[33] based their decision for extubation on only the most rudimentary clinical assessment. If the clinicians had made the decision to extubate using more sophisticated physiologic predictors (but still did not undertake a weaning trial), it is likely that the rate of reintubation would have been lower. The accuracy of weaning predictors in this study contrasts sharply with their accuracy in studies in which the investigators permitted a weaning trial (which altered clinician's extubation decisions) between measurement of the predictors and extubation (see Table 58-1 in Chapter 58).

Cuff-Leak Test

Some patients show satisfactory recovery of lung function but develop upper airway obstruction after extubation. The difficulty in defining the relationship between upper airway injury and postextubation stridor is that the presence of the endotracheal tube precludes direct visualization of the upper

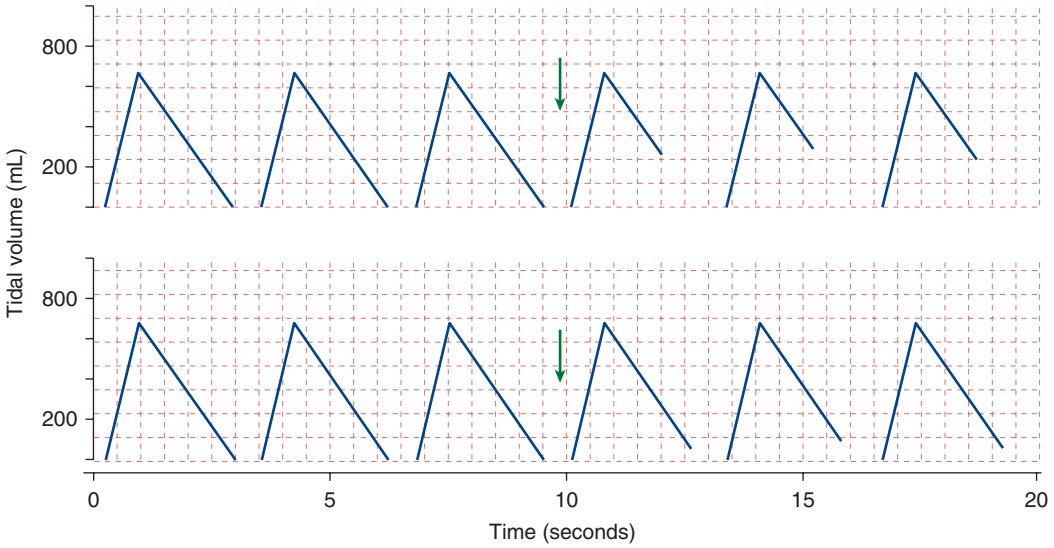

FIGURE 59-4 Cuff-leak test. Schematic of tidal volume during inhalation (*up going*) and exhalation (*down going*) in two patients before and after deflation of the cuff on the endotracheal tube (*arrow*). *Upper panel:* The patient develops a large leak after cuff deflation (positive-test result), as signified by the expired tidal volume being markedly smaller than the inspired tidal volume. *Lower panel:* The patient develops a small leak after cuff deflation (negative-test result), as signified by the expired tidal volume being only approximately 40 to 75 mL or 6% to 12% less than the inspired tidal volume.

airway before extubation. Several investigators have tested the hypothesis that the volume of air leaking around the outside of an endotracheal tube on deflating the balloon cuff will be inversely related to the degree of laryngeal obstruction generated by laryngeal edema (Fig. 59-4). The idea was first reported by Adderley and Mullins[34] who studied thirty-one planned extubations in twenty-eight children with croup. After extubation, reintubation was required in 13% (3/23) of children who had an audible leak (on coughing or when plateau pressure was 40 cm H_2O), and reintubation was required in 38% (3/8) of children without a leak. The cuff-leak test has since been evaluated with varying degrees of scientific rigor (Table 59-3).

Miller and Cole[35] undertook the first systematic evaluation of the cuff-leak test. They studied 100 intubations in eighty-eight ventilated patients. During assist-control ventilation, they noted that the set inspired tidal volume (V_T) and displayed expired V_T were always within 20 mL of each other (they did not state the volume setting). To measure the leak, they deflated the cuff and recorded expiratory V_T over the subsequent six cycles; they used the average of the three lowest values to calculate the leak. After extubation, 17% of patients required reintubation. Of the six patients who developed stridor, reintubation was required in three. The leak (measured during the 24 hours before extubation) was smaller in patients who subsequently developed

[a]Number of extubations.

postextubation stridor than in patients who did not: 180 ± 157 versus 360 ± 157 mL. ROC curve analysis indicated that a leak of less than 110 mL provided the best threshold for predicting postextubation stridor. A leak of less than 110 mL had a sensitivity of 0.67, a specificity of 0.99, and a positive-predictive value 0.80 (negative-predictive value was not reported).

A representative example of the methodology employed in subsequent investigations is illustrated by the approach used by Jaber et al[20] who evaluated the cuff-leak test in 112 patients. The leak was smaller in thirteen patients who developed postextubation stridor than in the ninety-nine patients who did not develop stridor after extubation: 59 ± 92 versus 372 ± 170 mL (with V_T 10 to 12 mL/kg during assist-control ventilation); expressed in terms of relative volumes, 9 ± 3% versus 56 ± 20%. Reintubation was required in 69.2% (9/13) of the patients with stridor as compared with 2.0% (2/99) of patients without stridor. They used ROC curve analysis to find the best threshold; they considered a true-positive test as a leak less than 130 mL or less than 12% of inspired V_T together with postextubation stridor. At this threshold, sensitivity was 0.85, specificity 0.95, positive-predictive value 0.69, and negative-predictive value 0.98.

A more rigorous methodology was employed by De Bast et al[22] who prospectively studied seventy-six patients who had been intubated 12 or more hours. They measured cuff leak as a percentage:

$$[(\text{Expired } V_T \text{ with cuff inflated} - \text{Expired } V_T \text{ with cuff deflated})/\text{Expired } V_T \text{ with cuff inflated}] \times 100.$$

They took the average of six measurements that varied by less than 30%. The measurements were not available to the staff in charge of patients. If patients developed stridor associated with signs of respiratory distress within 24 hours of extubation and required reintubation, laryngeal edema was confirmed or excluded by fiber-optic examination before the reintubation, or by direct examination of the glottis during reintubation. The investigators excluded patients who were reintubated for reasons other than laryngeal edema.

Within the first 24 hours, 10.5% (8/76) of the patients of De Bast et al[22] required reintubation for laryngeal edema. These patients had smaller leaks than did the other patients: 9% (3, 18; twenty-fifth, seventy-fifth percentiles) versus 35% (13, 53; twenty-fifth, seventy-fifth percentiles). (Of the ten patients who developed postextubation stridor, eight were reintubated.) ROC curve analysis revealed that the best threshold was a leak of 15.5%. This threshold had a sensitivity 0.75, specificity 0.72, positive-predictive value 0.25, and negative-predictive value 0.96. The low positive-predictive value, 0.25, indicates that 75% of the patients with a leak less than 15.5% were successfully extubated (without laryngeal edema or requiring reintubation). Thus, a low leak volume should not be used to postpone extubation indefinitely. The negative-predictive value of 0.96 means that when patients exhibit a large leak (a negative test result), they are not likely to require reintubation (because of laryngeal edema). A leak greater than 23% excluded all patients who required reintubation because of laryngeal edema.

Chung et al[36] also used endoscopic examination of the upper airway in a study involving ninety-five patients. The average duration of translaryngeal intubation was quite long, 28.1 ± 17.6 (standard deviation [SD]) days. Employing video bronchoscopy, the Taiwanese investigators observed a high rate of severe laryngeal edema, 36.8% (35/95). They used ROC curve analysis to select the most discriminatory cuff-leak threshold. At a threshold volume of 140 mL, 39% (37/95) of patients had positive test results. The performance of the cuff-leak test was superior to that observed by most other investigators (see Table 59-3).

Prinianakis et al[37] undertook a study to determine the physiologic determinants of the volume being leaked when the cuff-leak test is performed. The volume of the leak is calculated by obtaining several measurements of expired V_T after deflation of the cuff and subtracting the average value from the set inspired V_T. With the cuff deflated, however, the inspiratory V_T reaching the alveoli is also decreased. Thus, the measured leak has both inspiratory and expiratory components. By adding an inspiratory pause, Prinianakis et al[37] measured expiratory leak unaffected by the inspiratory leak. In fifteen critically ill patients receiving neuromuscular blocking agents, the expiratory leak was consistently lower than the total leak. To elucidate the physiologic determinants of the expiratory leak, the investigators employed a mechanical lung model. The cross-sectional area around an endotracheal tube was not the only factor affecting the magnitude of a leak, it was also influenced by the inspiratory component. The total leak was inversely related to inspiratory flow and system compliance. Although this study explains some of the imprecision of the cuff-leak test, it does not mean that clinicians should start using a more pure measure of expiratory leak in everyday practice. Prinianakis et al[37] did not compare the accuracy of the more pure measure of expiratory leak in predicting the occurrence of postextubation laryngeal edema or the need for reintubation.

In summary, the studies of the cuff-leak test are of varying quality. The method for performing the test has not been standardized. In particular, none of the investigators addressed the setting of inspired V_T, which may influence the size of the leak. The method for quantifying the leak varies between absolute units (milliliters) and percentage of inspired V_T. The outcome criterion is not always clearly stated: rate of reintubation for any reason, occurrence of stridor of any severity, or occurrence of stridor that requires reintubation. The rates of stridor vary considerably among studies, suggesting that investigators used different criteria (admittedly, it is not obvious that severity of stridor can be graded in any reproducible manner). Only De Bast et al[22] and Chung et al[36] used an objective method (fiber-optic endoscopy) to verify the presence of laryngeal edema.

In some studies, it is not clear whether the investigators carefully excluded reasons for reintubation other than stridor. If a patient is reintubated because of left-ventricular failure, it is not logical to expect the cuff-leak test to predict such

an event. What is the best reference standard? Should a true-positive test result be restricted to postextubation stridor that requires reintubation? Is it important to predict the development of postextubation stridor that will respond to aerosolized epinephrine? The manner of reporting test performance is not consistent. The thresholds for defining a significant leak vary. All calculations of test performance are inevitably overestimates, because none of the investigators split their data set into training and validation subsets. A fundamental problem with all of the studies is that the leak criterion used to define a positive test has been based on the assumption that the clinical consequences of false-positive and false-negative results are equal. Instead, physicians need to customize the threshold value according to the clinical circumstances. In cases where tracheal intubation is expected to be difficult, physicians may use a higher leak volume as the threshold for a positive test result. Conversely, when there is greater fear of the hazards of delayed extubation, physicians may accept a lower leak volume as the threshold for a positive test result.

Secretions and Cough

A proportion of patients fail either a weaning attempt or an extubation attempt because of excessive airway secretions. This proportion varies among reports, largely because there is no consistent definition of "excessive secretions" or even how best to quantify secretions. If one quantifies secretions according to the volume obtained by suctioning over a fixed time interval, a patient who coughs and expels secretions without difficulty may get classified as having a greater secretion problem than a patient who has thick viscid secretions that cannot be dislodged from the lower airways.

The act of suctioning per se is associated with a number of serious complications, such as life-threatening hypoxemia, mucosal trauma, hemorrhage, bronchoconstriction, atelectasis, cardiac arrhythmias, and even cardiac arrest.[38–41] Jubran and Tobin[42] investigated the possibility that a sawtooth pattern on the flow-volume curve might provide a noninvasive means of detecting secretions. In fifty intubated patients, the presence of a sawtooth pattern on flow-volume curves recorded during 1 minute of spontaneous breathing was a strong predictor of the presence of secretions (positive-predictive value: 94%), and the absence of this pattern suggested that secretions were unlikely to be present (negative-predictive value: 77%) (Fig. 59-5). Expressed in terms of likelihood ratios, a sawtooth pattern was approximately six to eight times more likely to be found in patients who had secretions than in patients without secretions. Conversely, a smooth flow-volume curve was about one-quarter as likely to be found in patients with secretions as in those without secretions. Clinical examination had much higher false-positive and false-negative rates (42% and 43%, respectively) than the flow-volume curves (12% and 14%, respectively). Accordingly, reliance on clinical examination will lead to unnecessary suctioning in patients without secretions and inadequate suctioning in patients with secretions.

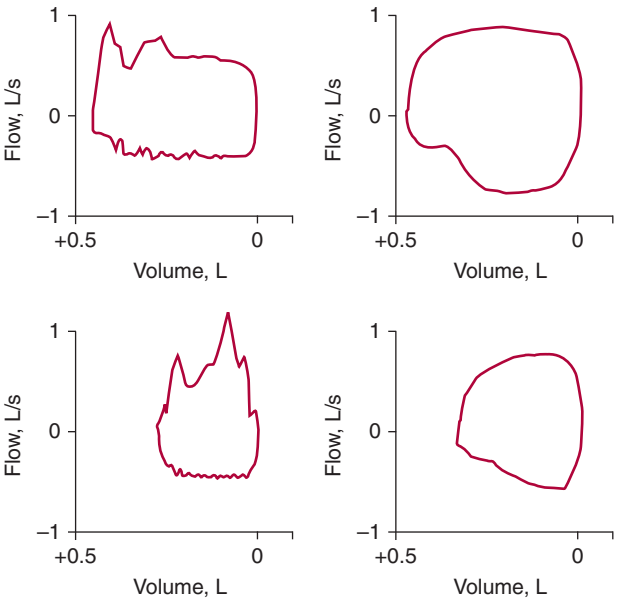

FIGURE 59-5 *Left panels, upper and lower*: Inspiratory and expiratory flow-volume curves obtained in two patients with secretions exhibit a sawtooth pattern. *Right panels, upper and lower*: Flow-volume curves obtained in two patients without secretions have a smooth contour. (Modified, with permission, from Jubran and Tobin.[42])

Measurement of secretions has been evaluated as a predictor of postextubation distress. Khamiees et al[43] attempted to quantify cough strength by placing a white card at 1 to 2 cm from the end of the endotracheal tube and requesting the patient to cough as many as three to four times just before extubation. Any wetness on the card was classified as a positive test (assessment was made by a single observer). This test was seen as a test of cough strength and not of the amount of secretions present. They studied 100 extubations in ninety-one patients; eighteen patients were classified as extubation failures and eleven were reintubated within 72 hours of extubation (the criteria for classifying the other seven patients as extubation failures are not clear). Extubation failure was three times more likely in patients with a negative white-card test (no secretions coughed onto the card). Three other measures also predicted extubation failure. Extubation failure was four times more likely among patients who had a weak or absent cough than in patients with a moderate or strong cough. Extubation failure was eight times more likely in patients classified as having moderate or abundant secretions by the nursing staff in the 4 to 6 hours preceding extubation than in patients with absent or mild secretions. Extubation failure was sixteen times more likely among patients whose secretions required suctioning every 2 hours or less.

Smina et al[16] of the same research group studied the ability to predict reintubation after 115 extubations in ninety-five patients (on this occasion, the investigators specify that extubation failure was synonymous with reintubation). Reintubation within 72 hours was required in 11.3%. The

magnitude of secretions was not associated with extubation failure, which contrasts with their previous report that extubation failure was increased sixteen times if patients required frequent suctioning. This failure to reproduce an earlier observation illustrates a common problem with all studies of clinical predictors. After the report of findings of an initial study, physicians modify their approach to a particular problem; in statistical terminology, clinicians change their pretest probability (based on the report). When a research team reinvestigates the same phenomenon in a new group of patients, they fail to reproduce the original finding. Many patients in the second study who had secretions were not advanced to extubation, leading to a decrease in the number of true-positive test results. The study of Khamiees et al[43] indicated that frequent suctioning was associated with a high reintubation rate. Smina et al,[16] however, found that only 4% of patients in their follow-up study had greater than 20 mL of secretions per hour before extubation. Clearly, physicians in the second study had reduced the number of extubations attempted in patients with larger volumes of secretions. The physicians had altered their pretest probability of extubation failure based on the need for frequent suctioning. The physicians refused to advance such patients to extubation (test-referral bias), and thus, the results of the study give an erroneous impression that frequent suctioning is not a good predictor of reintubation.

Maury et al[44] hypothesized that the occurrence of a cough in the first few seconds after complete deflation of the cuff on an endotracheal tube results from secretions, which had previously accumulated above the cuff and had now passed into the lower airways. They reasoned that the presence of a cough associated with respiratory gurgling (heard without a stethoscope and related to secretions) upon cuff deflation would indicate patency of the upper airway, whereas the absence of a cough would suggest upper airway edema—the same line of thinking on which the cuff-leak test is premised. They tested the hypothesis during 115 extubations in ninety-nine patients. The absence of a cough following cuff deflation was a strong predictor of postextubation stridor (negative predictive value: 0.98); positive-predictive value, however, was only 0.12.

Neurologic Assessment

Some ventilated patients demonstrate good respiratory function and tolerate a T-tube trial without distress, yet their physicians are reluctant to extubate them because they fear that the patients will not be able to protect their airway after extubation. Although widely used, the term *protecting the airway* is rarely clearly defined. We take it to mean that a patient has unsatisfactory neural control over the airway, such that the tongue (of a recumbent patient) may fall back and occlude the airway lumen (as happens in patients with sleep apnea), or the patient has impaired laryngeal (and other upper airway) reflexes, placing the patient at risk of aspiration of secretions (from the mouth and airways) or ingested food.

Concern about protecting the airway most often arises in a patient with evidence of brain injury. Three groups of investigators have studied the role of brain function in patients being considered for extubation. The most rigorous study is that by Coplin et al,[45] who studied 136 brain-injury patients. They evaluated patients for extubation using a broad screen: absence of neurologic deterioration on physical examination; intracranial pressure less than 20 mm Hg; satisfactory oxygenation, lung mechanics, f/V_T, blood pressure, and heart rate; and absence of a specific indication for mechanical ventilation (such as surgery planned within the subsequent 72 hours).

Of the 136 patients, 72.8% (99/136) were extubated within 48 hours of meeting the above readiness criteria; the other 27.2% (37/136) remained intubated for a median of 3 days (range: 2 to 19 days). They defined a delay in extubation as the time from meeting readiness criteria to the time of extubation, but subtracted 48 hours (to allow for time needed for communication among caregivers). Neurologic evaluation based on the Glasgow Coma Scale (GCS) score was performed daily. (This scale ranges from 3 to 15, with 15 indicating the best brain function and 3 indicating severe brain dysfunction; a score ≥13 indicates *possible* mild brain injury, 9 to 12 moderate injury, and ≤8 severe brain injury.)

Sixty patients were judged comatose (score ≤8 on the GCS) on the day of meeting extubation readiness criteria; extubation was delayed in 48.3% (29/60) as compared with 10.5% (8/76) of patients not classified as comatose. The two groups, however, exhibited considerable overlap. Of sixty comatose patients (score ≤8), 51.7% (31/60) were extubated without delay. Indeed, among patients with more severe brain injury, with GCS scores of 4 and lower, 40% (4/10) were extubated without delay. Conversely, 10.5% (8/76) of patients with scores ≥9 experienced delayed extubation. Coplin et al[45] assessed whether the decision to extubate was influenced by change in neurologic status over time: 57% (21/37) of patients improved between the day of meeting the readiness criteria and extubation, but the remaining 43% showed no change or deterioration in neurologic function.

Absence of a gag reflex has been considered a contraindication to extubation in the past. Approximately 20% of healthy people, however, do not have a gag reflex, and aspiration pneumonia may still occur in people who do.[46] The importance of the gag reflex in the extubation period was addressed by Coplin et al:[45] 89% (32/36) of patients with a weak or absent gag reflex were successfully extubated.

A major reason to postpone extubation in a neurologically impaired patient is the fear of aspiration pneumonia. The occurrence of pneumonia, however, was higher in patients experiencing delayed extubation: 38% versus 21%.[45] These patients also had longer stays in the ICU (8.6 vs. 3.8 days) and in hospital (19.9 vs. 13.2 days). Based on their data, Coplin et al[45] concluded that a depressed level of consciousness should never be used as the sole indication for prolonged intubation.

In contrast to Coplin et al,[45] Namen et al[13] concluded that the GCS helps in predicting successful extubation. They studied 100 brain-injury patients, whose mechanical ventilations were managed by neurosurgeons. On ROC curve analysis, a score of ≥8 on the GCS provided the best discrimination of extubation outcome. Extubation was successful in 36% of patients with GCS scores ≤7 as compared with 75% of patients with a score ≥8. The area under the ROC curve for GCS score, however, was only 0.681. A more fundamental problem is that twenty-two patients were extubated as part of the withdrawal of life-support therapy (all these patients died). Because these patients were not reintubated, it appears that the authors classified them as extubation successes. Irrespective of how these twenty-two patients were classified, it is impossible to interpret data on extubation predictors where half of the extubations arose from a decision to withdraw life support.

The studies of Coplin et al and Namen et al were conducted in patients with brain injury, whereas Salam et al[47] studied neurologic function as a predictor of reintubation in eighty-eight medical-cardiac ICU patients who underwent 100 extubations. Neurologic performance was quantified by requesting patients to perform four simple tasks[48]: to open their eyes, to follow an observer with their eyes, to grasp the observer's hand, and to stick out their tongue. Reintubation within 72 hours was required in 15.9% (14/88) of the patients. Patients tolerating extubation performed a higher number of tasks than did the reintubated patients: 3.8 ± 0.1 versus 2.9 ± 0.5. Patients who were unable to complete all four tasks were 4.3 times more likely to require reintubation than were patients who could complete all four tasks. The failure to perform any of the four tasks had a sensitivity of 0.42 and specificity of 0.91 in predicting reintubation.

TREATMENT OF POSTEXTUBATION LARYNGEAL EDEMA

Epinephrine

Trials of therapies for postextubation respiratory distress have largely been confined to patients with laryngeal edema. For decades, patients with postextubation stridor and other upper airway disorders have been treated with aerosolized racemic epinephrine. Racemic epinephrine consists of equal amounts of the dextro (D)-isomer and levo (L)-isomer. Most of epinephrine's pharmacologic action results from the levo-isomer, which is thirty times more potent than the dextro-isomer.[49] Popularity of the more expensive racemic form is based on the supposition that it produces epinephrine's vasoconstrictor action without rebound vasodilation; thus, less tachycardia, hypertension, and tremor is expected with aerosolized racemic epinephrine than with levo-epinephrine. The stated different actions, however, may have arisen from comparisons of inappropriate dosages.

Nutman et al[50] randomized twenty-eight children with postextubation stridor (average age: 1 year) to receive 0.25 mL of either 2.25% racemic epinephrine or 1% levo-epinephrine, each diluted with 2 mL of isotonic saline. These dosages were selected to reflect the relative potency of the two compounds. Each was delivered over 15 minutes by face mask. Both groups exhibited significant improvement: 71.4% of the levo-epinephrine group and 76.9% of the racemic group exhibited decreases of 2 points on an 8-point stridor score after 40 minutes. By 8 hours, the stridor score was less than 1 in both groups. These data reveal that levo-epinephrine is as effective as the more expensive racemic epinephrine in children with postextubation stridor, although it is not known how likely the stridor would have resolved without any aerosolized therapy.

Glucocorticoids

The ability of dexamethasone to prevent postextubation stridor in children has been evaluated by three groups of investigators. In the first two studies, dexamethasone (0.5 mg/kg every 6 hours for 6 doses, beginning 6 to 12 hours before extubation) was compared against placebo. In their study of 153 children, ranging from under 1 year old to older than 5 years, Tellez et al[51] observed postextubation stridor requiring therapy in 21.1% (16/76) of the dexamethasone group and 29.9% (23/77) of the control group. Reintubation was required in 11.8% (9/76) of the dexamethasone group and 5.2% (4/77) of the control group. In a study of sixty-six children younger than 5 years old, Anene et al[52] observed stridor at 10 minutes in 45.2% of the dexamethasone group and 87.5% of the control group. Epinephrine aerosol was required in 12.9% (4/31) of the dexamethasone group and 68.8% (22/32) of the control group. Reintubation was required in 0/31 of the dexamethasone group and 21.9% (7/32) of the control group. Apart from the different conclusions on the benefit of dexamethasone, the different outcomes in the two control groups is striking: postextubation stridor requiring therapy was reported in 68.8% of the patients of Anene et al[52] as contrasted with 29.9% of the patients of Tellez et al;[51] the respective rates for reintubation were 21.9% and 5.2%.

A more recent trial was undertaken by Cesar and de Carvalho[53] who randomized sixty-four children, ranging in age from younger than 1 year to 12 years, to intravenous dexamethasone (0.2 mg/kg every 6 hours), with or without nebulized levo-epinephrine (0.5 mg/kg every 4 hours), versus nebulized or intravenous isotonic saline solution in the control groups. Neither dexamethasone nor nebulized levo-epinephrine, alone or in combination, decreased the frequency of laryngeal edema.

Early randomized controlled trials of the administration of glucocorticoids before extubation in adult patients were negative. Darmon et al[24] randomized 663 patients to a bolus of dexamethasone 8 mg or placebo 1 hour before extubation. The overall incidence of laryngeal edema was 4.2% (28/663), and reintubation was necessary in 1% (7/663). No difference was seen between patients receiving dexamethasone or placebo. Ho et al[23] randomized seventy-seven intubated

patients to hydrocortisone 100 mg or placebo, given 1 hour before extubation. Overall, 22% (17/77) developed stridor within 24 hours, and only one patient required reintubation. Outcomes were equivalent for patients receiving hydrocortisone and placebo. More recent trials indicate that glucocorticoids can be beneficial, especially when administered for 12 or more hours before extubation to patients at high risk of postextubation laryngeal edema.

Cheng et al[54] selected a group of high-risk adults intubated for more than 24 hours with a decreased cuff-leak volume (<24% of inspired V_T). Patients were randomly assigned to multiple doses of methylprednisolone (40 mg every 6 hours for 4 doses) before a planned extubation, a single dose of methylprednisolone 24 hours before the planned extubation, or placebo (4 injections of saline every 6 hours). Postextubation stridor developed in 30.2% of placebo group, and 18.6% required reintubation. Treatment with either a single dose or multiple doses of methylprednisolone decreased the rate of postextubation stridor, 11.6% and 7.1%, respectively, and also the rate of reintubation, 4.7% and 7.1%, respectively. There was no difference between the effects of single and multiple doses of methylprednisolone.

In 761 adult patients admitted to fifteen medical-surgical ICUs and receiving more than 36 hours of mechanical ventilation, François et al[21] conducted a double-blind controlled trial. Patients were randomized to intravenous methylprednisolone—initiated 12 hours before planned extubation at a dose of 20 mg and continued every 4 hours with the last injection immediately before tube removal (total dose: 80 mg)—or placebo. Methylprednisolone decreased the incidence of postextubation laryngeal edema (11/355 [3%] vs. 76/343[22%]) and the overall reintubation rate (13/355 [4%]vs. 26/343 [8%]). The need for reintubation as a result of laryngeal edema was all but eliminated (1/355 [0.3%] vs. 14/343 [4.1%]). The number needed to treat to prevent one reintubation caused by laryngeal edema was slightly more than twenty-six. Although the number needed to treat was large, the number of adverse events in the intervention group was small; thus, methylprednisolone appears have a satisfactory risk-to-benefit ratio in this setting.

Lee at al[55] conducted a randomized, double-blind trial in eighty-six patients who were at high risk of postextubation airway obstruction, in that they had a cuff-leak volume of less than 110 mL. Patients were randomly assigned to receive placebo or dexamethasone 5 mg every 6 hours for 24 hours, and were extubated 24 hours later. Compared with placebo, dexamethasone produced an increase in cuff-leak volume, approximately 115 mL at 24 hours versus approximately 40 mL, and decreased the incidence of postextubation stridor, 10% versus 27.5%. The rate of reintubation did not differ between the dexamethasone and placebo group: 2.5% versus 5%.

Cheng et al[56] undertook a second randomized, controlled trial, and like their previous trial they selected a group of high-risk adults with a decreased cuff-leak volume (<24% of inspired V_T). Four hours before planned extubation, thirty-eight patients received a single injection of methylprednisolone, 40 mg, and thirty-three patients received normal saline. Methylprednisolone resulted in a lower incidence of postextubation stridor (15.8% vs. 39.4%) and lower reintubation rate (7.9% vs. 30.3%). The beneficial effects were accompanied by the upregulation of interleukin (IL)-4 and IL-10 and the downregulation of IL-6 and IL-8.

Jaber et al[57] conducted a meta-analysis of randomized controlled trials of the effects of glucocorticoids on postextubation stridor and reintubation. Fifty-six trials have been conducted, and Jaber et al[57] selected seven that satisfied predefined methodologic criteria. These included the above discussed trials of Darmon et al,[24] Ho et al,[23] Cheng et al,[54] François et al,[21] and Lee et al,[55] and two other studies—Shih et al[58] and Cheng et al[59]—that had only been presented in abstract form; the abstracted Cheng et al study has since been published as a full report.[56] Among an aggregate of 1846 patients, those receiving glucocorticoids had a lower incidence of stridor (relative risk [RR]: 0.48;95% confidence interval [CI] 0.26 to 0.87) and lower rate of reintubation (RR: 0.58; 95% CI 0.41 to 0.81). Subgroup analysis revealed that glucocorticoids decreased the risk of reintubation more strikingly in high-risk patients, defined as those with an abnormally low volume on the cuff-leak test. In this subgroup, the rate of reintubation decreased from 19.8% to 8.6% (RR: 0.38; 95% CI 0.21 to 0.72). The benefit of glucocorticoids was not as striking in patients who were not selected on the basis of risk of reintubation (RR: 0.67; 95% CI 0.45 to 1.00).

In patients at risk of postextubation laryngeal edema, glucocorticoids are presumed to exert their beneficial effect by inhibiting the release of inflammatory mediators and decreasing capillary permeability.[57] The initial antiinflammatory effects commence 1 to 2 hours after intravenous administration and are maximal between 2 and 24 hours later. Consistent with this knowledge, clinical trials in which glucocorticoids were administered 1 hour or less before planned extubation did not decrease postextubation stridor or the rate of reintubation benefit,[23,24] whereas benefit was observed in trials when glucocorticoids were administered as long as 24 hours before extubation.[21,54,55] It has been proposed that physicians should select patients for glucocorticoid therapy on the basis of the cuff-leak test and then wait for 24 hours to allow the agent to take effect. This proposal, however, is problematic, as it would unnecessarily prolong intubation by 24 hours in three of every four patients with a low cuff-leak volume. If the recent observation of Cheng et al[56] is confirmed—that a single dose of methylprednisolone, 40 mg, administered 4 hours before extubation is beneficial in patients with a low cuff-leak volume—such an approach would represent a satisfactory risk-to-benefit ratio.

INTERVENTION TO REDUCE NEED FOR REINTUBATION

Pronovost et al[60] investigated the effect of a new quality improvement intervention on the frequency of reintubation in their surgical ICU. Their study was undertaken in three

phases. In the first phase, they identified risk factors associated with reintubation. In the second phase, ten ICU physicians engaged in a Delphi process, attempting to develop clinical practice guidelines. The physicians could not agree on priorities; they concluded that there were too many conditional probabilities that would require the use of so many decisional nodes, as to render a guideline impractical. This group used data collected in the first phase to develop a preextubation worksheet designed to highlight factors associated with reintubation. In discussion with a patient's nurse and respiratory therapist, physicians listed several variables on this form. Variables included whether intubation had been difficult, ventilator settings, oxygen saturation, arterial blood-gas results, f/V_T, frequency of suctioning, and mental status. In the third phase of the study, they studied the effect of implementing the preextubation worksheet on physician behavior. Staff was instructed not to extubate a patient if the worksheet had not been filled out.

The rate of reintubation before the quality improvement intervention was 8 per 1000 ventilator days. After the intervention, reintubation decreased to 1.5 per 1000 ventilator days. In another (control) surgical ICU in the same hospital, the rate of reintubation did not change over the same period (Fig. 59-6). The average duration of mechanical ventilation decreased from 4.6 days in the first phase of the study to 3.4 days in the third phase. Three factors were associated with reintubation: suctioning more often than every 4 hours (OR: 11.3); being agitated or sedated versus alert (OR: 4.5); and S_{O_2} less than 95% on FI_{O_2} 0.40 (OR: 4.0). The accuracy of these and other variables is clearly influenced by test-referral bias. The authors speculate that the preextubation worksheet helped to bring directly to the staff's attention the most important factors to consider when deciding to extubate.

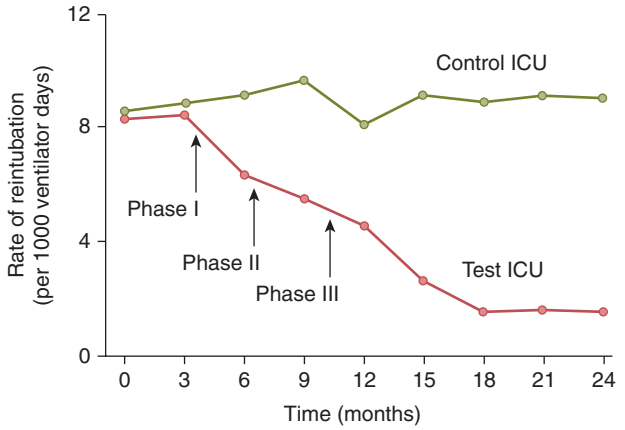

FIGURE 59-6 The rate of reintubation per 1000 ventilator days in a surgical ICU that introduced a new quality improvement intervention and in a control surgical ICU. The intervention was introduced in three phases in the study ICU. The intervention led to a decrease in the rate of reintubation from 8 to 1.5 per 1000 ventilator days. The rate of reintubation did not change in the control ICU. (Used, with permission, from Pronovost et al.[60])

NONINVASIVE VENTILATION IN WEANING AND EXTUBATION

Many investigators have sought to see if NIV can assist with the process of weaning and extubation. Some investigators have employed NIV as a bridge to ventilator discontinuation, where NIV is used in a patient who is believed to be not quite ready for extubation.[61] Other investigators have employed NIV as rescue therapy, where NIV is used in a patient who develops respiratory distress several hours after extubation.[6] The various studies that have addressed the use of NIV for these two purposes were discussed in considerable depth in the second edition of this book.

Three groups of investigators—Nava et al,[61] Girault et al,[62] Ferrer et al[63]—have evaluated the use of NIV as a weaning aid. These investigators instituted NIV at a point where a patient had failed a T-tube trial; patients typically received inspiratory positive airway pressure of 10 to 20 cm H_2O, and expiratory positive airway pressure of to 5 cm H_2O.[61,63] Patients in the intervention arm were placed on NIV immediately following extubation and were compared to a control group of patients who were reconnected to the ventilator and underwent conventional weaning (daily T-tube trials). Although the particularities of benefit differed among the three studies, all three research groups observed that the use of NIV as a bridge or weaning aid led to fewer days of mechanical ventilation, and two of the groups[61,63] observed a decrease in mortality as compared with conventional weaning.

These findings contrast with the use NIV as rescue therapy. Keenan et al[64] observed that institution of NIV at the point when a recently extubated patient developed respiratory distress, typically some hours after extubation, did not result in improved clinical outcome. Esteban et al[6] also employed NIV as rescue therapy in patients who developed postextubation distress. In contrast with all previous studies, they reported that NIV resulted in a greater mortality than observed with usual care: 25% versus 14%. Questions have been raised about the limited expertise of clinicians using NIV in the latter study and also that the employed level of pressure support was not reported. A striking feature was the outcome in twenty-eight patients in the usual care who crossed over to NIV. Despite being the sickest subgroup of the 107 patients in the usual-care group, mortality in the crossover subset was 11%—the lowest mortality of all groups requiring ventilator support.

Another feature that differs between the three studies with favorable outcomes[61–63] and the two studies with unfavorable outcomes[6,64] was that only 10% to 11% patients in the unfavorable studies had chronic obstructive pulmonary disease as contrasted with 44.2%,[63] 51.5%,[62] and 100%[61] in the studies with favorable outcomes. Patients who have hypercapnia as a result of chronic respiratory disorders, typically chronic obstructive pulmonary disease, have been shown repeatedly to exhibit an especially favorable response to NIV, and thus it becomes important to focus on the use of NIV as an extubation aid in such patients.

In 106 patients with chronic respiratory disorders who had received mechanical ventilation for at least 48 hours and

who exhibited a partial pressure of arterial carbon dioxide (Pa_{CO_2}) greater than 45 mm Hg during a T-piece weaning trial, Ferrer et al[65] randomly allocated fifty-four patients to NIV for the next 24 hours and fifty-two patients to conventional management. The primary end point was avoidance of respiratory failure (defined on meeting a number of predesignated laboratory or clinical criteria) within 72 hours following extubation. Such respiratory failure arose in fewer patients allocated to NIV than in those assigned to conventional management: eight of fifty-four (14.8%) versus twenty-five of fifty-two (48.1%); OR: 5.32 [95% CI 2.11 to 13.46], $p < 0.0001$).

When patients in either the NIV or control group met criteria for respiratory failure following extubation, but did not fulfill criteria for immediate reintubation, NIV was employed as rescue therapy. Among this subgroup, NIV resulted in avoidance of reintubation in two of seven patients assigned to NIV and fifteen of twenty controls. Overall, NIV was independently associated with a lower risk of respiratory failure after extubation (adjusted OR: 0.17 [95% CI 0.06 to 0.44]; $p < 0.0001$). Ninety-day mortality was lower in patients assigned to NIV than in those allocated to conventional treatment: six of fifty-four (11.1%) versus sixteen of fifty-two (30.8%); $p = 0.015$.

Given the impressive results achieved in this trial, it is important to note details of the way that Ferrer et al[65] employed NIV. The investigators used a ventilator specifically designed for NIV (BiPAP Vision, Respironics, Murrysville, PA), which provided effective compensation for leaks and real-time assessment of mask pressure. Inspiratory positive airway pressure was adjusted (12 to 20 cm H_2O) to achieve a respiratory rate less than 25 breaths/min (mean pressure: 17 ± 3 [SD] cm H_2O), expiratory positive airway pressure was fixed at 5 to 6 cm H_2O, and inspired oxygen concentration was titrated to achieve oxygen saturation of more than 92%. NIV was delivered for as much time as possible during the 24 hours that followed extubation (mean: 18 ± 7 [SD] hours); meals were not allowed during the first 24 hours.

In summary, data to date support the use of NIV as an aid to weaning patients who have chronic respiratory disorders and who exhibit hypercapnia during a weaning trial. In these patients, NIV appears to be beneficial as a bridge to ventilator discontinuation and also as rescue therapy in patients who develop respiratory failure following extubation. In patients who have underlying disease states other than a chronic respiratory disorder or who do not exhibit hypercapnia during a weaning trial, the role of NIV as a weaning aid is less clear. If it is to be used, it is likely to achieve greater success if instituted immediately after extubation[61–63] than employed as rescue therapy in patients who develop respiratory failure several hours after extubation.[6,64]

UNPLANNED EXTUBATION

Chapter 39 discusses unplanned extubation in detail. The subject is of particular importance for research on weaning because of the insight it may offer into unnecessary delays in the discontinuation of ventilation. The reported frequency of unplanned extubation ranges from less than 1% to 42% of intubated patients; a frequency of 8% to 12% is most commonly reported (Table 59-4). Unplanned extubation

Abbreviation: NR, not reported.

[a]Total number of ventilated or intubated patients.

is divided into two major subsets. Self-extubation refers to the deliberate removal of an endotracheal tube by a patient for whom the physician considers intubation beneficial. Accidental extubation refers to inadvertent extubation by a caregiver during a bedside procedure. Both of these situations differ from the usual planned extubation. Between 63% and 95% of unplanned extubations are self-extubations.

The rate of reintubation after unplanned extubation ranges from 4% to 78%, with many investigators reporting rates of 35% to 60%. These rates are considerably higher than reintubation rates of 10% to 20% after planned extubation. The rate of reintubation after accidental extubation is especially high, 83%[66] to 100%.[8,67] That 40% or more of self-extubated patients do not require reintubation is often used as evidence that physicians delay extubation unnecessarily. Extubation is undoubtedly delayed in some patients, but the two groups of patients may not be strictly comparable. Patients who have enough strength—and wit—to self-extubate may be less sick than the average ventilated patient, and thus would be expected to experience a lower reintubation rate. Moreover, it is totally unclear as to what the source of the delay is in these self-extubated patients. Is it caused by clinicians who are not aware of a patient's readiness for extubation because they have yet to measure weaning predictor tests? Is it because the predictor test readings represent false-negative results? Is it because the physician interprets the predictor test results incorrectly? Is it because the physician delays in ordering a weaning trial?[68] Is it because the physician delays extubating a patient who has passed a weaning trial?[68] A considerable body of data[13,68] suggests that the most likely source of delay is in ordering a weaning trial and extubating a patient who has passed the trial.

The rate of reintubation after unplanned extubation is lower in patients who have already entered the phase of weaning than in patients who are still receiving full ventilator support. Betbese et al[69] reported that 16% of thirty-two patients who experienced unplanned extubation during weaning required reintubation, as contrasted with 82% of twenty-seven patients who experienced unplanned extubation while receiving full ventilator support. Razek et al[70] reported reintubation after unplanned extubation in 15.2% of thirty-three weaning patients and 60.7% of twenty-eight patients requiring full ventilator support. And Epstein et al[71] reported reintubation after unplanned extubation in 30% of thirty-three weaning patients and 76% of forty-two patients requiring full ventilator support. Epstein et al[71] noted that patients who tolerated unplanned extubation tended to have shorter time from the onset of weaning to extubation than did a control group, 0.9 versus 2.0 days ($p = 0.06$), although the overall duration of mechanical ventilation did not differ.

Moons et al[67] found that most unplanned extubations occurred on the same day that extubation had been planned (42.9%), or the subsequent (42.9%) or preceding day (14.3%). Compared to a control group of forty-eight patients that did not experience unplanned extubation, a study group of twenty-six patients experiencing unplanned extubation had a lower Ramsay Sedation Scale score, 2 (1, 5; twenty-fifth, seventy-fifth percentiles) versus 5 (3.3, 6; twenty-fifth, seventy-fifth percentiles), and a higher GCS score, 12 (8, 13; twenty-fifth, seventy-fifth percentiles) versus 4 (3, 7; twenty-fifth, seventy-fifth percentiles). The difference between the two groups was confined to the subgroup experiencing deliberate self-extubation; patients experiencing accidental extubation were comparable to the control group. In a multiple logistic regression analysis, deliberate self-extubation was associated with a lower sedation score (OR: 2.04) and higher level of consciousness on the GCS (OR: 1.40). The model explained 67.3% of variance of deliberate self-extubation. These data suggest that the weaning period is a high-risk time for deliberate self-extubation because patients are receiving less sedative agents and have a higher level of consciousness.

De Lassence et al[8] undertook a prospective multicenter study of the morbidity and mortality associated with unplanned extubation. Compared with forty-five of 690 patients who required reintubation after planned extubation, the forty-six (of sixty) patients who were reintubated after an unplanned extubation experienced a longer duration of mechanical ventilation, 17 versus 6 days; longer ICU stay, 22 versus 9 days; and longer hospital stay, 34 versus 18 days. The frequency of nosocomial pneumonia was higher after unplanned extubation than after planned extubation: 28% versus 14%; this increase was entirely explained by accidental extubation. ICU mortality was 40.9% in patients with accidental extubation, 21.1% in patients with self-extubation, and 38% in the control group—these rates did not differ statistically.[8] In a retrospective case-control study, Epstein et al[65] also observed no difference in mortality between patients experiencing unplanned extubation, 32%, and a control group, 30%. The mortality in the control groups of both these series[8,71] is considerably higher than the mortality of less than 10% usually reported in successfully extubated patients.

Tominaga et al[72] undertook a prospective study of four interventions designed to influence the frequency of unplanned extubation. At baseline, 15.2% of intubated patients experienced unplanned extubation. When the investigators switched from their usual method of securing the endotracheal tube, cloth or Velcro ties, to the use of waterproof tape around the tube, upper lip, and face, the frequency of unplanned extubations decreased to 4% (8/213). The frequency was not altered by the more liberal use of sedative or paralytic agents. A decrease in the use of hand restraints led to an increase in the rate of unplanned extubations.

Thille et al[31] found that the distance between the endotracheal tube and the carina was significantly less in thirty-one patients who experienced unplanned extubation than in 168 instances of planned extubation: 4.1 ± 1.8 versus 5.6 ± 2.6 (SD). Given the high mortality rate in patients requiring reintubation, greater attention to the location of the tip of the endotracheal tube at the time of viewing chest radiographs could decrease this adverse event (Fig. 59-7).

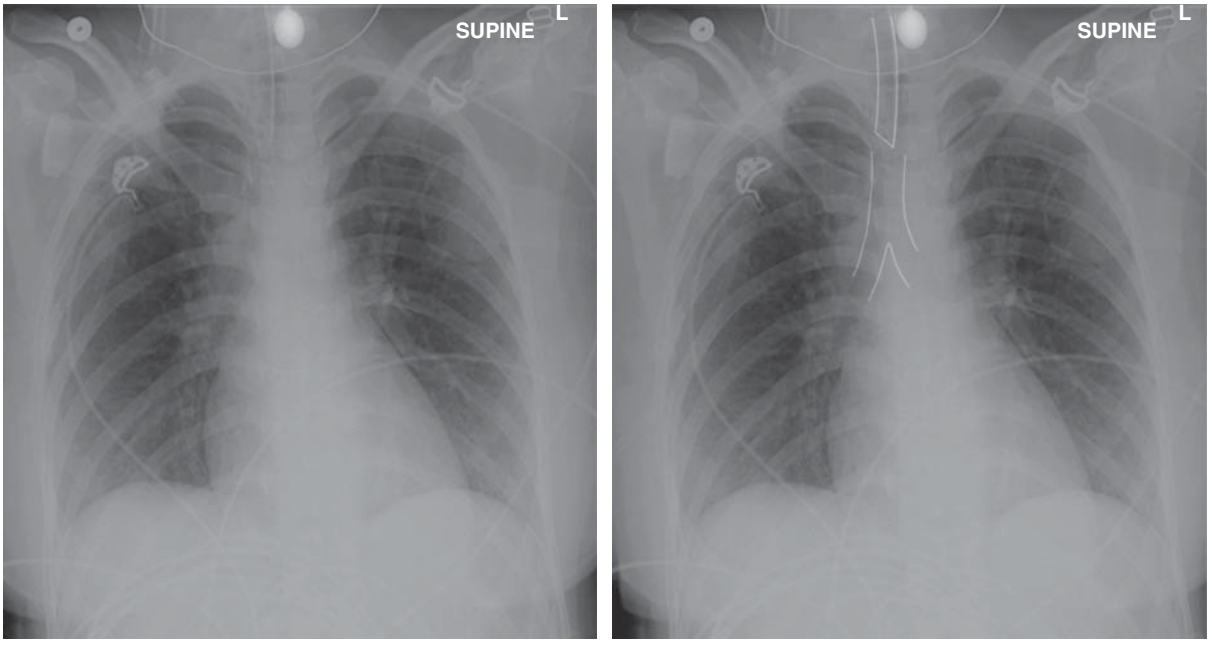

FIGURE 59-7 Endotracheal tube positioned too high. Portable anteroposterior chest radiograph of a 24-year-old woman intubated as a result of anaphylactic shock. The endotracheal tube is 5.5 cm above the carina.

CONCLUSION

The development of severe respiratory distress after removal of an endotracheal tube, if sufficient to require reintubation, is associated with a high mortality rate. Clinicians are accordingly cautious and try to avoid premature extubation. Despite such caution, as many as two of every ten extubated patients require reintubation. To improve accuracy in forecasting extubation outcome, clinicians use diagnostic testing. The major diagnostic test for this purpose is a weaning trial. But unlike weaning predictor diagnostic tests, the diagnostic accuracy of weaning trials in predicting the outcome of a trial of extubation is unknown. Moreover, the accuracy is impossible to determine, because the experiments necessary to measure the sensitivity and specificity of a weaning trial (for predicting extubation outcome) are unethical. The mechanisms of weaning failure have been intensely investigated. Enhanced understanding of the pathophysiology has led to new approaches to the timing of the weaning process, prediction of outcome, and techniques used for weaning. In contrast, understanding of the pathophysiology of severe respiratory distress in the postextubation period is rudimentary to nonexistent. Acquiring such knowledge poses a great research challenge, but holds great promise for significantly advancing patient care.

SURFACTANT

James F. Lewis
Valeria Puntorieri

Pulmonary surfactant lines the inner layer of the lung and serves to lower surface tension at the air–liquid interface, thereby maintaining alveolar stability. In the absence of surfactant, the work of breathing increases markedly ultimately resulting in respiratory failure secondary to atelectasis, alveolar flooding, and severe hypoxemia. The clinical correlate of surfactant deficiency is the neonatal respiratory distress syndrome (NRDS) in preterm infants, which before the mid-1980s was a devastating and fatal disease. Since the advent of exogenous surfactant replacement therapy, however, newborn mortality from NRDS has decreased approximately 56% from 1987 to 1995.[1] The primary surfactant deficiency of NRDS is now a well-characterized condition, and does not appear as complex as the various surfactant changes occurring during acute lung injury (ALI) and/or the acute respiratory distress syndrome (ARDS). Alterations of the endogenous surfactant system in the mature lungs of patients with these disorders are not as well understood, but currently represent an area of intense investigation. This complexity has resulted in inconsistent results of clinical trials evaluating exogenous surfactant administration in this patient population.

This chapter reviews surfactant metabolism and function in the mature lung and its role in maintaining normal lung homeostasis, including its more recently described host defense functions. The metabolism and function of surfactant in the injured lung is also outlined, with particular reference to the effects of mechanical ventilation on the alveolar surfactant system. Subsequently, the status of clinical trials evaluating exogenous surfactant administration in patients with ALI or ARDS is addressed, as are the various factors that may influence a host's response to this therapy. Future research directions relevant to the understanding of the role of surfactant both in ALI and ARDS and other lung diseases conclude the chapter.

SURFACTANT COMPOSITION AND METABOLISM

Composition

The composition of surfactant is remarkably similar among mammalian species, consisting of approximately 80% phospholipids, 10% surfactant-associated proteins,[2–4] and approximately 10% neutral lipids, among which cholesterol is the most abundant (80% to 90% by weight).[5,6] The major phospholipid component is phosphatidylcholine, half of which is the disaturated species, dipalmitoylphosphatidylcholine (DPPC).[4] This latter molecule is the major surface-active component responsible for lowering surface tension at the air–liquid interface, and is an essential component of all exogenous surfactant preparations currently available for clinical use. Other lipids include phosphatidylglycerol and a few minor lipid species, which are thought to be important in the generation and maintenance of the surface film.

The surfactant-associated proteins have been designated as SP-A, SP-B, SP-C, and SP-D.[7,8] SP-B and SP-C are small, hydrophobic proteins closely associated with the phospholipids, where they play a major role in generating and maintaining the surface tension-reducing surface film.[9–11] SP-B is an 18-kDa dimer, whereas SP-C is a 4-kDa monomer, the latter being the more hydrophobic of these two proteins.[12,13] The most clinically effective exogenous surfactant preparations currently in use contain at least one of these natural hydrophobic proteins, or similar types of synthetic and/or recombinant molecules. SP-A is an octodecamer made up of six trimers in a "bouquet" arrangement.[14,15] Under reducing conditions, it is a 28-kDa monomer with a 35-kDa glycosylated form. SP-D is a large, multimeric cruciform structure, which is 42 kDa under reducing conditions. Both proteins are very hydrophilic and belong to the collectin family of proteins. They are not components of any of the available natural exogenous preparations consequent to their removal with purification processes, and are not yet available as synthetic or recombinant molecules. Recent evidence suggests that they play a more important role in host defense than in biophysical functions, so there has been renewed interest in developing exogenous preparations containing some form of these proteins.[14–17]

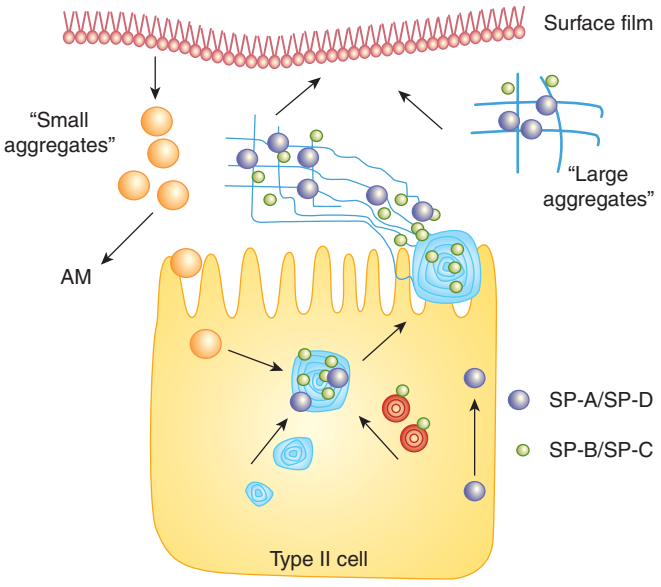

FIGURE 60-1 Surfactant metabolism starts with synthesis within the type II cell, secretion into the airspace as lamellar bodies containing both lipid and protein components, and formation of tubular myelin structures. Large aggregates are composed of tubular myelin and freshly secreted lamellar bodies and represent precursors to the surface film. With respiratory motion, small aggregates are formed, which are taken back up into type II cells or cleared via alveolar macrophages (*AM*).

Intracellular Metabolism

Surfactant is synthesized within alveolar type II cells (Fig. 60-1).[18] Initial assembly occurs in the endoplasmic reticulum with intracellular transport via the Golgi apparatus. Surfactant is stored within lamellar bodies of the type II cell and is secreted into the airspace via exocytosis.[19,20] Studies that have investigated the intracellular metabolic pathways of surfactant lipids and proteins have used radiolabeled precursors injected both intravenously and intratracheally. Basically, these studies have shown that although the hydrophobic proteins are assembled and secreted in conjunction with the lipids, SP-A and D are metabolized separately.[21] For example, the dominant route for SP-A secretion is by direct, constitutive pathways independent of lamellar body exocytosis, although smaller amounts undergo regulated secretion in association with these organelles.[22–24] SP-D is also metabolized independently of surfactant lipids, and, unlike the other surfactant proteins, has been identified in nonpulmonary organs such as the gut.[25,26] Within the healthy lung, various pharmacologic agents, such as β-agonists can stimulate surfactant secretion, as can physical stretch of alveolar type II cells.[27] This latter phenomenon is particularly relevant to specific aspects of mechanical ventilation because higher tidal volumes increase the stretch of the alveolus, leading to immediate surfactant secretion from type II cells. These effects are relatively short-lived, however, and may be quite different within the injured lung, where the preexisting health of type II cells, before the onset of mechanical ventilation, may be compromised.

Recent studies have focused on the extracellular metabolism of pulmonary surfactant, once the material has been secreted from the type II cell into the alveolus (see Fig. 60-1). Within the airspace, mechanical ventilation has a significant and immediate impact on the surfactant system by influencing the metabolism of extracellular surfactant aggregate forms. Because this effect may have important clinical consequences in patients with ALI or ARDS, and is directly affected by different modes of mechanical ventilation, a more detailed discussion of this area is warranted.

Extracellular Metabolism

Once secreted into the airspace, alveolar surfactant undergoes physical rearrangement from the lamellar structures into tubular myelin, a process involving SP-A, SP-B, DPPC, phosphatidylglycerol, and calcium.[28,29] After differential centrifugation of isolated lung lavage, large lipid structures containing SP-A, SP-B, and SP-C, representing the heavier and functionally active forms of alveolar surfactant form a pellet, and are called large aggregates (LA).[30,31] They adsorb rapidly to the air–liquid interface and are subsequently converted into smaller, vesicular forms called small aggregates (SA) (see Fig. 60-1). The SA subfractions are poorly functioning, contain little surfactant protein, and are thought to represent surfactant forms that have left the surface film and are subsequently available for reuptake via type II cells for resynthesis into new LA, and/or are cleared entirely from the airspace via catabolism, mainly within alveolar macrophages.[32–34]

The process of conversion of the functionally active LA forms into inactive SA within the airspace is specifically relevant when discussing the effects of mechanical ventilation on surfactant metabolism. In vitro studies using the surface area cycling technique show that this conversion of LA into SA is mediated by two main factors: a carboxylesterase enzyme called *convertase* and a phasic change in surface area.[31,35–37] The phasic change in surface area factor has been investigated *in vivo* using different tidal volumes to mechanically ventilate normal rabbits. These studies show that increasing tidal volume, but not positive end-expiratory pressure, results in an increased conversion of LA into SA, and that this conversion occurs relatively soon after the onset of ventilation (Fig. 60-2).[38] In normal lungs, these changes do not result in significant alterations in aggregate pool sizes, presumably because of the capabilities of the normal alveolar environment to regulate surfactant metabolism. This does not appear to be the case in the injured lung, however, where alterations in surfactant metabolism occur both intracellularly and extracellularly.[39,40] For example, within the lungs of patients with ALI or ARDS, increased aggregate conversion associated with higher tidal volumes is thought to result in increased SA pools, which, together with the associated decrease in functionally active LA pools, may contribute to progressive lung dysfunction. Indeed, these specific changes have been demonstrated in animal models of lung injury and have not only underscored the importance of instituting and maintaining optimal modes of mechanical ventilation within injured lungs, but also in the setting of exogenous surfactant, both during and after administration. This latter situation is discussed in more detail in subsequent sections.

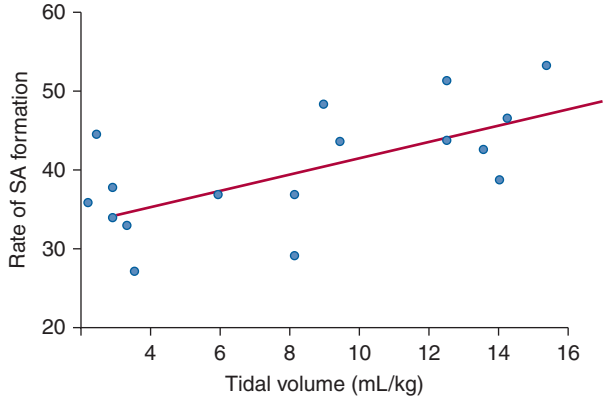

FIGURE 60-2 The rate of small aggregate (*SA*) formation increases in direct proportion to the tidal volumes used to ventilate normal adult rabbits. SA formation was determined by measuring ^{3}H-label recovery in the SA fraction of surfactant 1 hour after injection of a trace dose of ^{3}H-labeled large aggregates into the animals' lungs. SURFACTANT PHYSIOLOGY IN THE NORMAL LUNG

Biophysical Function

The major role of the surfactant system is related to its biophysical function of lowering surface tension at the air–liquid interface.[3,4,41] This is most evident clinically in preterm infants born deficient in surfactant who quickly die of respiratory failure unless supplemented with an exogenous surfactant preparation.[42–44] As noted previously, the major lipid component contributing to lowering surface tension is DPPC, although the hydrophobic proteins and some other lipids are also essential.[10–13] Full-term babies born deficient in SP-B develop severe lung dysfunction resistant to traditional surfactant therapy and ultimately require lung transplantation for survival.[45] Likewise, mice deficient in this protein suffering a similar outcome have also been shown to have abnormal processing of SP-C.[46] Mice deficient in SP-C alone, on the other hand, have relatively minor biophysical abnormalities, which predominantly manifest only at low lung volumes, suggesting a potential role for this protein in the surface film stabilization.[47]

From a physiologic perspective, the initial discovery that surface tension was important for lung stability was made by von Neergaard in 1929, when he observed that it took more pressure to inflate air-filled than saline-filled lungs.[48] This was the direct result of the surface tension forces existing at the air–liquid interface. This concept is further advanced by the Laplace law, which states that the pressure gradient across a sphere, which we can roughly extrapolate to an alveolus, is directly related to the surface tension within the sphere divided by the radius of the sphere ($\Delta P = 2\delta/r$), where P is pressure, δ is surface tension, and r is radius. From this equation, it is clear that during exhalation, when the alveolar radius decreases, the tendency for this alveolus to collapse increases (i.e., ΔP) unless surface tension decreases as well. Because of its strategic location at the air–liquid interface, and the presence of both hydrophobic and hydrophilic regions, a surfactant film lining the air–liquid interface is able to lower surface tension to near zero levels as the film is compressed at low lung volumes. This decrease in surface tension not only serves to maintain alveolar stability and decrease the work of breathing, but also prevents alveolar flooding because high surface tension tends to draw fluid from the interstitium into the airspace.[49] Finally, because surfactant also lines the conducting airways, its biophysical function serves to maintain the patency and stability of small airways and enhance ciliary clearance of particles.[50,51] These latter observations suggest that surfactant function may also be relevant in diseases such as asthma, chronic bronchitis, and cystic fibrosis.

Host-Defense Function

As noted previously, the surfactant proteins SP-A and SP-D are members of the collectin family and, secondary to their

molecular composition and structure, can bind a variety of bacteria, fungi, allergens, and viruses, thus mediating phagocytosis by immune cells and the killing of pathogens within the lung.[14,16,52] In addition, these proteins, as well as some of the hydrophobic components of surfactant, can influence production of nitric oxide, oxygen radicals, and inflammatory mediators from activated cells.[53–56] Underscoring the importance of SP-A in host-defense functions are *in vivo* studies demonstrating that mice deficient in this protein (which are phenotypically normal when not stressed) had increased pulmonary inflammation compared to wild-type animals when bacteria, viruses, or lipopolysaccharide was instilled into their lungs.[57,58] These changes were mitigated when exogenous SP-A was administered to these animals. Similar, albeit slightly modified functions of SP-D have been shown both *in vitro* and *in vivo*; unlike the normal phenotype of the SP-A null mice, however, the phenotype of unstressed SP-D knockout animals is abnormal with enlarged airspaces and significantly altered surfactant pool sizes.[59,60]

Although critical for the spreading and stabilization of the surfactant film, SP-B and SP-C also seem to contribute to the host-defense properties of surfactant. Mice deficient in SP-C show greater susceptibility to respiratory syncytial virus infection[61] and have increased pulmonary inflammation, decreased macrophage phagocytic activity, and decreased survival compared to wild-type animals following intratracheal instillation of bacteria.[62] The role of SP-B in host defense appears to be related to the aminoterminal propeptide of the protein, which improves phagocytosis and has antimicrobial activity at acidic pH.[63]

The host-defense functions of the various surfactant lipids have also been evaluated. It has been shown that these phospholipids downregulate inflammation and nitric oxide production, presumably because of their "coating" effects on particles and cells.[17,64–66] Additionally, surfactant lipids, and DPPC in particular, could have a direct effect in down-modulating the inflammatory response of immune cells, through the regulation of specific molecular pathways responsible for reactive oxygen species production.[67] Given the emerging role of the various surfactant components in host defense, future studies involving exogenous surfactant administration may focus more on inflammatory outcomes in addition to biophysical and physiological benefits.

SURFACTANT PHYSIOLOGY IN THE INJURED LUNG

Surfactant Alterations in Acute Lung Injury and Acute Respiratory Distress Syndrome

The definitions of ALI and ARDS are rather simplistic and are based on physiologic criteria more than specific etiologies. For example, any acute inflammatory insult that ultimately affects the lungs causing decreased lung compliance, hypoxemia, and bilateral infiltrates on chest radiography (not of cardiac origin) essentially fulfills the diagnostic criteria of ALI and ARDS.[68,69] The pathophysiologic changes that occur during this process, including the surfactant alterations reported in numerous studies, are complex and reflect the lack of effective treatments for this disorder.

The first postmortem descriptions of the lungs of patients dying from ARDS suggested that surfactant dysfunction may have played a role in their demise.[70] Subsequently, many studies have reported consistent changes in the surfactant system in lavage samples obtained from these patients, including decreased phosphatidylcholine and DPPC levels, decreased phosphatidylglycerol levels, decreased SP-A, SP-B, SP-C, and SP-D levels, and a decrease in the functionally active LA forms relative to SA.[71–73] Interestingly, in these severely ill patients, serum levels of SP-A and SP-D were shown to be elevated, likely consequent to the associated marked increase in pulmonary permeability in this setting.[74,75] The biophysical consequence of these collective changes in the endogenous surfactant system is an inability to adequately reduce surface tension, resulting in decreased lung compliance, increased permeability with edema formation, and hypoxemia. The next section addresses the mechanisms responsible for the surfactant changes observed in these patients. Only with a better understanding of these mechanisms will optimal treatment strategies be developed that are aimed at restoring normal surface tension forces within injured lungs, or perhaps, more importantly, preventing the development of these changes.

Mechanisms Responsible for Surfactant Alterations

Unlike NRDS, in which the preterm animal represents a reasonable correlate of the clinical condition of NRDS and is thus suitable for reliable mechanistic and therapeutic studies, no one animal model adequately reflects the complexity of patients with ALI or ARDS. Proposed mechanisms in the latter setting are, therefore, derived from many different animal models, a factor that needs to be considered when extrapolating results of such studies to the clinical situation.

The observed changes in the phospholipid composition of endogenous surfactant within the injured lung represent a relatively late finding in models of ALI when severe lung dysfunction is present. These changes are likely related to abnormal synthetic and/or secretory pathways within the type II cell, as well as alterations in the degradation process of some lipids within the airspace via increased phospholipase activity (Fig. 60-3).[76–79] A similar mechanism is likely responsible for the decreased surfactant protein levels observed in these lungs, although with the permeability abnormalities demonstrated in these patients, there may also be transfer of SP-A, SP-B, and SP-D across the alveolar–capillary barrier into the serum.[74,75] Interestingly, clinical studies show that serum levels of SP-A and SP-B are inversely related to oxygenation values in patients with

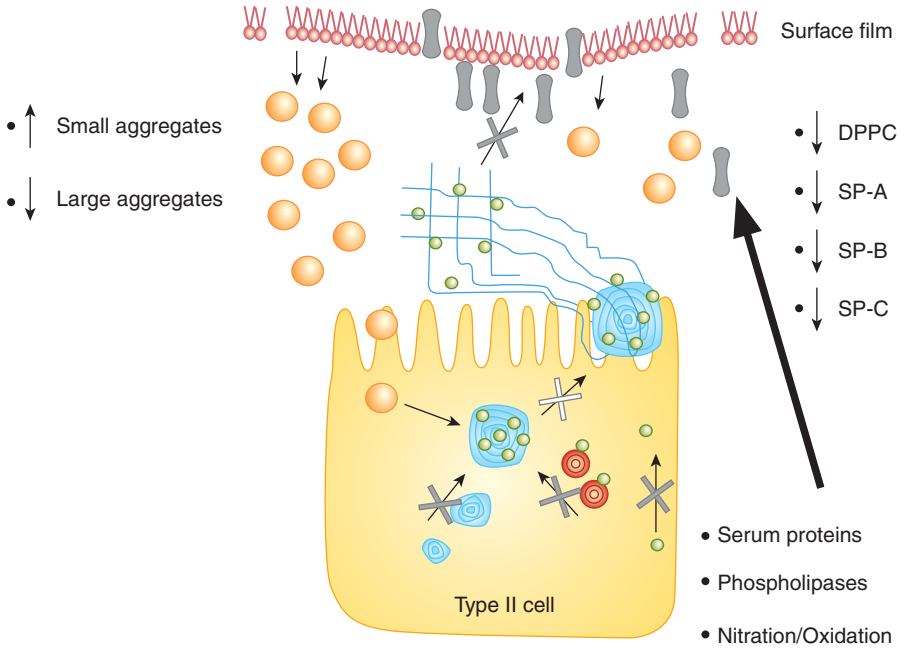

FIGURE 60-3 Mechanisms leading to surfactant alterations in the injured lung include abnormal type II cell metabolism, increased phospholipase activity, nitration and oxidation of surfactant, increased conversion of large aggregates into small aggregates, and inhibition of surfactant by serum proteins leaking into the airspace. See text for details.

ARDS, and serum SP-D levels positively correlate with the survival of these patients.[74,75] In addition to these quantitative changes in surfactant protein levels, there may also be modifications to their composition in the form of nitration and/or oxidation, which would also compromise their function but may not impact measurable levels.[80–82]

The mechanisms responsible for the changes observed in surfactant aggregate forms were alluded to earlier. Briefly, decreased LA pools may be caused by decreased type II cell synthesis and/or secretion in the severely injured lung, but an increased conversion of LA into SA forms likely occurs at earlier stages of the disease, particularly in patients undergoing mechanical ventilation.[37–40] This was recently investigated in animal studies in which spontaneously breathing septic rats with relatively mild lung dysfunction had unchanged LA pools, whereas SA pools were significantly decreased compared to sham animals.[83] These changes were opposite to those documented in severely injured lungs; it was hypothesized that they may have represented the host's compensatory response aimed at maintaining endogenous surfactant in LA forms. For example, by utilizing smaller tidal volumes (with higher respiratory rates), these animals would decrease LA conversion secondary to the smaller changes in alveolar surface area, thereby attempting to maintain lung function. Indeed, very soon after the onset of mechanical ventilation of these animals, which involved using higher tidal volumes than those associated with spontaneous breathing, conversion of LA into SA increased dramatically and lung function deteriorated rapidly.[84] Of clinical relevance, however, was the ability to mitigate both the aggregate conversion and progressive lung dysfunction observed by using lower tidal volumes from the onset of ventilation. In fact, high-frequency oscillation (HFO), a strategy involving extremely small tidal volumes with high respiratory rates, proved to be superior to all other "lung-protective" modes of ventilation with respect to aggregate conversion, lung function, and inflammatory changes.[85] Interestingly, these laboratory results are consistent with recent clinical trials evaluating different modes of mechanical ventilation in patients with ALI. One large trial showed that lower tidal volumes resulted in superior outcomes compared to higher tidal volumes in patients with ALI or ARDS.[86] Results of phase III clinical trials evaluating the outcome of patients specifically ventilated with HFO are pending.

Recent studies suggest another potential mechanism for surfactant dysfunction within the injured lung. Alterations in the cholesterol-to-phospholipids ratio of surfactant alter surfactant function. As noted earlier, cholesterol is the major neutral lipid in surfactant and when present in physiologic amounts, it enhances adsorption at the air–liquid interface. Studies focused on the specific role of neutral lipids and cholesterol in lung injury are scarce. *In vitro* studies that have altered the cholesterol-to-phospholipid ratio show that supraphysiologic levels of cholesterol affect surfactant film stability leading to the inhibition of its function.[87] This cholesterol-mediated dysfunction appears to be relevant *in vivo* as well, because surfactant isolated from animals exposed to high tidal-volume ventilation showed abnormal biophysical activity, which was subsequently restored upon cholesterol removal.[88]

Interestingly, these experimental results are consistent with clinical observations. Markart et al showed that

patients with ARDS had increased levels of the neutral lipid component in isolated LA forms, and impaired biophysical activity of their endogenous surfactant.[89] The source of the increased cholesterol in the surfactant of injured lungs is currently unknown. Altered synthesis by alveolar epithelial type II cells and/or leakage from the circulation into the alveolus are potential mechanisms, although this has not been formally evaluated. Further studies are necessary to address these issues, as well as to understand the biophysical mechanisms leading to cholesterol-mediated inactivation of surfactant.

Finally, within a permeable lung, characteristic of patients with ARDS, serum proteins such as albumin, hemoglobin, and fibrinogen can leak into the airspace and competitively inhibit the function of remaining LA forms.[90] This latter mechanism has been extensively studied over the past several years, and it has been shown that this inhibitory phenomenon may be overcome via the administration of large amounts of an effective exogenous surfactant preparation, thus providing important rationale for this therapeutic approach.[91]

EXOGENOUS SURFACTANT ADMINISTRATION IN THE INJURED LUNG

Results of Phase II and Phase III Clinical Trials

Exogenous surfactant administration has been evaluated in patients with ARDS based on the rationale that surfactant alterations contribute, at least in part, to the lung dysfunction associated with this disorder. Moreover, preclinical studies evaluating the efficacy of exogenous surfactant administration in animal models of ALI have shown promising results. Unfortunately, the outcomes of clinical trials conducted to date have been variable (Table 60-1). For example, the first large, randomized phase III clinical trial, involving more than 700 patients, administered aerosolized Exosurf (a preparation with no surfactant proteins) to patients with severe, sepsis-induced ARDS over a 5-day period.[92] Mortality was similar in the treatment (41%) and standard care (41%) groups. A subsequent, albeit smaller trial, with approximately fifty patients, evaluated tracheally instilled Survanta (a natural bovine preparation) in a relatively similar patient population with good results: a mortality of 19% compared to 44% in the control group.[93] In this latter study, the surfactant preparation contained both SP-B and SP-C, and much larger quantities of the material reached the airspace compared to the Exosurf trial. Other, relatively small clinical studies have included a phase II trial that used a porcine natural surfactant preparation, HL-10, which also contained SP-B and SP-C. The surfactant was instilled in large doses into the lungs of patients with severe ALI or ARDS. After somewhat promising results, a much larger, randomized phase III clinical trial was conducted, but was stopped prematurely for lack of efficacy.[94]

Surfaxin, a synthetic surfactant preparation containing an SP-B–like peptide (KL-4), was tested in twelve patients with severe ARDS and administered via a lung-lavage procedure.[95] Although these initial results were promising, there has been nothing further reported regarding results of a larger study.

Results from a large, randomized phase III trial that tested the efficacy of an exogenous surfactant preparation composed of a recombinant SP-C protein with lipids (Venticute) have been published.[96] The material was instilled into the lungs of patients with severe ARDS caused by multiple etiologies, and results showed no overall difference in mortality between the surfactant-treated group (36%) and standard therapy (32%). A post hoc analysis of these results however, showed a significant interaction between the surfactant treatment and the mechanism of lung injury. Patients with "direct" lung injuries, induced by pneumonia and/or aspiration, had a statistically significantly higher survival rate when treated with surfactant compared to standard therapy; no such relationship existed for patients with "indirect" causes of ARDS, such as sepsis and trauma.

This analysis resulted in a follow-up, prospective, randomized, blinded phase III clinical trial focused on the administration of the recombinant SP-C–based surfactant in patients with severe, direct lung injuries. Surprisingly, the results showed that exogenous surfactant instillation did not improve mortality, oxygenation, or the incidence of nonpulmonary organ failures and the study was stopped for futility.[97] This unexpected lack of efficacy was unexplained, but was thought to be related, in part, to a possible inactivation of the material during the reconstitution procedure.

TABLE 60-1: PUBLISHED PHASE II AND PHASE III CLINICAL TRIALS INVOLVING EXOGENOUS SURFACTANT

Surfactant Preparation and Concentration	Delivery Method	Dose	Mortality (vs. Standard Therapy)	Ref.
Exosurf (13.5 mg DPPC/mL)	Aerosolization	112 mg/kg/day × 5 days	41% vs. 41%	92
Survanta (25 mg DPPC/mL)	Bolus instillation	4 or 8 doses of 50 or 100 mg/kg	19% vs. 44%	93
Venticute (25 mg DPPC/mL)	Bolus instillation	Up to 4 doses of 50 mg lipid/kg	36% vs. 32%	96

Although results of clinical trials are inconsistent and certainly disappointing, the information gained from these trials, as well as preclinical studies, is insightful and supports the need for further research in this area. In the next section, the various factors that influence a host's response to exogenous surfactant are reviewed.

Factors Influencing the Efficacy of Exogenous Surfactant

SURFACTANT PREPARATION

A number of surfactant preparations have been tested in clinical trials involving patients with ARDS, and are generally classified based on their surfactant protein content (Table 60-2). Natural surfactant products contain various amounts of SP-B and SP-C along with natural lipids. They are derived from either bovine (Survanta, Infasurf, Alveofact, and bovine lipid extract surfactant [BLES]) or porcine (Curosurf and HL-10) sources, and have consistently been shown to have excellent biophysical activity. Currently available synthetic surfactant preparations contain either synthetic or recombinant surfactant-specific proteins combined with commercially available lipids. These preparations include Venticute and Surfaxin. Venticute is composed of a recombinant SP-C protein together with DPPC and smaller amounts of palmitoyloleoylphosphatidyl glycerol (POPG) and palmitic acid.[96] Surfaxin contains a synthetic SP-B–like peptide as well as DPPC, POPG, and palmitic acid.[95] Both Venticute and Surfaxin have been tested in preclinical studies involving models of ALI and phase II and phase III clinical trials. Two other synthetic surfactant preparations previously used in neonates with NRDS and tested in patients with ARDS include Exosurf (DPPC; hexadecanol, and tyloxapol) and artificial lung-expanding compound (ALEC, DPPC, and phosphatidylglycerol).[98] These preparations contain no surfactant proteins, perhaps explaining the poor results of these latter trials. No further studies are being conducted with these preparations at this time. Animal studies that have directly compared the various surfactant preparations have generally shown that those containing surfactant proteins, either from natural or synthetic or recombinant sources, are superior to those having no proteins.[99,100] Furthermore, meta-analyses of several studies involving neonates with NRDS also show that clinical trials utilizing natural products result in better outcomes than those using the synthetic preparations with no surfactant proteins.[101]

Based on preclinical data and results of these clinical trials, it is likely that some type of protein-containing surfactant will be required for optimal results in patients with ALI or ARDS. Whether the natural products will be more effective than the protein-containing, synthetic surfactants in this setting is unknown, and will be difficult to prove in this complex patient population. As a result, other factors may need to be considered when making this decision. For example, although animal-based products may well be as effective or superior to any synthetic products available (or to be developed in the future), they have the theoretical potential of transmitting molecules and/or infectious agents to the host. This, however, has not been demonstrated over the past 20 years of use in neonates. In addition, given the potentially large patient population that would ultimately benefit from this therapy, even if natural products are shown to be superior, availability may be a factor because of resource limitations. These issues do not exist for the recombinant and synthetic preparations, perhaps favoring further development of effective and easily manufactured synthetic products.

TABLE 60-2: EXOGENOUS SURFACTANT PREPARATIONS

Brand Name	Source/Composition
Natural Protein-Containing	
Survanta	Bovine-lung tissue extract
BLES	Bovine-lung lavage extract
Infasurf	Bovine-calf lavage extract
Alveofact	Bovine-lung lavage extract
Curosurf	Porcine-lung tissue extract
HL-10	Porcine-lung tissue extract
Synthetic/Recombinant Protein-Containing	
Surfaxin	DPPC, POPG, PA, "SP-B–like peptide"
Venticute	DPPC, POPG, PA, rSP-C
Non–Protein-Containing	
ALEC	DPPC, PG
Exosurf	DPPC, hexadecanol, tyloxapol

Abbreviations: ALEC, artificial lung-expanding compound; *BLES*, bovine lipid extract surfactant; *DPPC*, dipalmitoylphosphatidylcholine; *PA*, palmitic acid; *PG*, phosphatidyl glycerol; *POPG*, palmitoyloleoylphosphatidyl glycerol; *rSP-C*, recombinant human SP-C.

SURFACTANT DELIVERY AND DOSING

The various delivery methods that have been utilized for administering exogenous surfactant to patients with ALI include: (a) instillation of a liquid bolus through the endotracheal tube,[96] (b) bronchoscopic instillation of smaller aliquots of surfactant to the various segments of the lung,[102] (c) sequential segmental lavage of lung units with a surfactant preparation via the bronchoscope,[95] and (d) aerosolization of surfactant via a nebulizer, either in liquid form or as a dry powder.[92,103] For all methods of delivery, the common goal is to deliver sufficient amounts of material to the distal lung in an optimal distribution pattern. Unfortunately, the lung injury in critically ill patients is often non-uniform and varies over time as lung dysfunction deteriorates. As a result, it is likely that individual treatment strategies may have to be tailored to the specific patient involved. For example, patients with severe lung dysfunction with a nonuniform distribution of injury would not benefit from any aerosolized surfactant preparation delivered to the whole lung, because relatively small quantities of surfactant are deposited within lung tissue and most of the material would be deposited in the most

compliant regions of the lung, areas that need it the least.[104] In this situation, delivering large amounts of surfactant as a liquid bolus (50 to 200 mg lipid/kg body weight), either through the endotracheal tube or in sequential aliquots (with or without segmental lavage) via the bronchoscope, may be superior. The lavage approach may offer the advantage of removing inflammatory cell products and serum proteins, which tend to inhibit surfactant function, while leaving sufficient quantities of surfactant behind in the alveoli to improve lung function.[95,105] Although this latter approach is rather invasive, more time-consuming, and requires a skilled bronchoscopist to perform the procedure when compared to the bolus instillation technique, it may be optimal for specific types of severely ill patients. Currently, there is little doubt that patients with severe lung injury will require relatively large doses of surfactant to overcome surface tension inhibitory forces within the injured lung, the latter being induced either by serum proteins leaking into the airspace or inactivation of surfactant via nitration or oxidation or cholesterol, as previously described.[55,80,81,87,88,90]

Aerosolization would likely only be applicable to patients with milder disease who require smaller amounts of material and have relatively uniform injuries, a situation in which exogenous surfactant administration has yet to be tested in the clinical setting. In addition, a consistent and cost-effective nebulizer able to deliver reasonable amounts of surfactant over an extended period of time is not yet available, although dry powder delivery devices may achieve these objectives in the future.

Despite the numerous studies that have evaluated these various delivery methods in animals and humans, it is still not clear which delivery method should be used for specific types of patients, how much surfactant should be delivered per dose for the various delivery methods available, and how many doses will be required over time for each patient to achieve an optimal outcome. More research is certainly required in this area.

EFFECTS OF MECHANICAL VENTILATION

Mechanical ventilation is an important supportive therapy for patients with ALI or ARDS, and has recently been shown to impact the outcome of these patients.[86] Similar to its impact on the endogenous surfactant system, the specific mode of mechanical ventilation used in surfactant-treated lungs can influence the metabolism of the administered material. For example, animal studies have shown that lower tidal volumes resulted in superior physiologic responses compared to higher tidal volumes after exogenous surfactant was delivered as a liquid bolus; this was associated with less conversion of the administered LA forms into dysfunctional SA.[106,107] Clinically, these findings suggest that the mode of mechanical ventilation may have a significant impact on the duration of response to a particular dose of surfactant, which, in turn, would decrease the number of doses required. It is also important to optimize ventilation during and immediately after surfactant administration in order to optimize the distribution of the material and prevent airway obstruction. Positive end-expiratory pressure levels must be maintained during instillation to prevent alveolar collapse, and adequate tidal volumes must be delivered immediately after instillation to maintain recruitment and enhance peripheral distribution of the material.[106–108]

Similar to the situation in the non–surfactant-treated lung, the use of recruitment maneuvers in conjunction with exogenous surfactant is somewhat controversial, with both beneficial and even harmful effects reported.[109,110] It is likely that the timing and specific nature of the maneuver (i.e., frequency, duration, etc.) will impact its effects in the clinical setting of surfactant administration.

Finally, given the promising, albeit early, results of HFO in patients with ALI, some comments regarding its potential in the setting of exogenous surfactant administration are warranted. Very few studies have been performed to date, and results are inconsistent. Froese et al demonstrated that HFO was superior to conventional modes of ventilation after surfactant administration in saline-lavaged adult rabbits, but relatively high mean airway pressures were required to maintain lung recruitment with HFO.[111] On the other hand, a study in saline-lavaged adult sheep showed that exogenous surfactant may obstruct conducting airways when delivered in association with HFO, and that a period of more conventional tidal ventilation during and immediately following administration may be required for optimal distribution before switching over to HFO.[112] Further studies are required to determine how HFO and recruitment maneuvers should be used in conjunction with exogenous surfactant administration in patients with ALI or ARDS.

NATURE OF THE UNDERLYING INJURY

As alluded to in previous sections, the efficacy of a particular surfactant treatment strategy may predominantly depend on the specific type of patient involved, and, in this regard, influence all of the factors previously described (Fig. 60-4). ALI and ARDS can be initiated by several different insults, including those directly affecting the lung, such as aspiration and pneumonia, as well as indirect causes, such as systemic sepsis and trauma. The results of a recent phase III clinical trial, involving the synthetic surfactant preparation Venticute administered to patients with various types of ARDS, suggested that patients with direct lung injuries initiating the development of the disease would benefit the most from surfactant therapy.[96] A follow-up study, however, specifically focused on patients with direct lung injuries failed to confirm those observations, although there was some question of inactivation of the surfactant before administration.[97]

Previous studies have shown that several host factors, as well as timing of the intervention may influence a patient's response to surfactant; thus predicting consistent outcomes can be a problem in this patient population. Unfortunately, animal models that accurately reflect the various types of patients who develop ARDS, and ultimately those who would

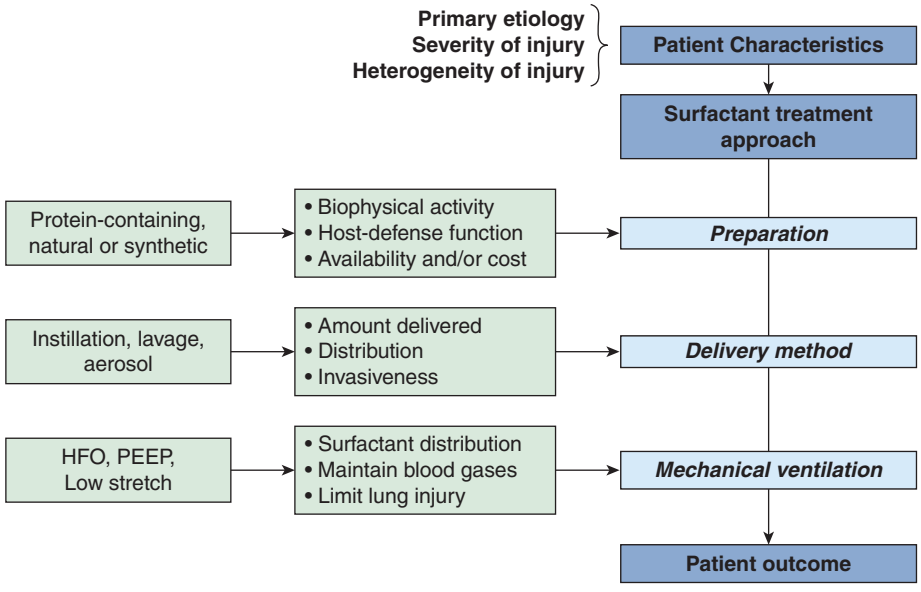

FIGURE 60-4 Various factors may influence a host's response to exogenous surfactant, including specific surfactant preparation, dosing and delivery method, mode of mechanical ventilation implemented during and after surfactant administration, and nature of the underlying injury. See text for details. *HFO*, high-frequency oscillation; *PEEP*, positive end-expiratory pressure.

respond to exogenous surfactant, are lacking. Patients with ARDS have a complex pathophysiology involving various types and severities of insults. As a result, we are left with the challenge of pursuing large, expensive, and time-consuming clinical trials with no guarantees that they will demonstrate beneficial results. It is imperative, therefore, that we gain as much insight as possible from the preclinical and clinical studies that have been conducted to date

FUTURE RESEARCH DIRECTIONS

Combination Therapies

The biophysical properties of surfactant make it a suitable candidate for combination therapies involving other agents.[113] For example, an effective surfactant adsorbs readily to the air–liquid interface and spreads rapidly across the alveolar space.[3,4,41] This puts the surfactant, as well as the added agent, in close proximity to alveolar epithelial cells as well as the pulmonary vasculature, ideally with a good distribution pattern. These particular characteristics would result in high local pulmonary concentrations of a therapeutic agent with minimal side effects or toxicity. Indeed, surfactant enhances the delivery as well as the expression of an adenoviral vector, and improves the peripheral distribution and activity of recombinant superoxide dismutases and antibiotics.[114–116] The combination of exogenous surfactant with other physiologically active compounds, such as nitric oxide and perfluorocarbons, also has been tested and shown to have synergistic effects.[117,118] Future applications for surfactant as a carrier vehicle and/or as part of a cocktail mixture for patients with lung injury require further investigation.

Role of Surfactant in Other Diseases

The vast majority of surfactant research that has focused on the mature lung has involved animal models and/or patients with ALI or ARDS. Recent evidence suggests, however, that alterations in the endogenous surfactant system also may be implicated in several other diseases of the lung, which potentially could lead to novel therapeutic approaches to these disorders in the future. One such disease reflecting alterations in endogenous surfactant metabolism is pulmonary alveolar proteinosis.[119] Increased synthesis and secretion together with decreased catabolism of surfactant results in excessive accumulation of surfactant lipids and proteins within the airspace. Removal of this excess material via whole-lung lavage has resulted in long-term benefits for most patients.

In addition, given the extensive *in vitro* and *in vivo* data showing that the various components of surfactant can affect immune-cell regulation, inflammatory cell responses, and bacterial and viral proliferation/killing, it is likely that surfactant also plays an important role in bacterial and viral pneumonia. Surfactant alterations have been consistently reported in these patients. A clinical trial involving children with respiratory syncytial virus showed improved lung function and shorter hospital stays in those receiving exogenous surfactant compared to non–surfactant-treated control subjects.[120,121] It is difficult, however, to separate the biophysical aspects of the improved lung function observed

from the immunomodulatory effects of surfactant on the development and progression of the infection itself. More animal studies and clinical trials evaluating early exogenous surfactant administration in this setting are necessary to determine if surfactant plays an important role in pulmonary infections.

Surfactant alterations also have been documented in patients with various interstitial lung diseases. These reports have shown decreased lipid and SP-A levels in the bronchoalveolar lavage fluid of patients with idiopathic pulmonary fibrosis, which in one study predicted 5-year survival.[122,123] SP-A levels were actually increased in the lungs of patients with sarcoidosis and hypersensitivity pneumonitis, suggesting that, similarly to the various types of ARDS, the role of surfactant may vary according to the specific type of interstitial disease and insult involved.[124]

Various studies suggest that surfactant plays an important role in obstructive lung diseases.[125] Surfactant facilitates ciliary function, downregulates some of the inflammatory processes implicated in these diseases (asthma and cystic fibrosis), and is important in maintaining the patency of conducting airways.[50,51] Although various studies report surfactant alterations in most obstructive diseases, only a few small studies have tested the efficacy of exogenous surfactant administration in this setting.[126] The results of these preliminary studies suggest that surfactant may be effective as therapy in asthma, although further research is required.

Finally, surfactant changes were demonstrated in the ischemia–reperfusion injury associated with lung transplantation. Exogenous surfactant, administered to the donor lung before storage, mitigated this injury, even in the setting of prolonged organ storage.[127] This indication for surfactant administration has not been tested in clinical trials to date.

SUMMARY AND CONCLUSIONS

Pulmonary surfactant is critical for maintaining alveolar stability and normal lung function. Although the composition of surfactant is relatively consistent among mammalian species, there is still much to be learned regarding the specific functions of the individual components of surfactant, particularly with respect to host defense. Most research to date involving surfactant perturbations in the mature lung has focused on the lung injury associated with ALI or ARDS, and has led to clinical trials evaluating the efficacy of exogenous surfactant administration in this setting. Unfortunately, results of these trials have been inconsistent, and somewhat disappointing. Careful analyses of these results, together with extensive preclinical studies, have provided important insight into the various factors that may influence a host's response to this therapy. Research conducted over the next few years should take advantage of the lessons learned from previous studies, and focus on the most important factors influencing a host's response to this therapy in various clinical settings, thereby optimizing patient outcomes.

NITRIC OXIDE AS AN ADJUNCT

Klaus Lewandowski

As the saying goes, unexpected scientific discoveries are often the most important. The "principle of limited sloppiness," a term coined to describe fortuitous or accidental discoveries, hit in the 1970s, when Zawadski, a technician in the laboratories of Robert F. Furchgott, failed to follow his superior's directions correctly and did not remove the endothelium in a rabbit aorta preparation. In this preparation, acetylcholine caused potent relaxation whereas contraction was expected. Shortly thereafter, it was established that acetylcholine was acting on endothelial cell receptors to produce a substance that could diffuse to the vascular smooth muscle and initiate its relaxation.[1] This substance was called endothelium-derived relaxing factor. It took another 8 years for independent working groups to confirm that the chemical structure of endothelium-derived relaxing factor was identical to that of nitric oxide (NO).[2,3]

The scientific and global community honored the substance itself and its discovery by naming NO "Molecule of the Year" in 1992.[4] The Nobel Prize in Physiology or Medicine for 1998 was awarded jointly to Robert F. Furchgott, Louis J. Ignarro, and Ferid Murad, for their breakthroughs concerning "nitric oxide as a signaling molecule in the cardiovascular system."

NO is a colorless and odorless gas. It is a toxic air pollutant, present in motor vehicle exhaust and power plant effluent. The gas is found in the atmosphere in the range of 10 to 500 parts per billion (ppb), and locations with heavy vehicular traffic can exceed 1.5 parts per million (ppm). In the hot cone of a glowing cigarette, concentrations of 1000 ppm were measured in a 40-mL puff. NO is a free radical; it quickly reacts with oxygen (O_2) to form poisonous nitrogen dioxide.

In the 1980s it became evident that NO is an essential molecule that regulates a wide range of human physiologic processes. Early studies revealed that NO is produced in endothelial cells and diffuses to vascular smooth muscle cells, where it mediates relaxation. Further studies demonstrated that the substance controls several other physiologic systems, including the immune system, platelet aggregation, and neurotransmission. The focus of this chapter is the prominent role of NO in respiratory physiology and its therapeutic application by inhalation.

ENDOGENOUS NITRIC OXIDE IN THE RESPIRATORY SYSTEM

Endogenous Nitric Oxide Synthesis

Endogenous NO is produced by the enzyme system, nitric oxide synthase (NOS). In human subjects, NOS activity can be found in the epithelium of nasal and paranasal mucosa, the bronchial epithelium, type II alveolar epithelial cells, airway nerves, inflammatory cells, airway and vascular smooth muscle cells, and endothelial cells. Three isoforms of the enzyme have been identified: the constitutive neuronal NOS, the inducible NOS (iNOS) that is incited by cytokines, and the constitutive endothelial NOS. There is evidence that a fourth isoform, mitochondrial NOS exists, which has important functions in cellular metabolism.

NO generated by neuronal NOS in the peripheral nervous system acts as a neurotransmitter that modulates smooth muscle relaxation in the respiratory tract. Inflammatory cells express iNOS that enhances NO synthesis. It is supposed that NO plays a self-regulatory role in host-defense and inflammatory processes. Yet, there are conflicting results whether NO mediates proinflammatory or antiinflammatory effects. Concurrently, overproduction of NO may also be associated with the worsening of certain infectious diseases. NO formed by endothelial NOS in vascular endothelial cells regulates pulmonary and systemic vascular tone. Mitochondrial NOS is assumed to provide substantial amounts of cardiac NO responding to heart hypoxia. Figure 61-1 shows the schematic pathway of NO signal transduction.

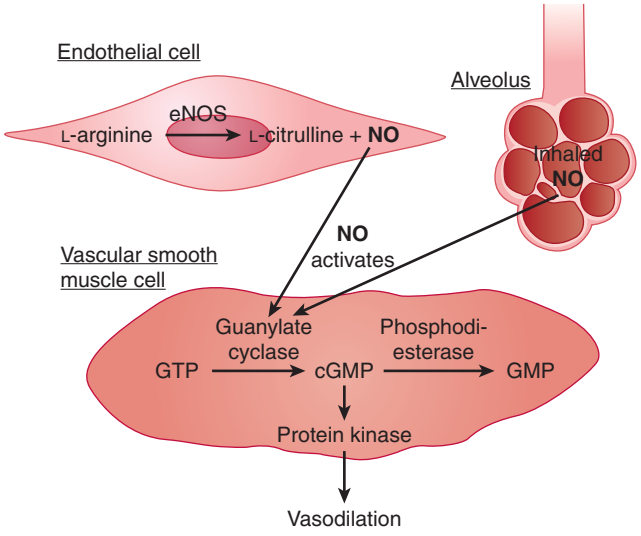

FIGURE 61-1 Endogenous or inhaled nitric oxide (*NO*) mediates vasodilation of vascular smooth muscle cells. NO is endogenously produced in endothelial cells of the pulmonary vasculature from the amino acid L-arginine, which is converted to L-citrulline and NO by the enzyme nitric oxide synthase. NO expressed by the endothelial cells, or inhaled NO, diffuses rapidly into the vascular smooth muscle cells, where it activates soluble guanylate cyclase, which converts guanosine triphosphate (*GTP*) into cyclic guanosine monophosphate (*cGMP*). The high intracellular concentration of cGMP relaxes the smooth muscle via cGMP-dependent protein kinase. cGMP is inactivated by the enzyme phosphodiesterase, which catalyzes the conversion of cGMP to guanosine monophosphate (*GMP*). *eNOS,* endothelial nitric oxide synthase.

Endogenous Nitric Oxide Concentrations in the Airways

The concentrations of NO in healthy human airways differ depending on the measurement site. Approximately 100 ppb were measured in the nasopharynx of healthy nonsmoking volunteers during nose breathing. During mouth breathing, even higher concentrations of 650 ppb were seen in the nasopharynx. The highest NO concentrations (1 to 30 ppm) were detected in the paranasal sinuses.[5] In the trachea of intubated patients the NO concentrations were markedly lower; they ranged between 5 and 10 ppb. The cilia of the epithelial cells of the maxillary sinuses contain high amounts of iNOS and can be viewed as a major production site of NO in the respiratory tract.[6]

Function of Endogenous Nitric Oxide in the Respiratory System

Endogenous NO was suggested to be an important signaling molecule in numerous physiologic processes. Autoinhaled NO from the paranasal sinuses is able to induce selective pulmonary vasodilation in ventilated areas. The blood flow through well-aerated lung areas with higher intraalveolar O_2 concentrations increases and ventilation–perfusion mismatch is antagonized.

Endogenous NO is also involved in host defense and has direct microbicidal effects. Especially the high levels of endogenous NO in the paranasal sinuses may be active in local nasopharyngeal host defense against bacterial or viral invaders. Other findings substantiate that endogenous NO increases airway mucus secretion. Ciliary beat frequency, responsible for microbial clearance, is also enhanced by iNOS stimulators.

Bronchodilation is suppressed by NOS inhibitors, indicating that endogenous NO modulates basal bronchial tone. There is evidence that endogenous NO may protect the airways of asthmatic patients from bronchoconstriction.[7] The high levels of NO, measured in the exhaled air of patients with asthma, however, are believed to mirror the stimulation of iNOS by proinflammatory cytokines and seem to have harmful effects, such as inflammation and increased vascular permeability.

NO is excreted by tumor and host cells and is a factor of promoting angiogenesis and tumor growth. The role of NO in cancer, however, is yet undetermined as it has been attributed both, tumoricidal as well as tumorigenic properties. There are indications that inhibiting iNOS may be beneficial in treatment of certain forms of cancer.

Furthermore, endogenous NO possibly regulates the coagulation system. Formation of endogenous NO also seems to be involved in mediating pulmonary vasodilation during transition of the pulmonary circulation at birth.

RATIONALE FOR THE USE OF INHALED NITRIC OXIDE AS AN ADJUNCT

Inhaled nitric oxide (iNO) acts as a selective pulmonary vasodilator. As a gas, it reaches only ventilated alveoli and produces relaxation of the accompanying pulmonary blood vessels. iNO acts by producing vasodilation in well-ventilated lung units and redistributing pulmonary blood flow from unventilated to ventilated regions of the lung. This results in improvement of ventilation–perfusion mismatch and oxygenation, in a decrease of pulmonary vascular resistance and pulmonary artery pressure (PAP), as well as in a lower right-ventricular afterload. The activity of iNO is mainly limited to the area of deposition when lower concentrations of iNO are applied because large amounts of the molecule are inactivated by binding to hemoglobin at the moment NO diffuses into the blood vessel. This explains why iNO has almost no systemic side effects and acts predominantly in the pulmonary circulation (Fig. 61-2).

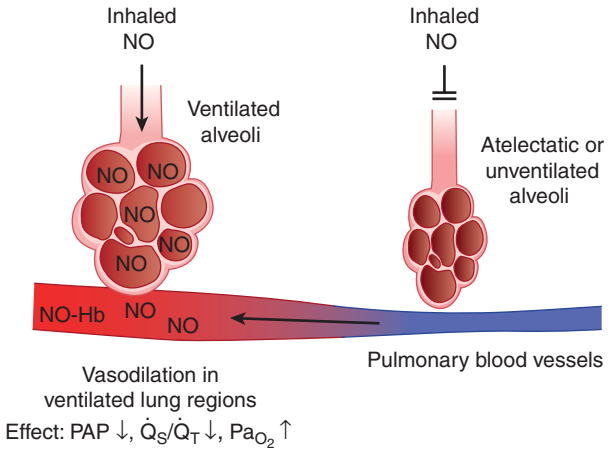

FIGURE 61-2 Inhaled NO selectively produces vasodilation in ventilated alveoli. iNO produces vasodilation in well-ventilated lung units and redistributes pulmonary blood flow from unventilated to ventilated lung regions. In patients with ventilation–perfusion mismatch (e.g., patients with acute respiratory distress syndrome), this leads to improvement in oxygenation and reduction of intrapulmonary right-to-left shunt. Selective vasodilation in the pulmonary circulation causes significant reduction of elevated pulmonary artery pressure; thus, iNO is a valuable therapy in patients with all kinds of pulmonary hypertension. Systemic vasodilation does not occur to a noteworthy extent because large amounts of NO rapidly bind to hemoglobin and are thereby inactivated. *Hb,* hemoglobin; *iNO,* inhaled nitric oxide; *NO,* nitric oxide; Pa_{O_2}, arterial partial pressure of oxygen; *PAP,* pulmonary arterial pressure; $\dot{Q}_S/\dot{Q}_T$, intrapulmonary right-to-left shunt.

INDICATIONS AND OUTCOME OF INHALED NITRIC OXIDE THERAPY

Adults and Older Children

Inhaling low concentrations of NO causes rapid and safe reduction of an elevated PAP, and improves the impaired oxygenation in many patients without causing systemic hypotension. In the early 1990s, iNO became an innovative treatment option for patients with acute respiratory failure and pulmonary hypertension.

In patients with acute respiratory distress syndrome (ARDS), improvement of oxygenation and reduction of PAP is an important therapeutic goal. iNO selectively enhances perfusion in ventilated lung areas and counteracts the ventilation–perfusion mismatch typical of this condition. Because NO works only in aerated lung tissue, measures that recruit previously collapsed alveoli can enhance the beneficial effect of NO. The overall effect of iNO is often an impressively increased arterial partial pressure of oxygen (PA_{O_2}) and a reduction of the elevated PAP. Several enthusiastic reports encouraged the hope that iNO would prove to be the promising new therapy that would ultimately improve the low survival rates in ARDS. Disappointingly, an improved outcome of ARDS patients could not be observed. A meta-analysis of twelve randomized controlled trials that included 1237 patients revealed that iNO significantly improves oxygenation during the first days of inhalation, although no benefit on survival could be detected. Treatment with iNO was further burdened with an increased risk of renal dysfunction.[8]

The significant improvements in oxygenation and reduction of elevated PAP by iNO, however, could not be denied, and prompted scientists to study the effect of iNO in other diseases associated with severe hypoxia or pulmonary hypertension. Table 61-1 presents a literature survey, focusing on iNO therapy in several diseases or conditions in adults or older children. It further provides expert recommendations for the application of iNO in the respective patient collectives. Synopsis of the information compiled in the table allows for the conclusion, that in most cases of severe oxygenation impairment or high PAP, iNO is effective. When considering iNO as a possible therapeutic option in adult patients, it is important to recognize that certain pathophysiologic variables may significantly improve, although in no instance was survival clearly enhanced.

What are still suitable indications for iNO in adults or older children? It may be indicated in patients who are in a phase of severely impaired gas exchange that is unresponsive to maximal medical therapy. In such settings, application of iNO can significantly enhance pulmonary gas exchange and thereby prevent hypoxic organ damage. Moreover, iNO can be tried in all patients suffering from severe pulmonary hypertension. In most cases, elevated PAP drops and relieves the right heart. When considering possible iNO treatment,

TABLE 61-1: iNO TREATMENT IN ADULTS AND OLDER CHILDREN: BENEFIT AND EXPERT RECOMMENDATIONS

Diagnosis	Effect of NO Inhalation	Expert Recommendations
Heart disease, heart failure (iNO for diagnostic purposes)	Pulmonary vascular reactivity testing with O_2 and iNO can identify patients with pulmonary hypertension suitable for corrective cardiac surgery or heart transplantation.[52] Patients with severe heart failure may experience pulmonary edema with inhalation of NO, probably because of increased left atrial filling after pulmonary vasodilation.[53]	iNO trial for identification of patients suitable for cardiac surgery or heart/lung transplantation is recommended. iNO testing in patients with left-heart dysfunction is dangerous, heart function should be optimized before iNO testing.[20]
Pulmonary arterial hypertension (iNO for diagnostic purposes)	iNO decreases PAP effectively in some patients. The acute decrease of PAP with iNO is the best predictor of long-term response to oral vasodilator treatment.[54] iNO can identify responders for a long-term treatment with calcium-channel blockers.[55]	iNO is recommended for acute vasodilator testing in a dosage of 10 to 20 ppm.[20] Insufficient data to recommend long-term inhalation of NO.[20]
Thromboembolism	In four cases of pulmonary embolism, iNO led to improvement of pulmonary hemodynamics and oxygenation.[56] In four further patients with acute massive pulmonary embolism, inhaled NO rapidly improved pulmonary and systemic blood pressures, heart rate, and gas exchange.[57]	No routine use of iNO in thromboembolic disease recommended because of insufficient data. In patients with severe right-ventricular failure or severe hypoxemia, iNO may be beneficial.[20]
Sickle cell disease	Most common complications of sickle-cell disease are the vasoocclusive pain crisis and the acute chest syndrome, a form of lung injury, as well as hemolysis. Hemolytic anemia is associated with pulmonary hypertension.[58] Results from two small randomized, placebo-controlled trials suggested that in severe vasoocclusive crisis, inhalation of 80 ppm NO decreased pain scores and morphine use.[59,60]	No routine use of iNO recommended because of insufficient data.[20]
Chronic obstructive pulmonary disease (COPD)	Effects of iNO in patients with COPD are contradictory. In one study, iNO improved oxygenation and reduced PAP while right-ventricular ejection fraction increased.[61] In another study, iNO reduced PAP but did not improve right-ventricular ejection fraction or arterial oxygenation in patients with acute respiratory failure caused by acute exacerbation.[62] In a third study, however, addition of iNO to inhaled oxygen did not improve or worsen arterial partial oxygen pressure, but caused a significant decrease in mean PAP. Cardiac output increased. Long-term use of iNO was effective.[63] In ten volunteers with very severe COPD iNO in concentrations of 40 to 40,000 ppb did not improve oxygenation.[64]	No evidence of a clinical benefit of iNO in patients with COPD.[20]
High-altitude pulmonary edema (HAPE)	In mountaineers prone to HAPE, iNO produced a marked decrease in PAP. In subjects with radiographic evidence of pulmonary edema, iNO improved oxygenation.[65] In fourteen patients with severe HAPE, iNO reduced PVR by 36% compared with room air. PVR fell by 54% when iNO was combined with 50% oxygen. Pa_{O_2} increased by 14% when iNO was applied.[66] In a rat model of HAPE, iNO improved survival.[67]	No recommendation because of insufficient data.
Myocardial infarction and cardiogenic shock	In thirteen patients with right ventricular myocardial infarction and cardiogenic shock iNO significantly decreased PAP and PVR, and increased CI by 24%.[68] Application of iNO before and during coronary reperfusion is able to reduce infarct size (animal experiment).[69]	No recommendation because of insufficient data.
Right-ventricular failure (RVF)	RVF responds favorably to afterload reduction. In RVF after myocardial contusion or after right-ventricular myocardial infarction with cardiogenic shock, iNO rapidly improved hemodynamics.[68,70]	No recommendation because of insufficient data.

Perioperative pulmonary hypertension and RVF in cardiac surgery	Cardiopulmonary bypass reduces NO production in pulmonary tissue that leads to pulmonary vasoconstriction and right-ventricular dysfunction postoperatively (animal experiment).[71] Inhalation of NO during and after cardiopulmonary bypass diminishes the release of markers of myocardial injury. Left ventricular dysfunction during and immediately after cardiopulmonary bypass is antagonized.[72] In twenty-three patients with pulmonary hypertension, treated with iNO immediately after cardiopulmonary bypass, iNO significantly reduced PAP and PVR and lead to increased cardiac output.[73]	In patients with perioperative acute right-ventricular dysfunction and pulmonary hypertension, RVF should be optimized first by conventional measures before a trial of iNO should be undertaken. iNO doses >20 ppm have no advantage.[20]
Left-ventricular assist devices (LVADs)	Pulmonary hypertension is frequent in patients treated with LVADs and may lead to right-ventricular dysfunction. Eleven patients with LVADs and pulmonary hypertension were randomized to iNO (20 ppm) and control therapy. iNO precipitated significant reductions in PAP and increased LVAD flow. In control patients, no hemodynamic improvement was recorded.[74] A recent randomized controlled trial studied the effect of iNO in forty-seven patients with implanted LVADs. Only in the iNO group did PVR decrease significantly, from 311 ± 35 to 225 ± 17 dyn sec cm^{-5} ($p < 0.01$).[75]	Expert panel believes that iNO improves pulmonary hemodynamics in patients with inadequate left-sided flow during use of LVADs and pulmonary hypertension refractory to conventional maneuvers. In this situation, they recommend application of iNO among other vasodilator therapies.[20]
Heart transplantation	Pulmonary hypertension is a frequent problem during heart transplantation and may contribute to life-threatening right-heart failure. In heart transplant recipients with pulmonary hypertension, iNO given in the postoperative period selectively reduced PVR and enhanced right-ventricular stroke work. Compared with a historical cohort, the NO treated group had better survival rates.[76] Fourteen patients with either heart transplantation or lung transplantation received iNO in the operating room when pulmonary hypertension, refractory hypoxemia, or right-ventricular dysfunction were present. Inhalation of 20 ppm NO lowered PAP and central venous pressure, increased cardiac index, and improved mixed venous oxygen saturation.[77]	iNO is used by several institutions with experience in cardiac transplantation. They recommend it as standard therapy for heart transplantation complicated by an elevated PVR.[20]
One-lung ventilation (OLV)	Hypoxia is a frequent complication during OLV. Sixteen patients who developed hypoxemia during OLV were randomized to iNO (20 ppm) or control groups (nitrogen). iNO when administered to the dependent lung was not superior to nitrogen.[78] In patients with pulmonary hypertension during OLV, iNO caused a significant reduction of mean PAP and improved oxygenation in patients with severe hypoxemia.[79] A combination of iNO with almitrine significantly improved oxygenation during OLV.[26]	Expert panel does not recommend routine use of iNO during OLV. Only in case of severe hypoxemia, refractory to conventional therapy, iNO may beneficial.[20]
Major lung resection	Postpneumonectomy pulmonary edema is a severe complication of lung resection and afflicted with high mortality rates. In a patient with major lung resection iNO was successfully applied to treat postpneumectomy pulmonary edema (case report).[80]	No recommendation because of lack of data.
Lung transplantation	There remains controversy whether iNO can prevent ischemia–reperfusion injury in lung-transplant recipients. Some studies performed in the 1990s reported that iNO reduced reperfusion injury in transplanted lungs. Another study, however, showed that prophylactic iNO does not prevent reperfusion injury. During reperfusion, however, patients with reperfusion injury experienced improved oxygenation and reduction of PAP.[81] Contrary to earlier studies, a large randomized, controlled trial could also not detect a significant effect on physiologic variables or outcomes in the group of iNO-treated patients, in whom iNO was initiated 10 minutes after reperfusion.[82] The occurrence of acute graft rejection, however, was less frequent in the iNO group in comparison with historical controls.[83] Recent randomized clinical trials could not detect a benefit of a prophylactic administration of iNO for prevention of primary graft failure, however, in case of development of a hypoxic phase during primary graft failure, iNO may reduce the need for extracorporeal membrane oxygenation in lung transplant patients.[84]	No evidence that iNO prevents reperfusion injury after lung transplantation.[20]

(*continued*)

TABLE 61-1: iNO TREATMENT IN ADULTS AND OLDER CHILDREN: BENEFIT AND EXPERT RECOMMENDATIONS (*CONTINUED*)

Diagnosis	Effect of NO Inhalation	Expert Recommendations
Acute lung injury (ALI)/ acute respiratory distress syndrome (ARDS)	iNO was found to reduce elevated PAP, improve oxygenation, and decrease intrapulmonary right-to-left shunt during the first days of treatment.[31] A meta-analysis of twelve randomized controlled trials that included 1237 patients revealed that iNO improves oxygenation during the first days of inhalation. No benefit on survival could be detected. Risk of renal dysfunction was increased in the iNO patients.[8] These findings were confirmed by a large systematic review of the Cochrane Collaboration.[29]	No routine use of iNO in ALI/ARDS. Trial of iNO as a rescue treatment in case of life-threatening hypoxemia.[20]
Influenza	Patients with H1N1 influenza very rapidly develop respiratory failure. Thirty-two patients of the H1N1 influenza epidemic 2009 in Spain were evaluated and 25% received iNO as a rescue therapy.[85] In Canada, 168 critically ill patients with influenza A (H1N1) were admitted to thirty-eight intensive care units and prospectively evaluated; 13.7% of the patients received iNO as a rescue therapy.[86]	ICUs treating influenza patients should provide advanced ventilatory support and rescue therapies including iNO.[87]
Inhalation injury	There are only few reports on use of iNO in burn patients with inhalation injury.[88–90] All studies reported an improved oxygenation with iNO therapy. An immediate and stronger early response to NO inhalation may eventually predict recovery, however, all studies were only performed in a small series of patients with the respective weakness of the reported results.	No routine use of iNO in inhalation injury. Trial of iNO as a rescue treatment in case of life-threatening hypoxemia after conventional treatment has been optimized. In case of early response to iNO, the inhalation should be continued.[91]
Asthma	Inhalation of NO results only in a minor relaxation of airway tone in adults.[92,93] In children with asthma, iNO has no apparent bronchodilatory effect.[94] In case of severe status asthmaticus, however, iNO might have a bronchodilatory effect (case report).[95] In five children with life-threatening status asthmaticus who required MV and did not respond to maximal medical management, iNO decreased Pa_{CO_2} significantly. Four children survived.[96]	No recommendation as to date no controlled studies on this topic have been performed.

Abbreviations: CI, cardiac index; *ICU,* intensive care unit; *iNO,* inhaled nitric oxide; *PAP,* pulmonary artery pressure; *PVR,* pulmonary vascular resistance.

however, it is strongly recommended to optimize conventional treatment before a trial of iNO is undertaken.

Infants

Application of iNO yielded the best results in critically ill infants. In 1999, the use of iNO was approved by the United States Food and Drug Administration (FDA) for the treatment of term and near-term newborns (>34 weeks of gestation) with hypoxic respiratory failure associated with pulmonary hypertension.

In neonates with respiratory failure, persistent pulmonary hypertension of the newborn (PPHN) is common. PPHN is characterized by elevated pulmonary resistance, pulmonary vasoconstriction, and altered vascular reactivity. Desaturated blood circulates partly through an extrapulmonary right-to-left shunt, across the foramen ovale and ductus arteriosus. Since 1970, extracorporeal membrane oxygenation (ECMO) has been the treatment of choice if PPHN is present. Survival rates of up to 80%[9] were achieved with ECMO therapy whereas survival with conservative therapy was approximately 50%.[10] In hypoxemic newborns with PPHN, clinical studies indicate that iNO increases systemic O_2 levels, decreases PAP, and mitigates ventilation–perfusion mismatch. Randomized, placebo-controlled trials of iNO in neonates with PPHN failed to show a significant decrease in mortality rates in the iNO group; iNO therapy did, however, reduce the requirement for ECMO.[11,12]

Some years ago, a large, randomized, controlled trial documented the effectiveness of iNO in 207 preterm neonates with respiratory failure. iNO decreased the incidence of chronic lung disease and death.[13] These encouraging findings, however, were not supported by further studies. A recent systematic review of fourteen randomized controlled trials that studied iNO therapy in preterm neonates unveiled a disappointing picture. iNO was not able to significantly decrease mortality rates and early rescue treatment is probably associated with a higher risk of intraventricular hemorrhage.[14] In a selected patient collective of premature infants with a birth weight between 1000 and 1250 g, however, early inhalation of NO might reduce the incidence of bronchopulmonary dysplasia.[15]

Perioperative pulmonary hypertension in infants with congenital heart defects is harmful and compromises their chance of survival. iNO, however, has not proven to reduce mortality or the number of pulmonary hypertensive crises.[16] A trial with iNO could only be recommended in infants with severe pulmonary hypertension in the perioperative setting of congenital heart surgery.[17,18]

From a pathophysiologic point of view, iNO therapy may be harmful for newborns with congenital heart disease dependent on right-to-left shunts and its routine use is not recommended in this setting.[11] Newborns with congestive heart failure and lethal congenital anomalies should also be excluded from iNO therapy.[11]

Table 61-2 presents an overview of the literature on the effect of iNO therapy in several diseases or conditions in infants together with expert recommendations. In a nutshell, physicians caring for infants with hypoxic respiratory failure and PPHN should be familiar with the use of iNO. In newborns it should be used liberally if these indications are present, because ECMO therapy can be avoided in many cases. In preterm infants, however, routine use of iNO is not recommended.[17]

TECHNIQUE OF NITRIC OXIDE INHALATION

It is strongly recommended to use a delivery device for iNO that is approved for clinical use.[11] The FDA has published a guidance document for approval of NO delivery systems that specifies the technical requirements for safe administration of iNO.[19] Important specifications are that the gas be supplied in a constant concentration during inspiratory flow; administered iNO concentrations should not vary with flow fluctuation within the inspiratory phase of the respiratory cycle; for regulation of iNO concentrations, a range of 0 to 80 ppm should be allowed; the system should be specified for connection with pharmaceutical grade NO gas cylinders containing 400 to 800 ppm NO in nitrogen; contact time of NO and O_2 should be short to limit NO_2 formation; the system should further be equipped with NO, NO_2, and O_2 gas analyzers and alarm functions to warn the intensivist against too low or too high levels of NO and O_2 concentrations, discontinuation of gas flow, or accumulation of NO_2;[11,19] NO analyzers should be able to measure iNO concentrations as low as 1 ppm;[19] and a manual back-up NO supply device for emergency or transport reasons should be available near the ventilator to ensure continuous delivery of the therapeutic gas.[20]

In clinical practice, iNO delivery devices are generally connected to anesthesia and intensive care ventilators, to high-frequency ventilators, to transport ventilators, and manual ventilation systems. In spontaneously breathing, nonintubated infants, iNO therapy is also established by nasal cannula and continuous positive airway pressure systems. It is recommended to check the manufacturers' specifications before connecting the iNO system to any ventilation device.[11]

DOSAGE OF INHALED NITRIC OXIDE

Dose–response studies in patients with ARDS show that very low concentrations of iNO, only 10 ppb, are able to enhance oxygenation; higher concentrations are necessary to decrease the elevated PAP. The respective effective doses whereby 50% of individuals will show the expected response to iNO are 100 ppb and 2 to 3 ppm. Improvement in oxygenation reached a maximum at 10 ppm and

TABLE 61-2: iNO TREATMENT IN INFANTS: BENEFIT AND EXPERT RECOMMENDATIONS

Application of iNO/ Diagnosis	Effect of NO Inhalation		Expert Recommendations
Assessment of the reversibility of pulmonary hypertension	When evaluating a patient for corrective heart surgery or heart transplantation, an iNO trial may be useful in determining operability. One hundred twenty-four patients with heart disease complicated by pulmonary hypertension received 100% oxygen and iNO to test pulmonary vascular reactivity. Test results could identify proper candidates for corrective surgery.[52] A recent retrospective trial studied children with pulmonary hypertension who underwent vasodilator testing before heart transplantation. Children who did not respond had increased rates of right-ventricular failure (RVF) and death from RVF. Preemptive use of iNO might decrease frequency of RVF.[97]		Pulmonary reactivity testing with iNO and oxygen is recommended in infants with heart disease complicated by pulmonary hypertension to identify proper candidates for corrective surgery.[18]
Hypoxia in term and near-term neonates	In 1999, use of iNO was approved by the FDA for treatment of hypoxic respiratory failure and pulmonary hypertension in term and near term neonates. The Cochrane Collaboration performed an analysis of fourteen randomized, controlled studies in term and near-term newborns with hypoxia. Use of iNO reduced the need for extracorporeal membrane oxygenation (ECMO) and improved oxygenation. Reduction of mortality was not evident. There were, however, indications that outcome of infants with diaphragmatic hernia was worsened.[12]		A trial of iNO is favored in newborns ≥34 weeks gestation, <14 days of age and with Pa_{O_2}/FI_{O_2} <100 mm Hg and/or an oxygenation index >25. iNO therapy should begin early in the course of the disease.[11]
Hypoxia in preterm neonates	Despite some encouraging early reports, iNO has not proven to be beneficial in preterm neonates. A recent systematic review performed by the Cochrane Collaboration analyzed fourteen randomized, controlled trials investigating iNO therapy in preterm neonates. Rescue therapy with iNO in case of severe hypoxia did not reduce mortality. Routine application of iNO in infants with pulmonary disease also could not reduce mortality. Although early rescue treatment was associated with a 20% higher incidence of intraventricular hemorrhage, this finding was not significant.[14]		Routine use of iNO in preterm infants (<34 weeks gestation) is not recommended.[17]
Persistent pulmonary hypertension of the newborn (PPHN) caused by lung parenchyma diseases leading to abnormally constricted pulmonary vasculature[98]	Meconium aspiration syndrome, Respiratory distress syndrome, Pneumonia	In 1999, use of iNO was approved by the FDA for treatment of hypoxic respiratory failure and pulmonary hypertension in term and near-term neonates. A recent systematic review for the development of evidence based clinical practice guidelines for use of iNO in newborns, presenting with hypoxemic respiratory failure associated with pulmonary hypertension, revealed the following results[11]: analysis of nine studies that reported mortality detected no significant effect of iNO on this parameter; eight studies evaluated long-term outcomes. Neurodevelopmental outcomes were similar in neonates treated with iNO and controls. Pulmonary outcomes in both groups were also similar. Eight studies reported requirement for ECMO. Meta-analysis of these data revealed less need of ECMO in the iNO groups.	A trial of iNO is recommended in newborns ≥34 weeks gestation, <14 days of age and with Pa_{O_2}/FI_{O_2} <100 mm Hg and/or an oxygenation index >25. iNO therapy should begin early in the course of the disease.[11] iNO therapy should start with 20 ppm. If there is no response to a 30- to 60-minute trial of iNO, iNO therapy should be terminated. In parenchymal lung disease optimal recruitment of lung tissue should be achieved before NO inhalation. Lowest effective dose of iNO and O_2 should be applied.[11]
PPHN due to abnormally remodeled pulmonary vasculature with normal lung parenchyma[98]	Idiopathic PPHN		

PPHN caused by hypoplastic pulmonary vasculature[98]	Congenital diaphragmatic hernia (CDH)	Patients with CDH seem to gain almost no benefit from iNO treatment. A randomized study in fifty-three term and near-term infants with CDH reported no significant improvement in oxygenation in the iNO group. Although patients of the iNO group needed more ECMO treatment and had a higher death rate than control patients, these findings were not significant.[99] Controversial results were offered by further studies. Early surgery and iNO improves the outcome and reduces the requirement for ECMO in the treatment of antenatally diagnosed congenital diaphragmatic hernia.[100] Retrospective data from sixty-one newborns with CDH give evidence that survival rates of infants with CDH have improved over the last 10 years, which was attributed by the study team to new therapies, including iNO.[101] This result is not concordant with data from a similar study in twenty-seven Norwegian neonates with CDH. The patient collective treated with novel therapeutic measures including iNO had a higher mortality than that treated before 1997, when these therapy options were not available.[102]	No convincing benefit for newborns with congenital diaphragmatic hernia. Routine use of iNO in these patients is not indicated.[11]
Bronchopulmonary dysplasia (BPD)	BPD is a chronic lung disease mainly of preterm infants, that often develops after postnatal injury by therapeutic measures, such as mechanical ventilation and high inspiratory oxygen concentrations.[98] Pulmonary hypertension and reduction of alveolar–capillary surface area are significant contributors to high mortality in these patients. There are no convincing results that support prophylactic inhalation of NO for prevention of BPD in preterm neonates. Only one study described a markedly lower incidence (30% vs. 60%) of BPD with iNO therapy in premature infants with a birth weight between 1000 and 1250 g.[15]		No recommendation because of a lack of data.
Perioperative pulmonary hypertension in congenital heart patients	Pulmonary hypertensive crises postoperatively after congenital heart surgery are dangerous and afflicted with high mortality. One hundred twenty-four infants with congenital heart defects were randomized to iNO or placebo therapy from heart surgery and postoperatively until extubation as a prophylaxis for prevention of pulmonary hypertension. Frequency of pulmonary hypertensive crises was less in infants receiving iNO (RR = 0.66).[103] These findings differ from that of a Cochrane review of four randomized trials that analyzed the effects of postoperative iNO versus placebo. No differences in several outcome variables (i.e., mortality, number of pulmonary hypertensive crises, oxygenation, etc.) between the two groups could be detected.[16]		No routine use of iNO in the postoperative management of hypoxic term or near-term infants with congenital heart disease.[11] More data from clinical trials are necessary to recommend routine prophylactic iNO administration in children who are at risk for pulmonary hypertension after congenital heart surgery.[17] A trial of iNO, however, is proposed in patients with significant pulmonary hypertension in the perioperative setting.[17,18]
Cavopulmonary circulations, Fontan-type procedures	iNO may be of use in the setting of cavopulmonary circulations. iNO administered in thirteen patients postoperatively after total cavopulmonary connection significantly decreased transpulmonary pressure gradient and improved oxygenation.[104] These findings were confirmed by a prospective randomized trial in forty-six patients with high PVR and impaired oxygenation after Fontan-type procedure. iNO significantly decreased the transpulmonary pressure gradient and improved the oxygenation, however, the combination of iNO with milrinone was even more effective.[105]		After cavopulmonary procedures a trial of iNO could be considered when a high transpulmonary gradient is present in the postoperative period.[18]

Abbreviations: iNO, inhaled nitric oxide; *PVR,* pulmonary vascular resistance; *RR,* relative risk.

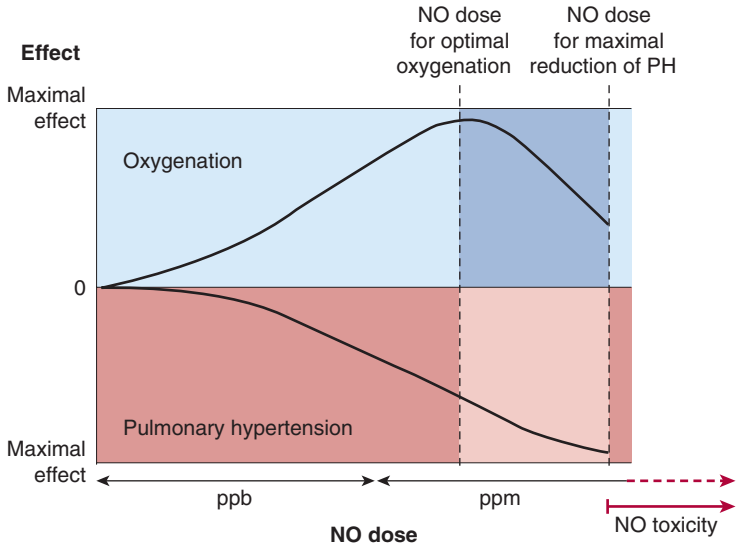

FIGURE 61-3 Schematic dose–response curve for patients with ARDS treated with iNO. Low doses of iNO (in the parts per billion range) are able to improve oxygenation whereas higher levels of iNO are necessary to significantly decrease the elevated PAP. Oxygenation improves to a maximum and then deteriorates at higher NO concentrations. Maximal reduction of PAP needs even higher doses of NO. It is recommended to verify the dose–response characteristics for each individual patient starting before NO treatment. *iNO,* inhaled nitric oxide; *NO,* nitric oxide; *PAP,* pulmonary arterial pressure; *PH,* pulmonary hypertension; *ppb,* parts per billion; *ppm,* parts per million.

deteriorated at higher NO doses; PAP further decreased with higher NO concentrations. Studies were stopped at 100 ppm.[21] Data suggest that higher doses of NO reach blood vessels supplying partially or nonventilated lung areas. For exact dosage, the registration of an individual dose–response curve for each patient is indispensable (Fig. 61-3). This approach is also desirable in patients with indications other than ARDS.

For improvement of oxygenation in adult patients with ARDS, iNO concentrations ranging from 1 to 20 ppm are effective, for reduction of mean PAP a dose in the range of 1 to 40 ppm is required.[22] Concentrations of 80 to 100 ppm should not be exceeded.

For neonates, it is recommended to start with a dose of 20 ppm iNO. If an improvement with iNO therapy is observed, the iNO concentration should be reduced to the lowest dose that sustains the response.[11]

RESPONDERS AND NONRESPONDERS

Regarding oxygenation and PAP, about a third of critically ill patients are nonresponders and do not react favorably to NO.[22] Reasons include persistent pulmonary blood flow to dorsal edematous lung areas; physical barriers, such as the presence of exudate or fibrosis; molecular mechanisms, such as increased activity of phosphodiesterase; unfavorable ventilator settings; and, most likely, a number of currently unknown factors. It appears sensible to evaluate a patient's response to iNO on a daily basis because initial nonresponders may convert to responders over time, and vice versa.

ADJUNCTIVE THERAPY

When the clinician faces a patient in acute respiratory failure who does not respond to iNO at all or the patient's response is very weak, adjunctive measures can positively change the situation.

Nonresponse to iNO may be related to lack of aerated lung tissue. Measures ensuring that the lungs inflate adequately and therapeutic options maintaining a sufficient end-expiratory lung volume, applied before NO inhalation, may lead to a satisfying NO response.

Re-evaluation of the level of positive end-expiratory pressure represents one of these measures. Recruiting additional alveoli may increase the number of alveoli, whereby NO can easily flow in and exert its beneficial effects. This idea has been tested in experimental and clinical trials. It was shown that when positive end-expiratory pressure led to alveolar recruitment, a rise in $P_{A_{O_2}}$ of more than 100 mm Hg could be achieved.[23,24]

Ventilating critically ill patients in the prone position may dramatically enhance oxygenation by antagonizing ventilation–perfusion mismatch. Exploiting this mechanism in patients receiving iNO therapy can further enhance oxygenation as compared with iNO in the supine position.[25]

Almitrine bismesylate acts as a pulmonary vasoconstrictor mainly in pulmonary vessels supplying hypoxic lung regions and reduces their perfusion. Theoretically, it was hoped that NO, a selective pulmonary vasodilator, and almitrine, a selective pulmonary vasoconstrictor, would act additively on oxygenation. iNO combined with almitrine was studied in patients with ARDS and during one-lung ventilation.[26,27] Addition of almitrine to iNO may lead to a further improvement in oxygenation, although a rise of

mean PAP of about 3 to 8 mm Hg has to be accepted. Given the potentially harmful effects of this strategy, its routine use is not advisable.

SIDE EFFECTS AND TOXICOLOGY

An adage attributed to the physician, astrologer, and theologian, Philippus Theophrastus Bombastus of Hohenheim, better known as Paracelsus (1493–1541), reads: "All substances are poisons; there is none which is not. The right dose differentiates a poison from a remedy." Regarding NO, this is surely true. Only a narrow margin exists between an effective and a toxic dose. Direct NO toxicity at clinically relevant doses, however, is uncommon, whereas exposure to NO_2 is potentially toxic.

Formation of Nitrogen Dioxide

NO reacts with O_2 and forms toxic nitrogen dioxide (NO_2). High O_2 concentrations combined with high NO concentrations react with the formation of that toxic by-product. Inhaled NO_2 at 2 ppm already affects alveolar permeability and NO_2 concentrations above 10 ppm may induce pulmonary edema, alveolar hemorrhage, methemoglobinemia, hypoxemia, changes in surfactant activity, hyperplasia of type II alveolar cells, intrapulmonary accumulation of fibrin, neutrophils, and macrophages, and eventually death.[28]

Synthesis of harmful concentrations of NO_2 is uncommon, especially when therapeutic doses of NO are inhaled. A study presented by the Cochrane Collaboration that analyzed fourteen randomized trials on acute lung injury/ARDS found no elevated risk for NO_2 formation associated with iNO therapy.[29] In clinical practice, it is recommended to limit the iNO concentration to 10 ppm or less when long-term application is necessary, to reduce possible genesis of toxic NO_2.[20] Alarm levels should be set to 2 ppm NO_2.[11]

Rebound after Nitric Oxide Withdrawal

During weaning from NO, its rapid withdrawal can cause marked rebound pulmonary vasospasm,[30] high intrapulmonary right-to-left shunt, and decreased PA_{O_2}.[31] Twenty-six percent of patients receiving iNO for acute hypoxemic respiratory failure (responders) exhibited only minimal changes in PA_{O_2} or hemodynamics after abrupt discontinuation of iNO, whereas 48% exhibited worsening of gas exchange. Another 26% of the patients reacted primarily with hemodynamic side effects. Reapplication of iNO immediately reversed the hemodynamic and oxygenation deterioration.[32] This phenomenon can be explained by downregulation of NO synthase activity in the presence of exogenous NO. In pediatric patients after cardiac surgery, longer continuation of iNO and its lower final concentration are factors that contribute to its successful weaning. Consequently, it seems prudent to slowly wean a patient from iNO. Rebound phenomena may be mitigated when iNO is not discontinued until a considerable clinical improvement is accomplished and the iNO dose is progressively reduced to 1 ppm before the gas is switched off. It is further recommended to increase FI_{O_2} before iNO cessation.[11]

Alternatively, the clinician can exchange NO for a different pulmonary vasodilator, or wait until the patient's endogenous production recommences. The drug sildenafil, given before discontinuation of iNO, has shown to effectively prevent rebound pulmonary hypertension in children.[33,34]

Systemic Vasodilation

For many years, a key characteristic of NO seemed to be its selectivity as a pulmonary vasodilator. This characteristic was explained by its rapid binding to the heme moiety of hemoglobin and its very short duration of action. Indeed, in many clinical trials and animal experiments, substantial effects on arterial blood pressure or other systemic circulation variables have not been observed. In some instances, however, reductions in systemic blood pressure and systemic vascular resistance were documented.[35,36] A new insight helps explain this phenomenon: NO can bind reversibly with albumin and hemoglobin and thereby enter the systemic circulation.[37–39] Circulating erythrocytes may be the vehicles that distribute NO to peripheral vascular beds. In areas of low O_2 tension, erythrocytes offload O_2 and NO, thereby inducing hypoxic vasodilation.[40] Furthermore, nitrite and nitrate, the oxidative end products of NO metabolism, exert systemic NO effects because they can be recycled to NO in blood and tissues.[41]

Methemoglobinemia

iNO can combine with hemoglobin to form nitrosyl hemoglobin, which is rapidly oxidized to methemoglobin. High iNO doses are associated with methemoglobin formation. In numerous clinical studies, however, severe methemoglobinemia was not observed with inhalation of NO. Two recent systematic reviews on the use of iNO in acute lung injury, revealed that methemoglobinemia is not a major concern when usual concentrations of iNO are applied.[8,29] It is recommended to measure methemoglobin level 4 hours after initiation of iNO and then once daily.[20] iNO is contraindicated in patients with methemoglobin reductase deficiency.[20] The patient, especially the neonate, should be weaned from iNO if methemoglobin level exceeds 5%.[11]

Interference with Surfactant

Analyses of surfactants recovered from experimental animals that had received 80 to 120 ppm iNO revealed reduced

quality, in terms of capacity to lower surface tension. It is unclear whether this is a consequence of the toxic actions of various NO by-products, such as peroxynitrite and NO_2, or if it is mediated by hemoglobin found in the alveoli when there is high-permeability lung edema.[42,43] Further experiments in preterm rabbits revealed that hyperoxia without iNO reduced large surfactant aggregates and surface activity. Addition of low-dose iNO (14 ppm per nose cannula) prevented or mitigated these deleterious effects on surfactant.[44]

Effects on Coagulation

Inhibition of human platelet aggregation by iNO has been reported in several studies. In addition, prolongation of bleeding time and inhibition of P-selectin expression with decreased binding of fibrinogen to the platelet glycoprotein IIb/IIIa receptor was demonstrated. Results from a randomized experimental animal study in twelve healthy piglets, however, do not support the hypothesis of an increased risk of bleeding associated with iNO. All coagulation variables including bleeding time were unaffected by iNO.[45] In healthy human volunteers, NO may[46] or may not[47] prolong bleeding time and exert effects on various coagulation variables. In patients with ARDS, iNO did not increase the risk of bleeding.[29] In infants with acute hypoxic respiratory failure, most randomized controlled trials did not report an increase in bleeding disorders with iNO therapy.[11] In premature infants with respiratory distress syndrome, however, a risk of intracranial hemorrhage may be considered.[14]

Nephrotoxicity

In the kidney, NO controls glomerular and tubular function, the tubuloglomerular feedback, renin release, and the extracellular fluid volume. Large amounts of NO may contribute to progression of renal disease, although NO may have protective qualities in acute renal failure.[48] Two large meta-analyses evaluated the adverse effects of iNO therapy.[8,29] Up to fourteen randomized, controlled trials of iNO treatment in children and adults with acute lung injury and ARDS were identified. Both meta-analyses reported a risk of renal impairment associated with iNO treatment in adults.[8,29] As the analysis of renal impairment was based only on four of all randomized, controlled trials, although the four studies enrolled 72% of the entire study collective, this result has to be interpreted with caution.[8]

A conclusive explanation for this observation cannot be offered. Inhibition of mitochondrial and enzymatic function, membrane damage or alterations of deoxyribonucleic acid have been discussed.[8] Renal failure in association with iNO treatment has not yet received much attention and needs further investigation.

SAFE INHALED NITRIC OXIDE THERAPY AND CONTRAINDICATIONS

Safe iNO therapy requires continuous analysis of NO and NO_2 concentrations, closely integrated respiratory and hemodynamic monitoring of the patient, periodic analyses of methemoglobin levels, use of certified NO delivery systems and tanks, and administration of the lowest concentration required. Rebound problems after withdrawal of iNO demand skill and endurance during weaning of the drug.

Contraindications to iNO therapy are based on its toxicology. In clinical practice, methemoglobin formation and elevated NO_2 levels are of interest, although both are uncommon during iNO therapy with normal therapeutic doses. These complications may become clinically important when patients are receiving higher doses of iNO. In patients with high levels of methemoglobin, additional iNO therapy may not be indicated and in patients with methemoglobin reductase deficiency, iNO therapy is contraindicated. The clinical risks of bleeding problems may be neglected. Data from large-scale meta-analyses in adults, children and infants did not reveal an elevated risk of coagulopathy associated with iNO. In patients with a hemorrhagic diathesis or coagulation or bleeding problems, however, iNO therapy should be well considered. There are indications that iNO might compromise renal function in adults with acute lung injury or ARDS. To date, this issue remains open.

THE FUTURE

What are upcoming scientific challenges in studying this extraordinary substance? What about the development of alternative NO therapies for the respiratory system?

First, more high-quality studies of diseases in which iNO therapy is of benefit are needed. These studies should evaluate not only survival rates with iNO therapy, but also outcome variables such as quality of life, cognitive impairment, and lung function. Dose–response studies for the different indications of iNO therapy are needed, and safety of long-term application of iNO should be investigated. The responder–nonresponder problem also needs to be probed.

Basic scientific work is needed to investigate the problem of the physiologic autoinhalation of endogenous NO from the paranasal sinuses, which is excluded in intubated and ventilated patients. It is assumed that some concentration of autoinhaled NO in the airways is necessary and protective against infection. During intubation and mechanical ventilation, low doses of iNO may restore the physiologic airway concentration of NO and protect against ventilator-associated pneumonia. It is possible that a patient's own nasal NO may be redirected into the inspiratory limb of the ventilatory circuit.

Therapy with iNO is expensive and technically demanding. Future research may yield cheaper, alternative drugs that selectively supply NO in ventilated lung regions. Inhalation

of prostacyclins, which also produces selective pulmonary vasodilation, may be a cheaper alternative, although further studies are necessary to advocate inhaled prostaglandins as a promising therapeutic option.

Is sildenafil the new iNO? In neonates with PPHN, sildenafil, administered orally or intravenously yielded promising results.[49,50] In most cases oxygenation improved significantly, and a randomized controlled trial of fifty-one term infants with PPHN reported a decrease in mortality.[50] It's a moot question, however, whether sildenafil is of benefit in adult patients with hypoxic respiratory failure. Limited data, however, suggest that sildenafil, does decrease PAP, but increases shunt fraction, which may make the drug unsuitable for treatment of patients with ARDS.[51]

The suspense continues. Will iNO survive in the long run or will it be replaced by intelligent, selective intravenous vasodilators?

SUMMARY AND CONCLUSION

NO is an important signaling molecule in the respiratory system. It modulates perfusion of lung units and it can prevent inflammatory processes. Administered by inhalation, low doses of NO selectively dilate pulmonary blood vessels in ventilated lung areas and redistribute blood flow from atelectatic to aerated lung units. When lower concentrations of iNO are applied, almost no systemic vasodilation can be observed because most of the NO rapidly binds to hemoglobin and is thus inactivated. The overall effect of NO inhalation is a sustained reduction of elevated PAP and improvement in oxygenation if a ventilation–perfusion mismatch of the lung is present. iNO is used to treat several cardiopulmonary disorders that are associated with hypoxia or pulmonary hypertension; its main application, however, is in neonatology. In infants with PPHN, iNO significantly reduces the need for ECMO. In no instance, however, was NO clearly shown to enhance long-term survival. There is no end in sight for the future role of NO inhalation. What we urgently need are more high-quality studies of the diseases in which iNO therapy is effective, and, hopefully, to demonstrate higher survival rates or at least improved secondary outcome variables, for example, reduced need of extrapulmonary oxygenation, fewer neurodevelopmental sequelae, or improved quality of life.

62 DIAPHRAGMATIC PACING

Anthony F. DiMarco

Chronic respiratory failure requiring ventilatory support is usually caused by severe derangements in the function of the lungs, chest wall, and/or respiratory muscles. Mechanical ventilation is the only feasible option for most patients with these disorders. In certain patients, however, the function of the respiratory apparatus is completely intact except for lack of adequate nervous output from the respiratory centers in the medulla (central hypoventilation syndrome [CHS])[1–3] or interruption of electrical signals from the medulla to the respiratory motoneurons in the spinal cord, which innervate the major inspiratory muscles (cervical spinal cord injury). These patients can be offered an alternative means of respiratory support by diaphragmatic pacing (DP), a more natural and physiologic form of breathing.[3–12]

Although straightforward in concept, DP required several significant scientific developments before becoming a clinically useful modality. A brief historical perspective provides some insight into the evolution of DP and understanding of its clinical utility.

It was more than two centuries ago that Caldani[13] first observed that diaphragm movement could be achieved by electrical stimulation of the phrenic nerve in animals. In the first human demonstration (1818), Ure[14] stimulated the phrenic nerve and restored breathing in a criminal immediately following execution. In the latter portion of the nineteenth century, the application of moistened sponges over the outer borders of the sternocleidomastoid muscles resulted in activation of the phrenic nerves, and this technique became an accepted method of restoring ventilation.[15,16] Duchenne found phrenic nerve stimulation to be the best method of producing natural respiration[17] and is credited to have placed electrophrenic stimulation on a solid physiologic foundation.[18] In the 1940s, Sarnoff et al[19,20] demonstrated that ventilation could be maintained in an acute setting in patients with bulbar poliomyelitis utilizing percutaneous electrodes. The lack of implantable devices that were safe and reliable, however, limited the long-term usefulness of DP to support ventilation. Consequently, the technique of phrenic nerve stimulation was supplanted by the development of the more reliable mechanical ventilators.

In the 1960s, the critically important work of Glenn et al resolved major technological issues, which led to the development and implementation of modern-day pacing systems.[21–23] These investigators defined the appropriate patient selection criteria, preoperative assessment methodology, surgical methods including optimal electrode placement, and appropriate stimulation parameters necessary to achieve full-time ventilatory support.[8–12,23,24] Further refinements to this early design were made by other investigators with regard to improved electrode design[25,26] and less-invasive methods of electrode placement.[27–30] As a consequence, DP

TABLE 62-1: POTENTIAL BENEFITS OF DIAPHRAGMATIC PACING

A. Improved quality of life
   1. Subjective sense of more normal breathing
      a. Utilization of breathing muscles
      b. Negative-pressure respiratory support
   2. Improved comfort level
      a. Elimination of pull of ventilator tubing
      b. Negative-pressure breathing
   3. Improved speech
   4. Restoration of olfactory sensation
   5. Increased mobility
      a. Easier transport outside the home
      b. Easier transfer to and from bed
   6. Reduced anxiety and embarrassment
      a. Elimination of ventilator noise
      b. Elimination of fear of ventilator disconnection
      c. Elimination of ventilator tubing
      d. Daytime closure of tracheostomy
B. Reduced overall costs
   1. Reduction or elimination of ventilator supplies
   2. Reduced level of nursing and respiratory therapy services

Source: Used, with permission, from Dimarco.[31]

has evolved into a safe and practical method of providing ventilatory support in select patient groups.

RATIONALE FOR DIAPHRAGMATIC PACING

For patients requiring chronic ventilatory support, DP provides several advantages compared to mechanical ventilation (Table 62-1).[5,6,11,31–35] Although the realized benefits of DP are subjective and vary between individuals, most patients describe an improved sense of well-being and overall health. This impression can be attributable to one or more factors. Because patients are utilizing their own breathing muscles, patients relate the sensation of more normal breathing. Negative pressure ventilation also has the potential to reduce the incidence of barotrauma and may have beneficial cardiovascular effects.[36] Because ventilator tubing is unnecessary, tension on the tracheostomy tube by attached tubing is eliminated, improving patient comfort.

Although the volume of speech may be less with DP than with mechanical ventilation, quality of speech is often improved because ventilator interference is eliminated. Speech can also be enhanced by use of an abdominal binder.[37] Olfactory sensation is also restored with DP contributing to improvement in life quality.[38] There is some evidence that the incidence of respiratory tract infections is less with DP compared to mechanical ventilation. In a prospective clinical trial of sixty-four patients over a 20-year period, there were significantly fewer respiratory infections in DP patients compared to those on mechanical ventilaton.[39] The patients on mechanical ventilation, however, were significantly older compared to those on DP (mean: 53 vs. 29 years old).[39]

A life-support system that requires attachment to a mechanical ventilator by connecting tubing is extremely restrictive. Patient mobility and patient transport therefore is usually enhanced by DP. Simple daily maneuvers such as transfer from bed to chair are less cumbersome and eventful. Transport of patients outside the home is also easier. Improved mobility may allow patients to acquire gainful employment, become eligible for participation in specific rehabilitation programs, and participate in more social events.[31,34,40–42] In a recent study, improved mobility and sense of freedom were described as the main benefits of DP.[38]

Other concerns for many patients include social embarrassment because of ventilator noise, attached tubing, and being tethered to a machine. Many patients cannot support themselves off the ventilator and live in constant fear of disconnection. By comparison, DP is virtually indistinguishable from normal breathing by observers, and the fear of ventilator disconnection is eliminated.

The institution of DP is very expensive. With direct phrenic nerve stimulation systems, total costs can easily exceed $100,000. Although substantially less, the total costs of the intramuscular DP system can be expected to exceed $40,000. Once in place, however, servicing and maintenance costs are minimal.[33,43] Despite the high initial cost, it can be argued that DP is cost effective. Many patients are transferred to less intensive and less expensive care settings.[31,32,44] The high cost of maintenance supplies necessary with mechanical ventilators is reduced. Because most patients who undergo DP are young and require respiratory support for many years, these cost savings can be substantial.[44–46]

EQUIPMENT

There are two basic types of commercially available DP pacing systems. In the first, electrodes are implanted directly on the phrenic nerves (direct phrenic nerve stimulation system). In another, more recently developed system, electrodes are implanted within the diaphragm (intramuscular DP system).

Direct Phrenic Nerve Stimulation Systems

Each of these systems is very similar in design, consisting of both implanted materials and external components (Fig. 62-1A). The electrodes and radiofrequency receivers comprise the surgically implanted components. An external power supply, radiofrequency transmitter, and antenna wires comprise components outside of the body.

With each system, a single stimulating electrode is surgically positioned on each phrenic nerve. With unipolar systems, an indifferent electrode is also implanted subcutaneously.[10] Wires are tunneled subcutaneously to connect each electrode to a radiofrequency receiver that is

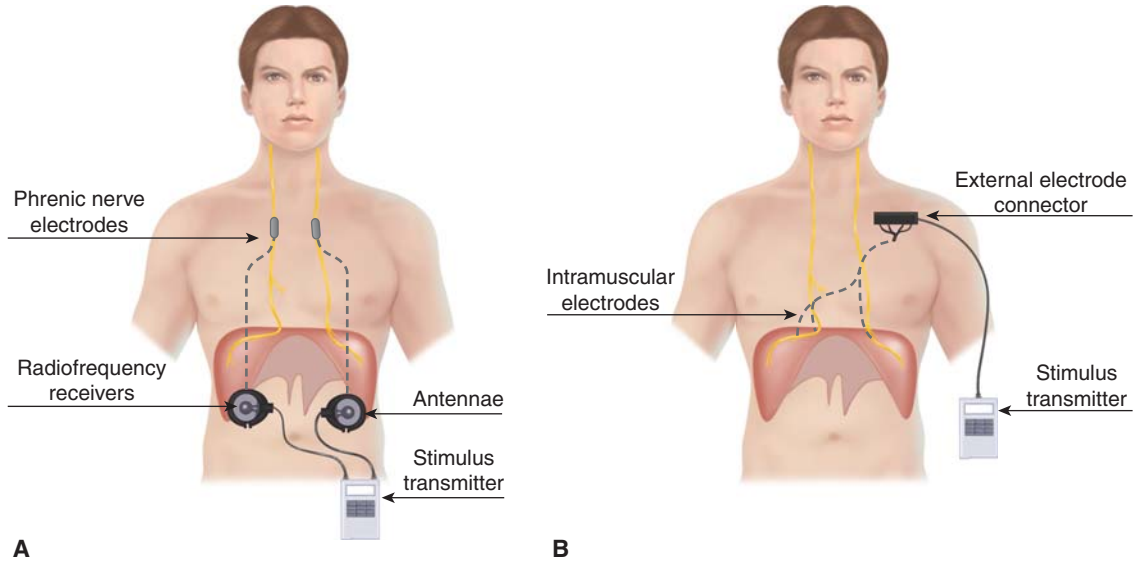

FIGURE 62-1 Basic design of commercially available diaphragmatic pacing systems. Direct phrenic nerve stimulation system (**A**) and intramuscular diaphragmatic pacing system (**B**). With the direct phrenic nerve stimulation system, the internal components consist of a single electrode implanted on each phrenic nerve in the thorax with a wire connected to each implanted radiofrequency receiver. The external components consist of a stimulus transmitter and attached rubberized antennae, which must be positioned over the radiofrequency receivers. The receiver converts radiofrequency signals from the transmitter into electrical signals, which stimulate the phrenic nerves to activate the diaphragm. With the intramuscular diaphragmatic pacing system, two wires are implanted into the body of each hemidiaphragm near the phrenic nerve motor points. These wires are tunneled subcutaneously to a site over the chest wall where they exit the skin and are attached to an external electrode connector.

positioned over the anterior chest wall, usually over the lower rib cage.[10] The external battery-powered transmitter generates radiofrequency signals, which are inductively coupled to the receivers via circular rubberized antennas. Each antenna must be positioned directly over each receiver and secured in place to ensure proper transmission of the signal. The transmitter signal is demodulated by the receivers, converting the radiofrequency signals to electrical signals, which are transmitted to the electrodes to stimulate the phrenic nerves and activate the diaphragm.[10,20]

The transmitter allows adjustment of stimulus amplitude (milliamperes [mA]) and stimulus frequency (Hertz [Hz]) to modulate the magnitude of tidal volume. Respiratory rate can be adjusted by altering the train rate. Inspiratory time and inspiratory flow rate can be adjusted, in tandem, by alterations of stimulus on-time. Sigh breaths can also be provided.

Surgical techniques have been developed for both cervical and thoracic placement of phrenic nerve electrodes.[8–12] Although less invasive from a surgical standpoint, the cervical approach has significant disadvantages. First, an accessory branch from a lower segment of the cervical cord may join the main trunk of the phrenic nerve low in the neck or in the upper thorax.[9] Activation of the cervical portion of the phrenic nerve may therefore lead to incomplete activation of the phrenic nerve and reduce the chance of successful pacing. Second, other nerves in close proximity to the phrenic nerve may also be activated, resulting in pain and/or unwanted movement.[41] Finally, neck movement may displace the electrode, resulting in incomplete diaphragm activation and/or place significant mechanical stress on the nerve increasing the risk of injury. Consequently, the thoracic approach is the preferred method of implantation.[26,32,48]

Phrenic nerve electrodes have been successfully placed thoracoscopically.[30,48] This procedure involves placement of trocars in several intercostal spaces and is technically quite demanding. Successful pacing was achieved for 12 to 14 hours/day while awake in a small group of children, primarily for management of congenital CHS. Moreover, although less invasive than thoracotomy, these patients also developed complications of pneumonia, atelectasis, and pneumothorax postoperatively. Additional studies are necessary to determine the long-term success of this procedure and its applicability to patients with cervical spinal cord injury.

Of the three commercially available DP systems, only the Avery system is available worldwide. Table 62-2 lists the technical characteristics of each device.

AVERY LABORATORIES MARK IV

Glenn et al performed the basic science and clinical studies that led to the commercial application of the Avery (Commack, NY) system in the 1960s.[49,50] The electrode consists of a semicircular platinum-iridium ribbon embedded in molded silicone rubber. The electrode contains a shallow trough for placement of the phrenic nerve. Monopolar and bipolar electrodes (recommended for patients with

TABLE 62-2: TECHNICAL FEATURES OF DIAPHRAGMATIC PACING SYSTEMS

cardiac pacemakers) are available.[9] The recent Avery Mark IV transmitter is lighter and provides a wider range of stimulus amplitudes than previous models.[33] An optional interface also allows biofeedback control from pulse oximetry and CO_2 monitoring.[33] Transtelephonic monitoring is available, which allows the electronic output and neurophysiologic response of the pacing system to be monitored by telephone.[51]

ATROTECH OY

The unique feature of the Atrotech (Tampere, Finland) system lies in its electrode technology, which consists of a four-pole electrode design.[25,52] The electrode consists of two identical strips of Teflon fabric with two platinum buttons mounted onto each strip. Theoretically, when appropriately placed, the phrenic nerve is divided equally into four stimulation compartments. Each quadrant of the nerve, which supplies a specific set of diaphragm motor units, is stimulated sequentially. During one stimulus sequence, which consists of four current combinations, one pole in turn acts as a cathode and one pole on the opposite side as an anode. The result is four excitation compartments around the nerve. Combined stimulation of all quadrants of the nerve (each at 5 to 6 Hz) results in activation of the diaphragm near its optimum fusion frequency of 20 to 25 Hz, resulting in smooth contraction of the diaphragm.[25,52]

By this method, the stimulation frequency of individual axons is less than with monopolar stimulation. The slower stimulus frequency should provide more time for recovery, improve the endurance characteristics of the diaphragm, and shorten the conditioning process, compared to conventional unipolar stimulation.[25,52,53] This technique had been approved by the FDA through an investigational device exemption. As of October 2005, however, the investigational device exemption study has been terminated. Therefore, this device is no longer available in the United States.

MEDIMPLANT BIOTECHNISCHES LABOR

The Medimplant Biotechnisches Labor (Vienna, Austria) system is also differentiated by a unique electrode design.[26] A complex microsurgical technique involving placement of four electrode leads around each phrenic nerve is required. The nerve tissue between each electrode lead comprises different stimulating compartments, only one of which is stimulated during any single inspiration. The various compartments are stimulated in sequence during subsequent inspirations (carousel stimulation).[54] Sixteen different electrode combinations can be adjusted individually for each nerve. Similar to the Atrotech device, only a portion of the nerve is stimulated at any given time, allowing more recovery time and therefore less chance for the development of fatigue compared to the unipolar design. Availability of this system is limited predominantly to Austria and Germany.

Intramuscular Diaphragmatic Pacing System

The phrenic nerves can also be activated via placement of electrodes directly into the diaphragm (Fig. 62-1B).[27,28,55,56] The major advantage of this method compared to direct phrenic nerve stimulation systems is that electrode placement does not require a thoracotomy. A thoracotomy

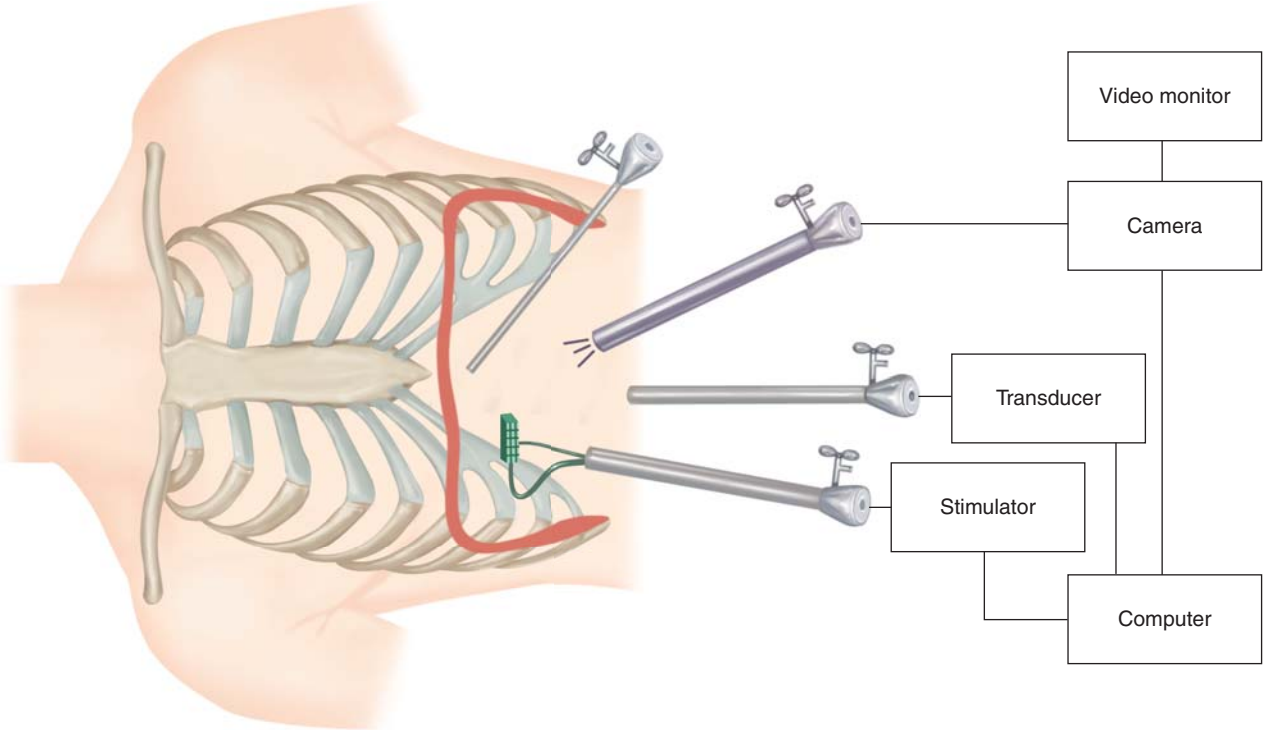

FIGURE 62-2 Schematic of laparoscopic implant materials required for implantation of intramuscular diaphragmatic electrodes. Four laparoscopic ports are necessary to provide access to the abdominal cavity. Ports are necessary for visualization, insufflation of the abdominal cavity, diaphragmatic mapping, and insertion of the electrode implant tool. is associated with significant perioperative morbidity, requiring an inpatient hospital stay and high cost. These disadvantages have limited the number of patients undergoing this procedure and are significant obstacles for patients undertaking phrenic nerve pacing. Intramuscular diaphragm electrodes can be positioned using minimally invasive laparoscopic techniques. This procedure can be performed on an outpatient basis or with an overnight observational stay, significantly reducing costs.[27,28,56,57] The risk of nerve injury is virtually eliminated because this procedure does not require manipulation of the phrenic nerve. Postoperative pain is less for patients with CHS and recovery times are reduced significantly.

SYNAPSE BIOMEDICAL

Conventional laparoscopy is employed for electrode placement of the Synapse Biomedical (Oberlin, OH) system.[58] Four laparoscopic ports are required to provide access to the abdominal cavity for visualization, insufflation of the abdominal cavity, diaphragm mapping, and insertion of the implant tool (Fig. 62-2). Specially designed surgical tools and intramuscular electrodes are required for implantation.[27–29,59–61] Two intramuscular electrodes are implanted into each hemidiaphragm near the phrenic nerve motor points (Fig. 62-3).[62,63] A mapping procedure is required for appropriate electrode placement.[27,28] By this method, full-time respiratory support can also be maintained in ventilator-dependent tetraplegic patients (both children and adults) with success rates similar to those of direct phrenic nerve stimulation.[19,27,28,34,64] It is important to note that despite the fact that electrodes are positioned within the diaphragm muscle, the mechanism of diaphragmatic activation by this method is stimulation of the phrenic nerve motor points. This technique, therefore, represents a form of phrenic nerve stimulation, rather than direct diaphragm muscle stimulation.

Combined Intercostal and Diaphragmatic Pacing

Many patients with cervical spinal cord injury have damage to one or both phrenic motor neuron pools in the spinal cord and/or phrenic rootlets, and therefore cannot be offered DP.[31,65,66] By placing electrodes epidurally on the ventral surface of the upper thoracic spinal cord, however, the inspiratory intercostal muscles of the upper rib cage can also be stimulated to produce large inspired volumes.[67–69] Moreover, gas exchange during intercostal breathing alone is comparable to diaphragmatic breathing.[70]

In initial clinical trials, in patients with absent diaphragmatic function, stimulation of the intercostal muscles alone produced inspired volumes of similar magnitude to those

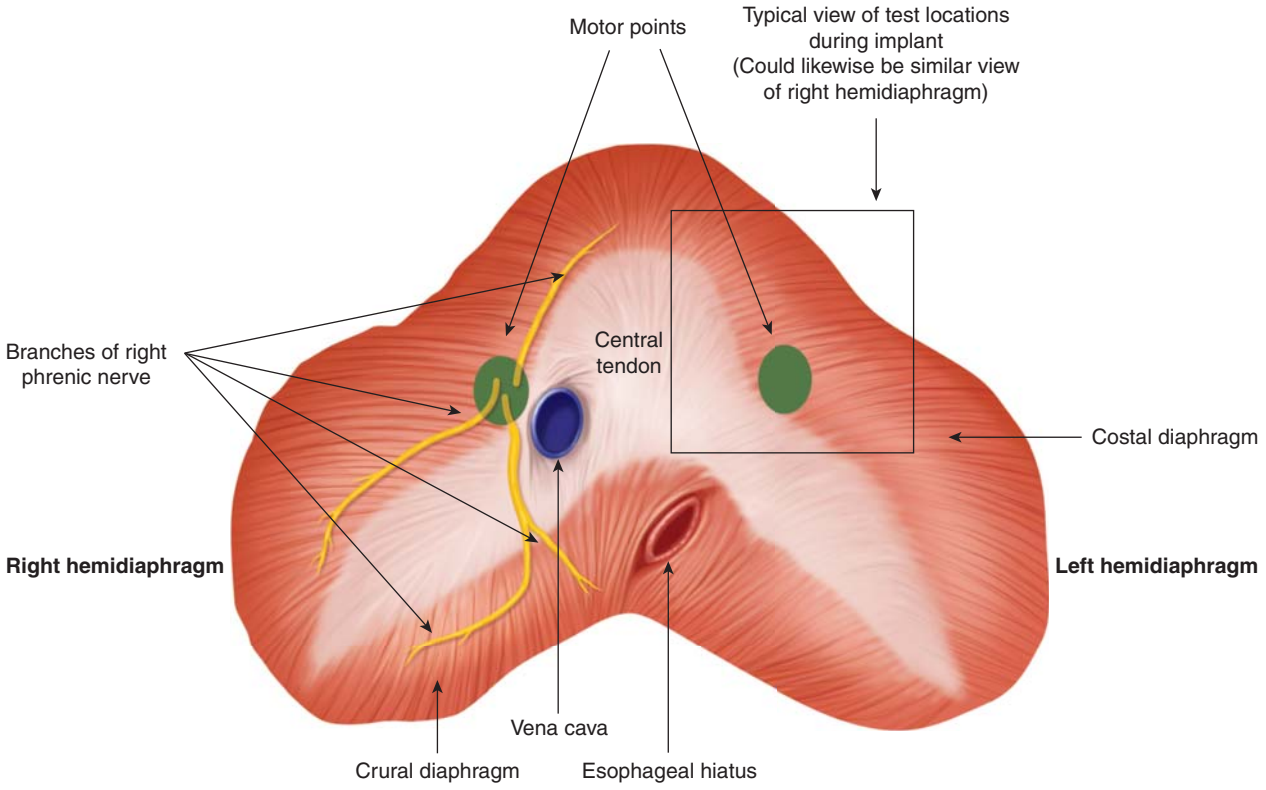

FIGURE 62-3 Schematic of the anatomy of the diaphragm from the abdominal surface and entrance points of each phrenic nerve into each hemidiaphragm (phrenic nerve motor points). resulting from activation of a single hemidiaphragm.[69] Inspired volume, however, was not sufficient to support ventilation for prolonged periods. In subsequent trials in tetraplegic patients with unilateral diaphragm function, however, stimulation of the intercostal muscles in combination with unilateral phrenic nerve stimulation was successful in providing long-term ventilatory support.[71]

Side effects of intercostal muscle stimulation included mild flexion of both hands and contraction of the muscles of the upper torso, which was well tolerated.[69,71] Intercostal pacing may be a useful adjunct to enhance tidal volume in patients whose inspired volume with phrenic nerve pacing is suboptimal.

This technique is not yet commercially available but has received approval by the FDA through an investigational device exemption.

PATIENT SELECTION

As mentioned, DP provides clinical benefit in two patient groups: ventilator-dependent tetraplegics[8,11,34] and patients with CHS.[5,6,72] Although phrenic nerve pacing has been tried in patients with chronic obstructive pulmonary disease to prevent ventilatory depression associated with oxygen administration,[73] noninvasive ventilator support is of equal or greater effectiveness.

In all patients, significant lung, chest wall, cardiac, or primary skeletal muscle disease must be excluded because these conditions may preclude successful pacing.[40,47,74]

Ventilator-Dependent Tetraplegia

Respiratory failure is common following acute cervical spinal cord injury.[65,66] Fortunately, most patients achieve significant recovery following their initial presentation and are able to breathe spontaneously. Nonetheless, approximately 4% require lifelong respiratory support.[57] Although the time course of recovery is variable, the degree of impairment is likely permanent 12 to 15 months following injury.[66,75] Given the high cost and the invasive procedure required, direct phrenic nerve DP should not be considered before this time. However, given the minimally invasive nature of intramuscular DP, and the significant advantages of DP compared to mechanical ventilation, much earlier placement of this system should be considered. In the event that the clinical status of the patient improves to the point that spontaneous breathing is restored, the DP system can be removed.

Vigorous attempts should be made to wean tetraplegic patients from mechanical ventilation. Vital capacity measurements of less than 10 mL/kg suggest inadequate inspiratory muscle function to maintain spontaneous breathing.[66] In some patients with sufficient inspiratory muscle strength,

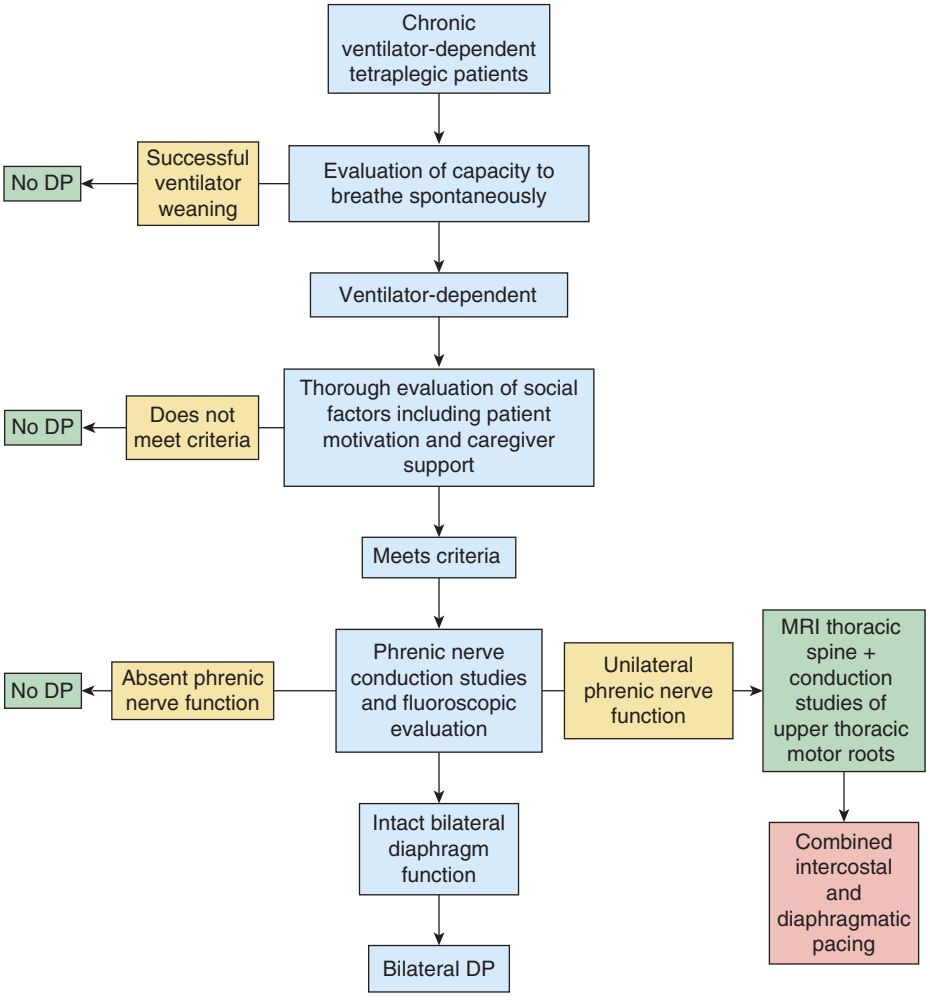

FIGURE 62-4 Evaluation of potential candidates with cervical spinal cord injury for diaphragmatic pacing.

however, noninvasive ventilator support may be a suitable alternative to DP.[76,77]

Individual psychosocial conditions are important factors in the ultimate success of phrenic nerve pacing.[27,31,34,49] A high level of motivation and cooperation of the patient and family members is imperative. A home situation in which the family unit is anxious to improve the mobility, social interaction, occupational potential, and ability of the patient to function independently is optimal. Consequently, a psychosocial evaluation should be conducted before any technical evaluation. Figure 62-4 shows the evaluation process of potential candidates for DP.

Central Hypoventilation Syndromes

Patients with CHS consist mainly of infants and children. Pacing is not instituted before 6 to 12 months of age to allow time to identify other potential abnormalities and determine the full extent of the ventilatory deficit.[4] CHS can be congenital[1–3] or secondary to brainstem injury from injury, bleeding, tumor, encephalitis, or Arnold-Chiari malformations.[4,11] To assess the presence and degree of hypoventilation, arterial blood gases, nocturnal polysomnograms, and ventilatory responses to hypercarbia and hypoxia should be performed.

The diagnosis of congenital CHS is usually made shortly after birth. Many of these patients have normal wake ventilation and therefore require DP only during sleep.[3–5] Patients who require full-time ventilator support are paced during the day and maintained on mechanical ventilation during sleep. A psychosocial evaluation of these patients should also be performed.

Evaluation of Phrenic Nerve Function

Before instituting DP, a thorough evaluation of phrenic nerve function is mandatory in all patients.[10,23,27,72] Phrenic nerve function can be assessed by measurements of nerve conduction times.[45,78,79] Diaphragmatic action potentials are monitored by surface electrodes positioned between the

seventh and ninth intercostal spaces. The phrenic nerves can be electrically stimulated by surface electrodes or monopolar needle electrodes at the posterior border of the sternocleidomastoid muscle at the level of the cricoid cartilage. Electrical current is applied with single pulses of gradually increasing intensity until a supramaximal M wave is seen. With stimulation, the abdominal wall expands outward. Phrenic nerve conduction time can be determined by measuring the time interval between the applied stimulus and onset of the compound muscle action potential (CMAP). Phrenic nerve function can also be assessed by cervical magnetic stimulation of the phrenic nerves.[80,81] Mean onset latency is 7 to 9 milliseconds in normal adults.[45,78,79] Mild prolongation of conduction times (up to 14 milliseconds), however, does not preclude successful pacing.[12] In children, latencies are significantly shorter at 2.2 milliseconds at 6 months of age, but increase to 4.2 milliseconds between 5 and 11 years of age.[7,82] The magnitude of the CMAP is a less reliable indicator of phrenic nerve function compared to conduction time.[32,78]

Fluoroscopy is also a useful method to assess phrenic nerve function. The diaphragm should descend at least 3 to 4 cm following stimulation.[10,31,45] In children with CHS, diaphragmatic descent of at least two rib spaces following spontaneous effort indicates adequate phrenic nerve function.[4] In this population, phrenic nerve stimulation is reserved for patients in whom the fluoroscopic results are questionable.

A recent study[83] evaluated the use of diaphragmatic compound muscle action potentials (CMAPs) to evaluate phrenic nerve function. The investigators found that diaphragmatic CMAPs were recorded only when the diaphragm was observed to move on fluoroscopic examination. These results suggest that assessment of the presence of diaphragmatic CMAPs can be used interchangeably with fluoroscopic evaluation to assess phrenic nerve integrity. Because of false-positives and false-negatives associated with conduction time measurements, and technical challenges associated with this test, fluoroscopy should be performed on all patients being evaluated for DP (personal observation).

Phrenic nerve function can also be assessed by measurements of transdiaphragmatic pressure (Pdi) (i.e., the pressure difference across the diaphragm).[43] By this method, small balloon-tipped catheters are placed into the esophagus and stomach to determine intrathoracic and intraabdominal pressures, respectively. Single-shock stimulation results in Pdi values of approximately 10 cm H_2O for each side in normal subjects.[84] Because of diaphragmatic atrophy, this value may be reduced significantly in ventilator-dependent patients. In spontaneously breathing individuals, diaphragmatic strength can be assessed by measuring Pdi during a maximal sniff maneuver.[84]

IMPLEMENTATION

The various surgical techniques to implant electrodes necessary for DP have been described elsewhere[9,12,85] and are beyond the scope of this chapter.

DP should not commence until 10 to 14 days postoperatively to allow resolution of inflammation and edema at the electrode–nerve interface and initial healing of surgical wounds.[10] In patients who have been maintained on mechanical ventilation for prolonged periods, the transition to DP requires a gradual conditioning period, because of diaphragmatic atrophy.[11,23,24,86] Too rapid institution of pacing carries the risk of diaphragmatic fatigue and possible injury.

Determination of Stimulus-Output Values

Ideally, several parameters should be determined initially and then monitored regularly.[12,32] These include stimulus threshold values (minimum stimulus amplitude that results in visible or palpable diaphragmatic contraction) and supramaximal amplitudes and frequencies (lowest stimulus parameters that result in maximum inspired volume production). Changes in airway pressure during airway occlusion also provide a useful assessment of diaphragmatic force. The magnitude of inspired volumes and force generation gradually increase during the conditioning phase. Plateaus in these indices over time suggest that the conditioning phase is complete and optimum diaphragmatic function has been achieved. Assessment of diaphragmatic action potentials may also be useful in the determination of maximum stimulus amplitude.[4]

Determination of Stimulus Parameters to Achieve Adequate Ventilation

Utilizing supramaximal amplitudes, tidal volume is adjusted by changing stimulus frequency. With respiratory rates (stimulus train rates) between 8 and 14 breaths/min, stimulus frequency is adjusted to achieve inspired volumes resulting in partial pressure of carbon dioxide (P_{CO_2}) values in the low normal range. Stimulus frequency should be set at the lowest level possible and should not exceed 20 Hz. Respiratory rate and tidal volume are further adjusted for patient comfort. Inspired volume measurements should be made both in the supine and upright postures. While sitting, spinal cord-injured patients should wear a snug fitting abdominal binder because of the shorter diaphragm length and higher resting lung volume associated with this posture. Higher stimulus parameters may be required in this posture to achieve adequate ventilation.

Institution of Diaphragmatic Pacing

The methods of transition from mechanical ventilation to pacing are somewhat arbitrary. With the objective of achieving full-time DP as quickly as possible, but without the development of diaphragmatic fatigue, the following protocol is suggested. Utilizing the above-mentioned stimulus parameters, continuous bilateral DP is initially provided

until significant blood gas derangements (reductions in oxygen saturation or elevations in end-tidal P_{CO_2}), reductions in inspired volume generation (monitored every 5 to 10 minutes), or patient discomfort related to air hunger are observed. Pacing is then initiated for a somewhat shorter time period (approximately 5 minutes) every hour during the day, for the first week. This assessment is repeated weekly and a new pacing schedule is applied accordingly. After full-time pacing is achieved during wakefulness, pacing is provided during sleep. Most patients cap their cuffless tracheostomy tube while pacing during the daytime. During sleep, however, airflow through the tracheostomy should be maintained to prevent upper airway obstruction. This occurs secondary to the dyssynchrony between upper airway and diaphragmatic contraction during sleep.[5,23]

Previous studies have demonstrated that chronic diaphragmatic stimulation at high frequencies can be associated with myopathic changes and consequent reductions in force generation.[8,34,87] Consequently, it is important that DP occur at low stimulus frequencies (<20 Hz), which convert the diaphragm from a mixed-fiber-type population to predominantly high-oxidative, slow-twitch fatigue-resistant type I fibers.[8,88] As the conditioning phase progresses, stimulation frequencies and respiratory rates should be gradually reduced to the lowest values that maintain adequate ventilation and patient comfort. With the Avery system, stimulation frequency can usually be reduced to 7 to 9 Hz with respiratory rates of 6 to 12 breaths/min in the supine position.[8] Less adjustment is usually required with the Atrotech device secondary to the initial application of low frequencies via sequential nerve stimulation. With intramuscular stimulation, stimulation is initiated with four electrodes at 20 Hz. Stimulation frequency can be reduced to as low as 11 Hz with stimulation of only two electrodes.[27] Infants and young children require higher respiratory rates in the range of 20 breaths/min, but can be maintained with lower inspiratory times of 0.6 to 0.9 second compared to the requirement of 1 to 1.4 second in adults.[5,89] Conditioning time can vary between 4 weeks and several months. In most instances, however, conditioning is accomplished within 6 to 10 weeks.

In patients with CHS who employ DP only during sleep, DP should be adjusted in a sleep laboratory.[4] Given the high compliance of the rib cage and higher ventilatory requirements, bilateral pacing is always necessary to support ventilation in infants and young children.[4,5] In patients undergoing daytime pacing, pacing parameters must be reevaluated because ventilatory requirements are typically higher during wakefulness.

Combining Pacing with Mechanical Ventilation

Full-time pacing is generally not advisable in infants and small children to avoid fatigue and the risk of permanent injury to the diaphragm and phrenic nerves.[3–5,89] Consequently, children with tetraplegia and those with CHS who require full-time ventilator support utilize DP during the day and are maintained on mechanical ventilation at night.[3] Likewise, adult patients who do not achieve inspired volumes sufficient to maintain full-time pacing can be maintained on ventilator support at night. Because the major advantages of DP are realized during the day and most patients still require a tracheostomy, part-time DP does not detract significantly from the benefits of this device.

In some instances, patients cannot tolerate significant time off mechanical ventilation and initial inspired volumes achieved by pacing are insufficient to maintain adequate ventilation for even short periods.[59] In these patients, the initial phase of muscle reconditioning can be performed in conjunction with mechanical ventilation. This can be accomplished by setting the ventilator in the assist mode. The negative inspiratory pressure generated at the tracheal opening by pacing can be used to trigger the ventilator.

EFFECT OF DIAPHRAGMATIC PACING ON PATIENT OUTCOME

Clinical studies reveal that DP is a feasible and effective means of providing ventilatory support in patients with tetraplegia and CHS. In most patients requiring full-time ventilatory support, DP can be utilized as the sole mode of respiration.[8,11,27,34]

The actual success rate of DP, however, is difficult to ascertain because most patients have undergone this technique at centers where patient numbers are small.[35,41,90] Moreover, previous large series have evaluated the outcome of DP while technology was still in development.[23,91–93] Consequently, these results are not applicable to systems available today.

In a recent report, the clinical outcome of patients whose DP systems were implanted before 1981 was compared to patients implanted between 1981 and 1987.[34] The earlier group underwent high-frequency DP; the success rate in terms of achieving full-time pacing was small because of the development of diaphragmatic fatigue. The latter group underwent low-frequency stimulation at low respiratory rates; DP was successful in each of the twelve patients, stressing the importance of current pacing regimes. Six patients continued pacing for a mean duration of 14.8 years. The other six patients did not achieve sustained long-term pacing because of lack of adequate financial and social support or concomitant medical conditions. The results of this analysis indicate that the long-term success of DP depends heavily on adherence to strict criteria for patient selection. High success rates have also been observed in infants and children in whom a more modest goal of part-time pacing (<15 hours/day) was achieved.[4]

The more recently developed quadripolar electrode design and receiver (Atrotech OY) is associated with high success rates. Based on analysis of sixty-four patients, successful pacing was achieved in 94% of pediatric and 86% of

adult patients.[53] At the time of study, however, the average duration of pacing was approximately 2 years.

COMPLICATIONS AND SIDE EFFECTS

Technical developments and clinical experience with DP over the past 20 years have markedly reduced the incidence of complications and side effects. With modern-day equipment, appropriate patient selection, proper use of stimulus paradigms, and adequate patient monitoring, complications are few. As with any life-support system, patients must be carefully monitored because pacemaker failure can have catastrophic consequences. For this reason, all patients who are unable to maintain adequate spontaneous ventilation for prolonged periods should have emergency access to mechanical ventilation.

Several technical problems can cause reductions in volume production (Table 62-3). The most common cause of mechanical failure is loss of battery power. With current pacing systems, however, routine maintenance requires regular battery changes and recharging schedules. Low-battery alarms are also present. Breakage of the external antenna wires at stress points, either near the connection to the transmitter or more commonly at the connection to the antennae, can occur. With the intramuscular DP system, wire breakage can occur at the skin exit site.

Concerning the internally implanted components with direct phrenic nerve stimulation systems, failure of the radiofrequency receiver was a fairly common problem with older systems, secondary to leakage of body fluid through the epoxy encapsulation. Wire breakage within the receiver was also an issue.[91] With older systems, this problem often occurred within 5 years of implantation.[23,47,91] With improvement in housing materials, receiver life has been extended significantly and reports of receiver failure are much less common.[53] Electrode wire malfunction or breakage is also much less common but can occur unpredictably at variable time periods following implantation. The most recent analysis of the quadripolar electrode system in patients who had undergone DP for approximately 2 years, demonstrated an electrode failure rate of 3.1%.[53] Failure rates were similar in tetraplegics and patients with CHS, and in adults and children. Failure of one or more of the four electrode combinations was fairly common, but usually did not interfere with successful pacing.[53]

Iatrogenic injury of the phrenic nerve can occur secondary to mechanical trauma during electrode implantation or secondary to subsequent tissue reaction and fibrosis around the electrode.[11,23,88] When performed at centers, however, by surgeons with expertise in DP and use of monopolar or quadripolar electrodes, rather than the older bipolar cuff electrodes that encircled the nerve, phrenic injury is infrequent.[53]

As with any foreign body, implantation of the internal components carries some risk of infection. Since the institution of this technique in the 1970s, infection rates have been relatively constant in the range of 3% to 5%.[22,53,91] The higher infection rate observed in active children with CHS is thought to occur as a result of the greater likelihood of local trauma in this population.[53] The development of infection usually requires the removal of all implanted materials.

Although there are some reports of successful tracheostomy closure following institution of DP, these are very uncommon. During the daytime, the state of wakefulness is associated with synchronous activation of the upper airway muscles and diaphragm during DP. During sleep, however, there is reduced activation of the upper airway dilator muscles and a greater tendency toward asynchronous upper airway muscle contraction resulting in upper airway obstruction, a form of obstructive sleep apnea.[5,94,95] With few exceptions, therefore, patients undergoing DP require a patent tracheostomy for nocturnal use. Maintenance of a tracheostomy also facilitates application of mechanical ventilation in the event of pacemaker malfunction or instances of increased respiratory demand such as acute infections.

With direct phrenic nerve pacing systems, monopolar stimulation may interfere with demand-type cardiac pacemakers. For this reason, if a cardiac pacemaker is present, it is advisable to use bipolar electrodes for DP.[96] The electrodes should be at least 10 cm from the cardiac pacemaker.[96,97] The presence of cardiac pacemakers, however, is not a contraindication for use of the intramuscular DP system. In twenty tetraplegic subjects with cardiac pacemakers and DP, there were no device-to-device interactions.[98]

In young children, paradoxical movement of the rib cage may occur as a result of the high chest wall compliance, resulting in reduced inspired volume generation. Consequently, bilateral pacing is required because of the paradoxical movement of the contralateral diaphragm and chest wall during DP.[4,23]

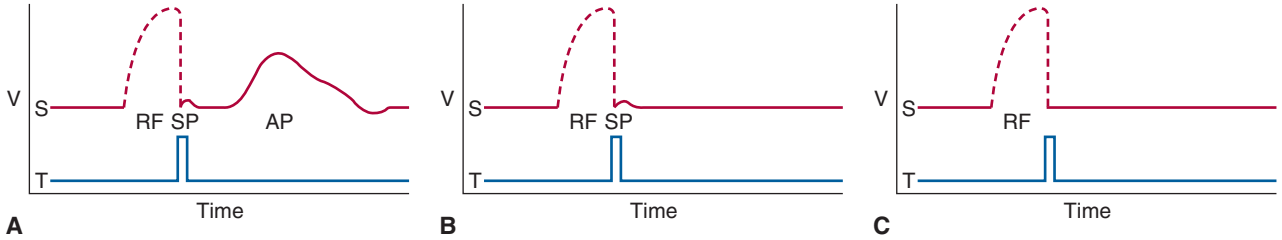

FIGURE 62-5 **A.** Schematic of an oscilloscopic tracing showing a properly functioning diaphragmatic pacing system. The lower tracing *T* represents the output from an extra receiver that was used to trigger the oscilloscope sweep. The upper trace (*S*) represents the signal obtained from the percutaneous leads on the chest. Shown in sequence are the radiofrequency signal (*RF*) from the transmitting antenna, the stimulus pulse (*SP*) from the electrode on the phrenic nerve, and the compound action potential (*AP*) from the diaphragm. **B.** Schematic of a malfunctioning pacing system. The tracing is the same except for the absence of the action potential. Breakage of wire insulation, lack of adequate phrenic nerve/electrode contact, or phrenic nerve damage are consistent with this finding. **C.** Schematic of another type of malfunctioning pacing system. In this case, the action potential and radiofrequency signal are absent. This finding suggests receiver malfunction. (Used, with permission, from Weese-Mayer et al.[94])

Finally, strong magnetic fields, such as those that occur with magnetic resonance imaging scanning, can override the electronic circuitry of pacing systems. The substantial energy transmission associated with this scanning could be transmitted to the electrode resulting in phrenic nerve injury. The pacing system's internal components would also be attracted to the magnet. Exposure to electrotherapeutic devices that generate strong radiofrequency fields should also be avoided because they may interfere with the pacing system.

MONITORING

Unlike mechanical ventilators, DP systems have no alarm systems that reflect inadequate levels of ventilation. When not receiving direct attendance by caregivers, patients should employ a pulse oximeter as a monitor for possible pacemaker malfunction or inadequate tidal volume generation secondary to patient-related issues.

Bedside Evaluation

For all patients supported by DP, breathing should be comfortable and effortless. Caregivers should evaluate pacemaker function on a routine basis and also in situations that give rise to dyspnea. On palpation of the chest wall, inspiration should be associated with vigorous lateral expansion of the lower rib cage and anterior abdominal wall, bilaterally. Attachment of a spirometer to the tracheostomy tube allows easy measurement of tidal volume. The transmitter enables separate stimulation of each hemidiaphragm, allowing evaluation of each side independently. Adequacy of ventilation should be assessed with pulse oximetry and end-tidal CO_2 measurements.[31,32,43,70]

TROUBLESHOOTING

If inspired volume is inadequate, the function of the external components should be evaluated first. Initially, the batteries should be replaced because this is the most common cause of pacemaker malfunction. Subsequently, the antenna should be replaced. If function is not restored, the back-up transmitter should then be changed.[4]

The occurrence of abnormal lung mechanics can also cause reductions in inspired-volume generation during DP. For example, most tetraplegics have a markedly reduced ability to cough and consequently accumulate airway secretions that require regular evacuation. Retained secretions cause increases in airway resistance and the development of atelectasis with secondary reductions in lung compliance. These mechanical derangements will reduce inspired-volume generation. Removal of secretions usually results in prompt improvement. Likewise, bronchitis and pneumonia will also result in reductions in inspired volume. If reductions in inspired volume are persistent, therefore, chest radiography may be necessary. This test is also useful to evaluate for wire breakage and electrode position.

With the direct phrenic nerve stimulation systems, evaluation of the internal components can be performed according to previously described techniques.[91] Surface electrodes are placed at the costal margin to record the pacemaker stimulus pulse and diaphragmatic action potential. The signals are amplified and recorded on an oscilloscope. Figure 62-5 is a schematic of the signals obtained from the chest leads. The DP system is functioning properly if the radiofrequency signal from the transmitting antenna, stimulus pulse from the phrenic nerve electrode, and diaphragmatic action potential are seen on the oscilloscope. If the radiofrequency signal and stimulus pulse are observed without the action potential, this indicates that the wire insulation is no longer intact, the phrenic nerve is not in contact with the electrode, or the phrenic nerve has been damaged. If the stimulus pulse and action potential are both not seen, the receiver is not functional.

IMPORTANT UNKNOWNS

The impact of DP, compared to mechanical ventilation, on long-term survival is unknown. Carter et al,[99] however, compared survival rates in a retrospective analysis.

Overall survival rates were similar between groups, but the patients on mechanical ventilation expired earlier than did patients maintained on DP. In a more recent clinical trial of sixty-four patients over a 20-year period, there was no significant difference in longevity between use of DP and mechanical ventilation.[39] Respiratory tract infections, however, were a more common cause of death in the mechanical ventilation group.

In the absence of depressed mental status and weakness of oropharyngeal muscles, some investigators have demonstrated that direct airway pressure methods, including mouth and nasal intermittent positive-pressure ventilation, can maintain adequate ventilation in tetraplegic patients.[74,75] These modalities offer the significant advantage of tracheostomy closure. Given the high cost and invasive nature of phrenic nerve implantation, these modalities may be better suited for some individuals. Newer methods of electrode placement, however, may swing the advantage in favor of DP.[27,28]

THE FUTURE

Although existing DP systems provide substantial lifestyle advantages to patients compared to mechanical ventilation, current systems are somewhat cumbersome and have significant disadvantages and limitations. With the ultimate goal of complete restoration of normal respiratory system function, several refinements are needed.

Perhaps most significant is the future development of systems that synchronize upper-airway muscle and diaphragmatic contraction, which would eliminate upper-airway obstruction during DP.[94,95] One option is to use an upper-airway muscle signal to trigger diaphragm activation. Such a device would not only eliminate the need for a tracheostomy but also provide ventilation on demand, allowing for changes in ventilatory requirements. A totally implantable system has not yet been developed, in part because of the high energy requirements of phrenic nerve pacing. A totally implantable system, similar to cardiac pacemakers, would eliminate the need for attachment of materials to the body surface, connection to a transmitter box, and battery changes. This development would further improve patient convenience and mobility.

DP in tetraplegic patients often requires a long reconditioning program because of disuse atrophy. Implantation of less-invasive intramuscular electrodes soon after injury would allow more tetraplegic patients to use DP in place of mechanical ventilation. In patients in whom weaning is possible, electrodes can subsequently be removed without injury. Using this technique, it is also conceivable that intensive care unit patients who require prolonged mechanical ventilation with the expectation of eventual recovery may benefit from DP to prevent diaphragmatic atrophy and consequent difficulty in weaning.

Finally, in patients with bilateral phrenic nerve injury, intercostal to phrenic nerve transfer may restore phrenic nerve viability and provide patients with the option of DP.[100]

SUMMARY AND CONCLUSIONS

In patients with ventilator-dependent tetraplegia and CHS, DP represents a practical method of ventilatory support with significant health and lifestyle advantages compared to mechanical ventilation. Advantages include increased mobility and level of independence, improved speech, improved sense of smell, and reduced anxiety and embarrassment associated with mechanical ventilation. The DP systems are smaller and more portable than ventilators and require less maintenance. Patients, however, must be carefully screened for social factors, including level of patient motivation and caregiver support, as well as coexisting medical conditions. Adequacy of phrenic nerve function must also be thoroughly evaluated preoperatively. In some patients, other means of support such as noninvasive ventilation may be more appropriate. Clinical studies examining methods of activating the inspiratory intercostal muscles are underway. These new techniques are likely to increase the number of eligible patients and expand the clinical indications for DP.

63 BRONCHODILATOR THERAPY

Rajiv Dhand

Bronchodilators relax constricted airway smooth muscle in vitro. Because of this property, bronchodilators reverse airway obstruction, prevent bronchoconstriction and provide protection from constrictor stimuli.[1] In this chapter, bronchodilators employed in mechanically ventilated patients are discussed with a special emphasis on inhalation therapy.

RATIONALE

Ventilator-dependent patients with acute exacerbations of chronic obstructive pulmonary disease (COPD) and acute severe asthma routinely receive bronchodilators to relieve bronchoconstriction. By reducing airway resistance, bronchodilators reduce the pressure required to ventilate the lung. This reduction in pressure may protect the lung against injury and enhance patient comfort. A general population of ventilated patients in a medical intensive care unit (ICU)[2,3] and patients with acute respiratory distress syndrome[4,5] showed improvement in expiratory airflow and airway resistance after bronchodilators. Infants with bronchopulmonary dysplasia, and children with asthma, or bronchiolitis also receive bronchodilators on a routine basis.[6–10] In ventilated patients with COPD, elevated airway resistance and intrinsic positive end-expiratory pressure are major causes for weaning failure.[11] In these patients, bronchodilators may facilitate weaning.[12] Therapy with bronchodilators is, therefore, routinely and commonly employed for many indications in ventilator-dependent patients.[13]

PHARMACOLOGIC AGENTS

β-adrenergic agonists, anticholinergic drugs, and methylxanthines are the three major classes of bronchodilators employed in the ICU. β-adrenergic agonists and anticholinergics are usually administered by the inhaled route, whereas methylxanthines can only be administered enterally or parenterally. Although they are not bronchodilators in the classic sense, corticosteroids, both inhaled and systemic, are commonly employed in acutely ill patients to reduce airway inflammation and increase airway caliber.[14–16]

TABLE 63-1: DOSES AND DURATION OF ACTION OF COMMONLY USED BRONCHODILATORS IN VENTILATED PATIENTS[a]

Agents	Dose	Time Course (Onset, Peak, Duration)	Frequency of Dosing
Albuterol (Salbutamol)	SVN: 0.083% solution, 3 mL (2.5 mg), pMDI: 90 mcg/puff, 4 puffs	5 to 15 minutes, 30 to 60 minutes, 5 to 8 hours	4 to 6 times daily
Levalbuterol	SVN: 0.63 mg, or 1.25 mg	15 minutes, 30 to 60 minutes, 5 to 8 hours	3 to 4 times daily
Formoterol	SVN: 20 mcg/2 mL solution	1 to 3 minutes, 1 to 3 hours, 8 to 12 hours	2 times daily
Arformoterol	SVN: 15 mcg/2ml solution	1 to 3 minutes, 1 to 3 hours, 8 to 12 hours	2 times daily
Ipratropium	pMDI: 18 mcg/puff, 4 puffs SVN: 0.02% solution, 2.5 mL (0.5 mg)	15 minutes, 90 to 120 minutes, 6 to 8 hours	4 to 6 times daily
Albuterol + Ipratropium	pMDI: 90 mcg + 18 mcg/puff, 4 puffs SVN: 2.5 mg + 0.5 mg/dose	5 to 15 minutes, 30 to 60 minutes, 6 to 8 hours	4 to 6 times daily

Abbreviations: pMDI, pressurized metered-dose inhaler; *SVN*, small-volume nebulizer.

[a]Dry powder inhalers are not routinely employed in ventilated patients.

β-Agonists

The pharmacology of the β-agonists was extensively reviewed in the second edition of this textbook,[17] and other excellent reviews are available.[18]

ROUTE OF ADMINISTRATION OF β_2-ADRENERGIC AGONISTS

β-agonists have been given by oral, subcutaneous, intravenous, and inhaled routes. Table 63-1 lists doses for individual drugs. Inhaled therapy is preferred because the drug is delivered directly to its site of action in the airways, a smaller quantity of drug produces an effect comparable to that observed with systemic administration, onset of effect is rapid, and systemic absorption of the drug is limited, thus minimizing side effects. The oral approach has been all but abandoned, and there appears to be no advantage to the intravenous route even in severe asthma with hypercapnia.[19] A meta-analysis found no evidence of benefit for the intravenous use of β-agonists in patients who are refractory to inhaled β-agonists.[20]

INDIVIDUAL AGENTS

Albuterol. Albuterol is today's standard short-acting bronchodilator. Its pharmacokinetics depend on the dose administered, the formulation of albuterol used (dry powder, pressurized metered-dose inhaler [pMDI], or nebulized) and the clinical situation (mechanically ventilated or ambulatory). Although increasing doses of albuterol produce greater bronchodilation, the optimum dose is difficult to predict. Peak bronchodilator response after 10 puffs of albuterol in ventilated patients was seen within 5 minutes and sustained for 60 minutes.[12] Duration of action of 6 puffs of albuterol delivered from a pMDI to ventilated patients ranged from less than 2 hours to more than 4 hours.[21] Systemic effects are dose related, usually appearing within an hour of administration with a return to baseline within 4 hours.[22]

Levalbuterol. Commonly available racemic albuterol is a 50-50 mixture of R-albuterol and S-albuterol. Levalbuterol, the R-enantiomer, was formulated to avoid possible adverse effects of the S-enantiomer. For doses that produce similar increases in forced expiratory volume in 1 second (FEV_1), increases in heart rate are less with levalbuterol (2 to 4 beats/min) than with albuterol,[23] and the bronchodilator effect is greater in patients with acute asthma.[24,25] In patients receiving long-term mechanical ventilation, levalbuterol produced an increase in secretion volume but the effect dissipated rapidly.[26]

Salmeterol. Salmeterol is a long-acting β_2-agonist. Its onset of action is slower than that of albuterol in vitro (mean: 6.4 vs. 1.9 minutes)[27] and in vivo (mean: 10 vs. 4 minutes).[28] With salmeterol, peak bronchodilator response was seen at 5 hours versus 1 hour with albuterol, and FEV_1 was higher than predose FEV_1 levels for 12 hours.[28] Systemic effects of salmeterol are dose related, manifest later, and last longer; maximum effects on heart rate occur within 75 to 135 minutes and are still evident after 4 hours.[22] In ventilated patients with acute exacerbations of COPD, four doses of salmeterol by pMDI (100 mcg) produced a bronchodilator effect within 30 minutes that was maintained for approximately 8 hours, with significant variability in the magnitude and duration of the response among patients.[29]

Formoterol. Formoterol is a long-acting agent like salmeterol but is distinguished by its relatively quicker onset of action.[30] Duration of effect is approximately 12 hours. Because of its rapid onset of effect, formoterol is effective during acute exacerbations.[31] Stereoselective formoterol (arformoterol) is available as a nebulized solution.

Once-Daily Long-Acting β-Agonists. Indacaterol, vilanterol, and carmoterol have duration of action of 24 hours or more and are in various stages of clinical development.[32]

Anticholinergics

ANTICHOLINERGIC ACTION AND AIRWAY SMOOTH MUSCLE RELAXATION

The principal mechanism of action of muscarinic antagonists is to block vagally mediated bronchoconstriction. In patients with COPD, a greater bronchodilator response occurs after atropine than after albuterol. The bronchodilator response to atropine in patients with COPD is greater than that in normal subjects. These data suggest enhanced parasympathetic activity in COPD.[33,34] Patients with chronic asthma do not show as much benefit with anticholinergic agents, although patients with acute asthma exacerbations benefit from inhaled anticholinergic agents.

OTHER EFFECTS OF ANTICHOLINERGIC ACTION IN THE LUNGS

The quaternary ammonium-containing muscarinic antagonists in current use have no significant effects on mucus secretion or the rheologic properties of mucus,[35] although some reports do suggest a decrease in sputum volume.[36] Mucociliary clearance is unchanged with inhaled ipratropium.[37,38]

Acetylcholine can stimulate alveolar macrophages to release chemotactic factors.[39] Long-acting anticholinergics may thus decrease airway inflammation by blocking the actions of acetylcholine.[40]

SIDE EFFECTS OF ANTICHOLINERGICS

Although muscarinic receptors are widespread in the body, the quaternary ammonium group in modern antimuscarinic agents (ipratropium and tiotropium) results in poor systemic absorption allowing higher doses to be inhaled with few systemic effects.

Dryness of the mouth is a common side effect of anticholinergics, whereas blurring of vision occurs infrequently. Unilateral mydriasis is believed to result from direct contact of the nebulized solution with the eyes.[41,42] Ipratropium inhalation does not worsen arterial oxygenation,[43] and tolerance to the bronchodilator or bronchoprotective effects of anticholinergics does not occur. Systemic side effects (tachycardia, palpitations, urinary hesitancy, constipation, blurred vision, or glaucoma) are more common with tertiary ammonium compounds, such as atropine, than with ipratropium or tiotropium. In the Lung Health Study, Anthonisen et al found a higher incidence of supraventricular arrhythmias as well as significant increases in hospitalization and mortality rates in the ipratropium group as compared to the placebo group.[44] A slightly higher risk of developing cerebrovascular accidents was suggested for patients receiving tiotropium (http://www.fda.gov/medwatch/safety/2008/safety08.htm#Tiotropium), and a metaanalysis found a higher risk of cardiovascular events in patients with COPD receiving ipratropium or tiotropium,[45] although these have not been observed in a recently concluded large randomized controlled trial.[46] Nevertheless, ipratropium and tiotropium should be used with caution in patients with renal failure, prostatic hypertrophy, urinary retention, or glaucoma.

INDIVIDUAL AGENTS

Ipratropium. The usual dose is 36 mcg (2 puffs from a pMDI) every 4 to 6 hours. There is a plateau in the achievable improvement in FEV_1 with increasing doses with no significant improvement beyond a dose of 72 mcg.[47] In patients with severe airway obstruction, however, the amount of drug delivered to the site of action may vary and higher doses may be needed. The usual nebulized dose is 500 mcg every 6 hours. The onset of action is within 30 minutes of an inhaled dose and the effects last for about 4 to 6 hours.

Tiotropium. Tiotropium is a long-acting bronchodilator that has equal binding affinity for M_1, M_2, and M_3 receptor subtypes. It dissociates much more slowly from M_3 receptors than from M_2 receptors.[48] In view of the role of M_2 receptors in inhibiting acetylcholine release, this may represent a beneficial aspect of its action. Tiotropium is inhaled once daily. Onset of action is within 30 minutes. An increase in FEV_1 from baseline is present at 24 hours.[49]

Corticosteroids

Corticosteroids have no direct action on contraction of airway smooth muscle; hence, they are not bronchodilators in the classic sense. Corticosteroids, however, offer bronchoprotection, and they improve airway obstruction by reducing airway inflammation and via vasoconstrictor effects.[16,50] Corticosteroids reduce airway inflammation by several mechanisms,[51–54] decrease airway hyperresponsiveness and reduce the predilection to acute episodes of airflow obstruction. Corticosteroids also upregulate β-receptor expression on cell membranes, increase the proportion of β receptors in a high-affinity binding state, and inhibit the release of inflammatory mediators such as phospholipase A_2, which could destabilize membrane support of the β receptor.[55]

Several corticosteroids, such as hydrocortisone, cortisone, prednisone, prednisolone, and methylprednisolone are given parenterally or orally for treatment of inflammation in asthma and COPD. Agents with high topical activity are employed as inhaled corticosteroids (ICSs), such as beclomethasone, triamcinolone, flunisolide, fluticasone, budesonide, mometasone, and ciclesonide, because they produce direct antiinflammatory effects while minimizing unwanted systemic side effects.

Systemic administration of corticosteroids is associated with several adverse side effects.[56] The use of ICSs is attractive mainly to reduce the side effects observed with systemic therapy.[57,58] Side effects of therapy with ICSs include oropharyngeal fungal infections, hoarseness, hypothalamic–pituitary–adrenal axis suppression, reduction in bone mass, growth restriction in children, skin bruising, and increased propensity to develop pneumonia.[57–60]

Clinical Use of Bronchodilator Drugs

Patients presenting with acute severe asthma and acute exacerbations of COPD are in urgent need of bronchodilation. Inhalation is the preferred route of administration of bronchodilator agents because it produces a rapid onset of action, requires smaller doses than those needed orally or parenterally, and minimizes systemic side effects.[61] For administration of short-acting β-agonists the use of pMDI and holding chamber (a chamber spacer that incorporates a valve, so that aerosol is retained within the chamber for a finite time after pMDI actuation) is a convenient and cost-effective option and provides efficacy similar to that achieved with a jet nebulizer.[62]

β-AGONISTS IN ASTHMA AND CHRONIC OBSTRUCTIVE PULMONARY DISEASE

In general, repeated administration of short-acting β-agonists at frequent intervals is recommended for relief of symptoms in patients with acute asthma.[50,63] There is a dose–response relationship with increasing doses of β-agonists resulting in increasing bronchodilation.[64,65] Rodrigo and Rodrigo, however, noted that 2.4 mg of albuterol every hour (400 mcg every 10 minutes) delivered via a pMDI/holding chamber produced clinically significant bronchodilation, and higher doses increased the incidence of adverse effects without enhancing bronchodilation.[66,67] Other investigators have concluded that the cumulative dose, and not the dosage regimen, influences the bronchodilator response (i.e., the same response was obtained when 5 mg was given as a single dose as when it was given as two doses of 2.5 mg).[68,69] The usual dose necessary to produce bronchodilation in severe asthma is between 5 and 10 mg of albuterol.[70] Use of higher doses during the initial phase of an acute exacerbation of asthma may have clinical utility. A faster response may be seen, and, because most patients respond to 5 to 10 mg of albuterol, nonresponders could be identified. Nonresponders, defined as those requiring admission, not discharge, to an emergency department, were found to have a flatter dose–response curve to albuterol, with peak expiratory flow remaining below 45% despite administration of high doses of albuterol.[68,71,72]

The logistical problem in repeatedly administering doses of nebulized albuterol (intermittent therapy) stimulated interest in continuous nebulization. Various investigators have reported conflicting findings with continuous nebulization.[73,74] Two meta-analysis of published trials also reached different conclusions.[75,76] Overall, it appears that patients with more severe airway obstruction could benefit from continuous nebulization,[4,77] especially if they do not respond to therapy within the first hour in the emergency department.

Both formoterol and arformoterol are effective for treatment of patients with COPD.[78–81] There is not much published experience with their use during acute exacerbations of asthma or COPD.

In summary, the severity of an individual episode is better measured as response to bronchodilator therapy rather than by baseline pulmonary function. Continuous nebulization may be employed in patients with acute severe asthma in whom pulmonary function does not improve by the end of the first hour of intensive bronchodilator therapy.

CHOICE OF DELIVERY SYSTEM

In clinical studies evaluating bronchodilator administration through pMDI/holding chamber versus nebulizers, equivalent changes in FEV_1 were produced by 6 mg/hour of albuterol given by the nebulized route and 2.4 mg/hour of albuterol given by pMDI/holding chamber, an equivalent dose ratio of 2.5:1. A higher incidence of tremor and anxiety and higher serum albuterol was seen in the nebulizer group.[82] Improvement in pulmonary function is similar[70,83,84] or slightly better[85,86] with pMDI/holding chamber than with nebulizers, while increases in heart rate are more frequent with nebulizers.[70]

ANTICHOLINERGICS IN ASTHMA AND CHRONIC OBSTRUCTIVE PULMONARY DISEASE

The ideal bronchodilator and optimal regimen for acute exacerbations of COPD have not been established. A pooled analysis comparing the effects of β-agonists (fenoterol and metaproterenol) and anticholinergics (ipratropium) found no significant differences in improvement in FEV_1.[87] If response to β-agonists is suboptimal or the exacerbation is severe, ipratropium can be added.[88]

CORTICOSTEROIDS IN ASTHMA AND CHRONIC OBSTRUCTIVE PULMONARY DISEASE

A short course of systemic corticosteroids may be necessary to gain control of asthma symptoms. ICS may be started at the same time and the systemic steroid tapered slowly. Subsequent adjustments in ICS dose are based on assessments of symptoms, rescue use of short-acting β-agonists, and measurement of peak expiratory flow rates.

High-dose ICSs administered by pMDI to patients with acute asthma exacerbations achieve similar improvements in symptoms and pulmonary function as systemically administered corticosteroids.[89–91]

Corticosteroids for Chronic Obstructive Pulmonary Disease. In patients with COPD, regular use of ICSs produces a small increase in pulmonary function and

improves health status.[92–94] ICSs, however, do not alter the rate of decline in FEV_1 and they do not reduce mortality.[95] In acute exacerbations, oral or parenteral corticosteroids are often employed with some benefit for patients who are admitted to the hospital.[96,97] Current evidence favors moderate over high doses, and short courses of oral corticosteroids over intravenous therapy for treating acute exacerbations.[98–100]

Risk-to-benefit considerations have prompted investigation of ICS use for treatment of acute exacerbations of COPD. Several investigators have shown that the efficacy of nebulized budesonide is comparable to that observed with systemic corticosteroids, except in the most severely ill patients.[101–104]

In patients receiving long-term ventilation for severe COPD, Nava et al observed a small, but statistically significant, reduction in airway resistance with fluticasone.[105] The optimal methods of administering ICS and the appropriate doses in ventilated patients have not been determined, but are likely to be higher than those used for maintenance therapy in COPD.[16,101–104] Moreover, many ventilated patients receive systemic corticosteroids for acute exacerbations of asthma and COPD, and it is unclear if patients derive additional benefits from ICSs in the presence of high-dose therapy with oral or parenteral corticosteroids. Finally, regular use of ICSs in ambulatory patients with COPD is associated with a higher risk of pneumonia.[60] Because ventilated patients are already vulnerable to developing pneumonia for a variety of reasons, the potential to add another risk factor by administering ICSs requires serious consideration. In summary, ICSs may have a limited role in ventilated patients, but further investigations are needed to determine the appropriate dosing regimen and risk-to-benefit ratio of using ICSs in this group of patients.

Combination Therapy

β-AGONISTS AND ANTICHOLINERGICS

In acute asthma, some investigators found additional benefits with combined anticholinergic and β-agonist therapy over β-agonists alone,[106–108] whereas others[109,110] found no difference. A meta-analysis that compared albuterol alone to albuterol with ipratropium found an overall improvement of 7.3% in FEV_1 and 22.1% in peak expiratory flow rates, and reduction in hospitalization rates for studies in which data were available.[111] A more recent meta-analysis by Rodrigo and Rodrigo[112] found benefit for a combination of anticholinergics with albuterol in severe asthma (FEV_1 <50%).

In patients with acute exacerbations of COPD, adding an anticholinergic to a β-agonist may[113] or may not[114–116] provide greater bronchodilation. Fernandez et al[117] found an improvement in airway pressures in ventilated patients with the combination of ipratropium and fenoterol in comparison to ipratropium; ipratropium alone achieved no benefit.

BRONCHODILATORS AND INHALED CORTICOSTEROIDS

There is little doubt that combinations of ICSs plus long-acting β-agonists (Advair Diskus; Advair pMDI; Symbicort pMDI) are the most effective and widely used treatments currently available for treatment of asthma. A combination of formoterol and budesonide, used as a reliever as well as maintenance therapy, may be employed for treatment of mild to moderate acute asthma exacerbations that could be managed at home. This management strategy significantly reduces the frequency of more severe exacerbations.[118] Currently, there is limited experience with bronchodilator and ICS combination therapy for treatment of acute exacerbations of COPD, especially in ventilated patients.

Methylxanthines

Theophylline is an inexpensive and commonly employed bronchodilator in many developing countries. The reader is referred to the second edition of this book[17] for details on its pharmacology and mechanisms of action.

Theophylline administration requires empiric loading and maintenance dosing with frequent measurement of serum levels and dose adjustment.[119] Plasma theophylline levels should be maintained between 5 and 15 mg/L because adverse effects frequently occur with higher levels.[120–122] At concentrations less than 15 mg/L, theophylline is a relatively weak bronchodilator and its beneficial effects are more likely explained by its antiinflammatory action, particularly in synergy with corticosteroids.[123]

In acute asthma, theophylline does not confer additional bronchodilation in patients receiving intensive therapy with inhaled β-agonists and intravenous corticosteroids.[124–126] Likewise, routine use of theophylline in acute exacerbations of COPD is not supported by randomized controlled trials.[114] Theophylline may have a role in reducing hospitalization among patients receiving emergency department treatment for asthma and COPD,[127] and in promoting corticosteroid activity in patients with acute exacerbations of COPD.[128] Few investigators have reported on the use of theophylline in ventilated patients.[117,129,130] In the neonatal ICU, theophylline is employed to prevent apneas.[131] In adults, loading doses of intravenous theophylline produced significant bronchodilation, comparable to that achieved with two inhalations of either albuterol or ipratropium bromide.[117,129,130] The increased respiratory muscle strength with theophylline[132–134] may help in weaning.

Frequent side effects with theophylline, especially nausea and vomiting, are a major drawback. Older patients and those with a low serum albumin are particularly susceptible to serious theophylline toxicity, such as cardiac arrhythmias and seizures.[135–137] In summary, the high frequency of side effects, its relatively low efficacy, frequent drug interactions, complicated dosing regimens, and the need for repeatedly monitoring serum levels have significantly limited theophylline use in the ICU.

Selective Phosphodiesterase E_4 Inhibitors

Phosphodiesterase E_4 (PDE_4) is the predominant isozyme responsible for metabolizing cyclic adenosine monophosphate in airway smooth muscle, and in immune and inflammatory cells.[138,139] Elevation of cyclic adenosine monophosphate by selective PDE_4 inhibition has a wide variety of pharmacologic effects. Orally administered selective PDE_4 inhibitors have bronchodilator and antiinflammatory effects in patients with asthma and COPD.[140–145] Unlike theophylline, these agents do not exhibit significant drug interactions.[146,147] Side effects, such as nausea and headache, are generally mild to moderate, but could limit the use of these agents in critically ill patients.

Leukotriene-Modifying Agents

Leukotrienes are formed by the action of 5-lipoxygenase on cell membrane-derived arachidonic acid. Zileuton blocks 5-lipoxygenase and inhibits leukotriene synthesis, whereas zafirlukast, montelukast, and pranlukast all block the final step in the action of leukotrienes on the leukotriene receptor. The leukotrienes are mainly employed in patients with chronic asthma as adjuncts to ICSs. In acute asthma, intravenous montelukast achieves modest early gains in lung function without significant improvement in rates of hospital admission.[148]

FACTORS INFLUENCING AEROSOL DELIVERY DURING MECHANICAL VENTILATION

Several factors influence aerosol delivery during mechanical ventilation, including variables related to the aerosol-generating device, the ventilator and ventilator circuit, the inhaled drug or agent, and the patient (Fig. 63-1). Aerosol delivery during mechanical ventilation depends to a great extent on the type of aerosol-generating device employed.

Aerosol-Generating Devices

NEBULIZERS

Several types of nebulizers, jet, ultrasonic, vibrating mesh, and soft-mist inhalers convert liquids into aerosols for inhalation (Fig. 63-2).[61]

Jet Nebulizers. Aerosol particle size is influenced by nebulizer design, solution characteristics (density, viscosity, and surface tension) and volume, gas pressure and flow, baffle design, and ratio of liquid to gas flow.[149–151] Droplet size decreases when gas flow increases, whereas droplet size increases with increase in the ratio of liquid to gas flow. A certain volume of solution (dead or residual volume)

cannot be nebulized. Residual volume varies from 1 to 3 mL; it can be reduced by using a nebulizer with a conical shape, improving the wetness of the plastic surfaces, and reducing the internal surface area of the nebulizer.[149,151] During operation, the solution concentration increases and its temperature decreases secondary to evaporative losses.[152,153] Both increased solution concentration and cooling influence nebulizer output and particle size.[151,154] Significant disadvantages of jet nebulizers are the requirement for a power source, inconveniently long treatment time, need for equipment setup and cleaning, and significant variations in the performance of various nebulizers, both within the same brand and across different brands.[155–157]

Ultrasonic Nebulizers. Most ultrasonic nebulizers have a higher rate of nebulization and require a shorter time of operation than jet nebulizers (see Fig. 63-2). Generally, the aerosol particle size is larger with ultrasonic nebulizers compared to jet nebulizers. The cost and bulk of ultrasonic nebulizers and their relative inefficiency in nebulizing drug suspensions are major limitations to their use, although smaller ultrasonic nebulizers are available and have been employed during mechanical ventilation.[158–162]

Vibrating Mesh Nebulizers. Newer-generation nebulizers employ a vibrating mesh or plate with multiple apertures to produce an aerosol.[163,164] Because the frequency of vibration of the plates is lower than that in ultrasonic nebulizers, these devices can be operated with a battery pack and or electrical source. As a result, these devices are portable and less noisy. Moreover, these devices have negligible residual volume, and this property significantly improves the drug output. The Aeroneb Pro (Aerogen Inc., Mountain View, CA) is specifically designed as an inline nebulizer (see Fig. 63-2); a breath-synchronized version of the Aeroneb Pro—the Pulmonary Drug Delivery System (PDDS, Nektar Therapeutics, San Francisco, CA)[165]—has been successfully employed in ventilated patients.[166] The vibrating mesh nebulizers have a high rate of nebulization, and drug output is two to four times higher than with jet nebulizers.[167] Unlike ultrasonic nebulizers, the temperature of the solution does not change during operation of the vibrating mesh nebulizers,

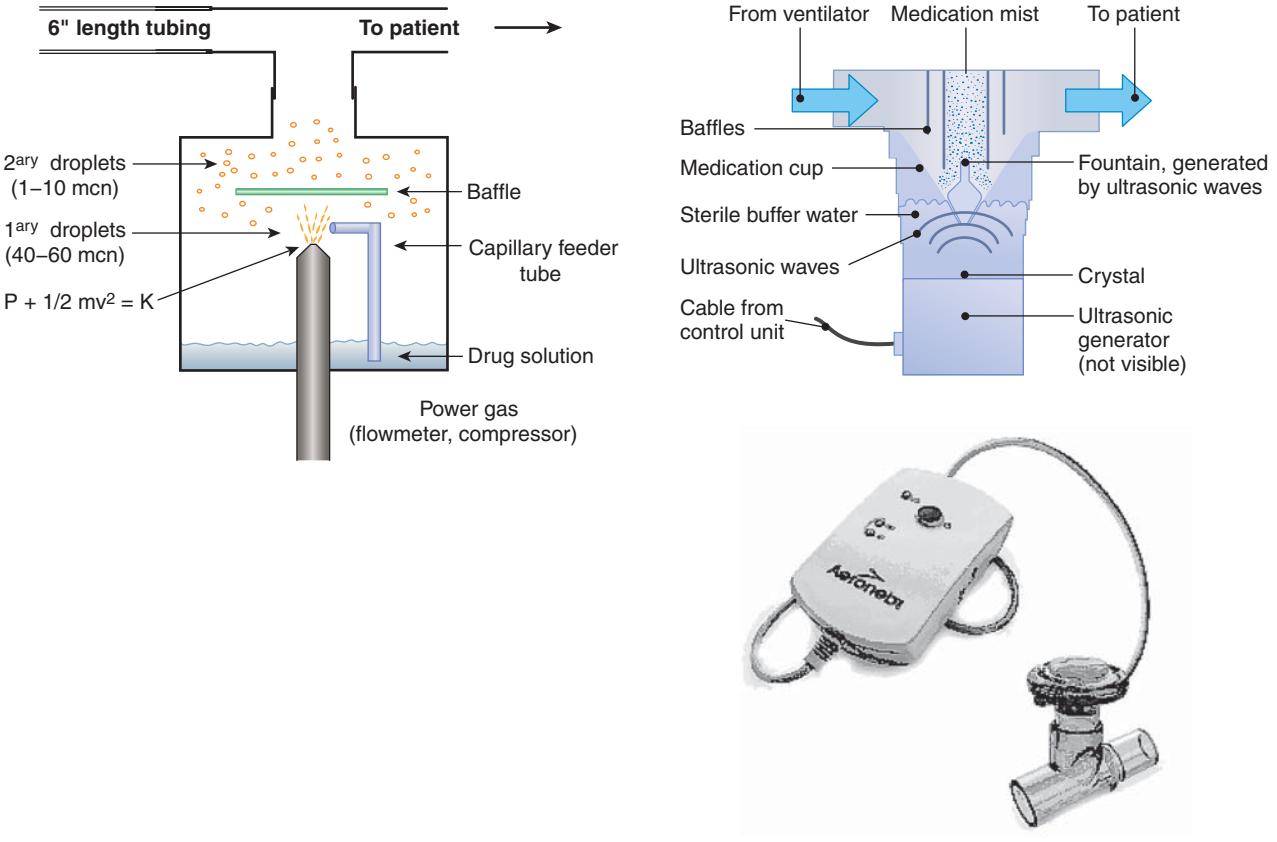

FIGURE 63-2 Several types of nebulizers are available for clinical use, including jet nebulizers (*left*), ultrasonic nebulizers (*upper right*), and vibrating mesh nebulizers (*lower right*). The jet nebulizers employ compressed gas or air to generate an aerosol. In ultrasonic nebulizers, aerosol is generated by vibration of a piezoelectric crystal at ultrasonic frequencies. In the vibrating mesh nebulizers, aerosol is produced by high-frequency vibration of a plate with multiple apertures. Vibration of the aperture plate pushes the liquid to be nebulized through the apertures and generates a fine particle mist. *mcn*, micron.

and proteins and peptides can be nebulized with minimal risk of denaturation.

Intratracheal Catheter. The intracorporeal nebulizing catheter (Aeroprobe; Trudell Medical International, London, Ontario, Canada) is a novel, investigational device that produces an aerosol in the trachea.[168,169] Preliminary data suggest that lung deposition is improved with its use compared to more conventional forms of aerosol administration.[170,171]

PRESSURIZED METERED-DOSE INHALERS

The pMDI canister contains a pressurized mixture of propellants, surfactants, preservatives, flavoring agents, and active drug, the latter comprising approximately 1% of the total contents.[172,173] This mixture is released from the canister through a metering valve and stem, which fits into an actuator boot.[172,173] Previously, most pMDIs used chlorofluorocarbon (CFC) propellants, but a newer generation of pMDIs contain hydrofluoroalkane (HFA) propellants.[174] The formulation, metering valve, and actuator design of HFA-pMDIs are different from those of CFC-pMDIs.[61]

The efficiency of drug delivery with a pMDI depends on how well the canister stem fits into the spacer adapter. In bench models of mechanical ventilation, HFA-pMDIs used with an AeroVent spacer provided lower drug delivery than that achieved with CFC-pMDIs.[175] In contrast, beclomethasone HFA-pMDIs employed with an AeroChamber HV MV spacer (Monaghan Medical, Plattsburgh, NY) had a higher efficiency of drug delivery than the beclomethasone CFC-pMDI.[176] Likewise, HFA-pMDIs were shown to achieve drug delivery similar to CFC-pMDIs in pediatric and neonatal bench models of mechanical ventilation.[177,178] To improve drug delivery with HFA-pMDIs during mechanical ventilation, actuators that better fit the stem of the HFA-pMDI canister must be employed.

DRY POWDER INHALERS

Dry powder inhalers could be employed inline in ventilator circuits either by employing the ventilator's inspiratory airflow to generate an aerosol or by first producing an aerosol and then entraining the drug particles into the airflow from the ventilator. Everard et al[179] employed a modified Turbuhaler in a dry ventilator circuit, and found that approximately 20% of the nominal dose was delivered to a filter placed at the distal end of the endotracheal tube. Humidity reduces drug delivery from dry powder inhalers,[180] and because ventilated patients routinely receive warm and humidified gas, the feasibility of administering dry powders during mechanical ventilation needs further evaluation.

FACE MASKS

Aerosol deposition in nasal passages significantly reduces drug delivery to the lung[181–183] and could reduce bronchodilator efficacy;[184] however, face masks may be necessary for treatment of acutely dyspneic or uncooperative patients. For optimal efficacy, the face mask should produce a tight seal[185–187] to avoid aerosol leakage and increased aerosol deposition around the eyes.[188]

The orientation of the nebulizer with respect to the face mask influences the pattern of aerosol deposition. In "front-loaded" masks the nebulizer is inserted directly into the face mask, whereas in "bottom-loaded" masks the aerosol enters the mask from below. Front-loaded masks provide greater inhaled mass but also produce greater facial and ocular deposition.[189] Deposition of aerosol on the face and eyes could be minimized by employing masks that incorporate vents and have cut outs in the region of the eyes.[189,190]

HIGH-FLOW NASAL CANNULAE

Humidified high flow nasal cannulae are increasingly employed in the ICU to enhance gas exchange and avoid mechanical ventilation.[191] In a bench study, the inhaled mass of aerosol and aerosol particle size with high-flow nasal cannulae were comparable to those obtained with mouthpiece inhalation from a continuously operating jet nebulizer.[192]

Methods to Assess Aerosol Delivery during Mechanical Ventilation

In the past, pMDIs and nebulizers[193,194] were shown to have poor efficiency during mechanical ventilation, mainly because of drug deposition in the ventilator circuit and artificial airway.[195,196] Both in vitro and in vivo studies have helped in understanding the complex factors governing aerosol delivery during mechanical ventilation.[196–198]

Whereas in vitro methods measure *drug delivery* to the lower respiratory tract, in vivo methods measure the amount of *drug deposition* in the lung. This distinction is important because a variable portion of inhaled particles do not deposit in the lung and are exhaled. A "mass balance" technique that matches ventilator circuits and ventilator parameters has been employed to determine the correlation between the results of in vitro tests and those in ventilator-supported patients.[199,200] With such techniques, it was estimated that approximately 5% of the nominal dose of albuterol administered by a pMDI is exhaled by ventilated patients,[175] compared to less than 1% exhaled by ambulatory patients.[201] The mean exhaled fraction (7%) with nebulizers in ventilated patients is similar to that with pMDIs, but there is considerable variability (coefficient of variation: 74%) among patients.[199]

The particle size of the aerosol is an important determinant of aerosol delivery to the lung. Devices that produce aerosols with mass median aerodynamic diameter less than 2 μm are more efficient during mechanical ventilation than devices that produce aerosols with larger particles.[199,200] Nebulizers that produce smaller particle size have been employed, but they require a considerably greater time to deliver a standard dose.[200,202] Moreover, a significant

TABLE 63-2: DETERMINATION OF LOWER RESPIRATORY TRACT DEPOSITION OF AEROSOL DELIVERED BY A PRESSURIZED METERED-DOSE INHALER USING IN VITRO MODELS

Type of model and Ref.	Type of Adapter	Breath Type	Measurement	Results
ETT (6.0, 7.5 and 9.0 mm) in trachea[204]	Swivel adapter	Continuous flow or MDI actuation then flow	Filter weight	Greater efficiency with larger ETT and actuation into continuous flow
ETT and laser spectrometer[205]	Three different adapters inline or cylindrical spacer	V_T 800 mL; flow 60 L min^{-1}	Particle volume 1 to 5 μm	Adapters produced lower volume of particles than standard actuator
Ventilator circuit; ETT (8 mm)[209]	Swivel adapter at ETT or cylindrical spacer	V_T 800 mL; flow 48 L min^{-1}	Albuterol assay	Greater deposition with cylindrical spacer
ETT and laser spectrometer[206]	Nine different MDI spacers or adapters	–	Particle volume 0.7 to 5.0 μm	Chamber spacers delivered greater volume than other adapters
Ventilator circuit[207]	MDI with large chamber or small chamber spacer	V_T 700 mL; flow 50 L min^{-1}	Radioactivity	Similar delivery with the devices
Plastic syringe and simulated carina[210]	MDI with catheter	–	Albuterol assay	≈90% of dose delivered beyond ETT
ETT (6 mm) and swivel adapter[211]	Catheters placed in ETT (13 or 22 cm long)	Flow 30 L min^{-1}	Albuterol assay	Longer catheters delivered greater dose than shorter catheters
Model of trachea and main bronchi[195]	Cylindrical spacer 8 mm ETT	Flow 40 L min^{-1}	Albuterol assay	Decreased deposition with humidification and CMV breaths

Abbreviations: CMV, controlled mechanical ventilation; *ETT*, endotracheal tube; *pMDI*, pressurized metered dose inhaler; V_T, tidal volume.

proportion of submicronic particles (<1 μm) are exhaled.[199] For optimal pulmonary deposition, the size of the particles in the aerosol should be small enough to allow maximum penetration through the artificial airway, yet large enough to avoid being carried back out into the atmosphere with the exhaled breath.

IN VITRO STUDIES

Carefully performed in vitro tests that simulate the conditions of actual clinical use have played an important role in determining the optimal techniques for administering aerosols to ventilated patients.[175,176,199,200,202–209] Table 63-2 shows various bench models that were used. Models that employ a tracheobronchial model and directly measure the amount of drug deposited on a filter placed distal to the endotracheal tube[175,176,195,209–211] have produced the most reproducible results.

For any given aerosol-generating device, the efficiency of drug delivered varies widely; for pMDIs, it varies from 0.3% to 97.5% and for nebulizers from 0% to 42%. These variations in drug delivery underscore the need for optimizing the techniques of administration with each device. With pMDIs, the type of pMDI propellant formulation[176] and the drug formulation[203] also influence drug delivery.

Configuration of the Device with Metered-Dose Inhalers. For a pMDI to be employed in a ventilator circuit, the canister must be removed from the actuator (supplied by the manufacturer) and connected to the ventilator circuit with another different adapter, thereby making it a unique device with different aerosol characteristics and performance. Several types of adapters, including elbow adapters, inline devices that may be unidirectional or bidirectional, and chamber or reservoir adapters, are commercially available (Fig. 63-3).[162,212] The adapter efficiency could have a significant influence on the dose required to produce a therapeutic effect.[213] Several investigators have shown that employing a chamber spacer with a pMDI in a ventilator circuit results in fourfold to sixfold greater aerosol drug delivery compared with either an elbow adapter or a unidirectional inline spacer.[202,205,209,214] A pMDI and chamber spacer placed at a distance of approximately 15 cm from the endotracheal tube provides efficient aerosol delivery and elicits a significant bronchodilator response.[12,197,215] The efficiency of a bidirectional inline spacer was higher than that of a unidirectional inline spacer[203] and was comparable to that achieved with chamber spacers,[203] although the performance of the bidirectional spacer has not been established in clinical studies.

Configuration of the Device with Nebulizers. Both jet and ultrasonic nebulizers are connected in the inspiratory limb of the ventilator circuit or at the patient Y. Placing a jet nebulizer at a distance from the endotracheal tube improves its efficiency compared with placing it between the patient Y and endotracheal tube.[208,216,217,218] Placement of the continuously operating jet nebulizer before the humidifier (i.e., between the humidifier and ventilator) had

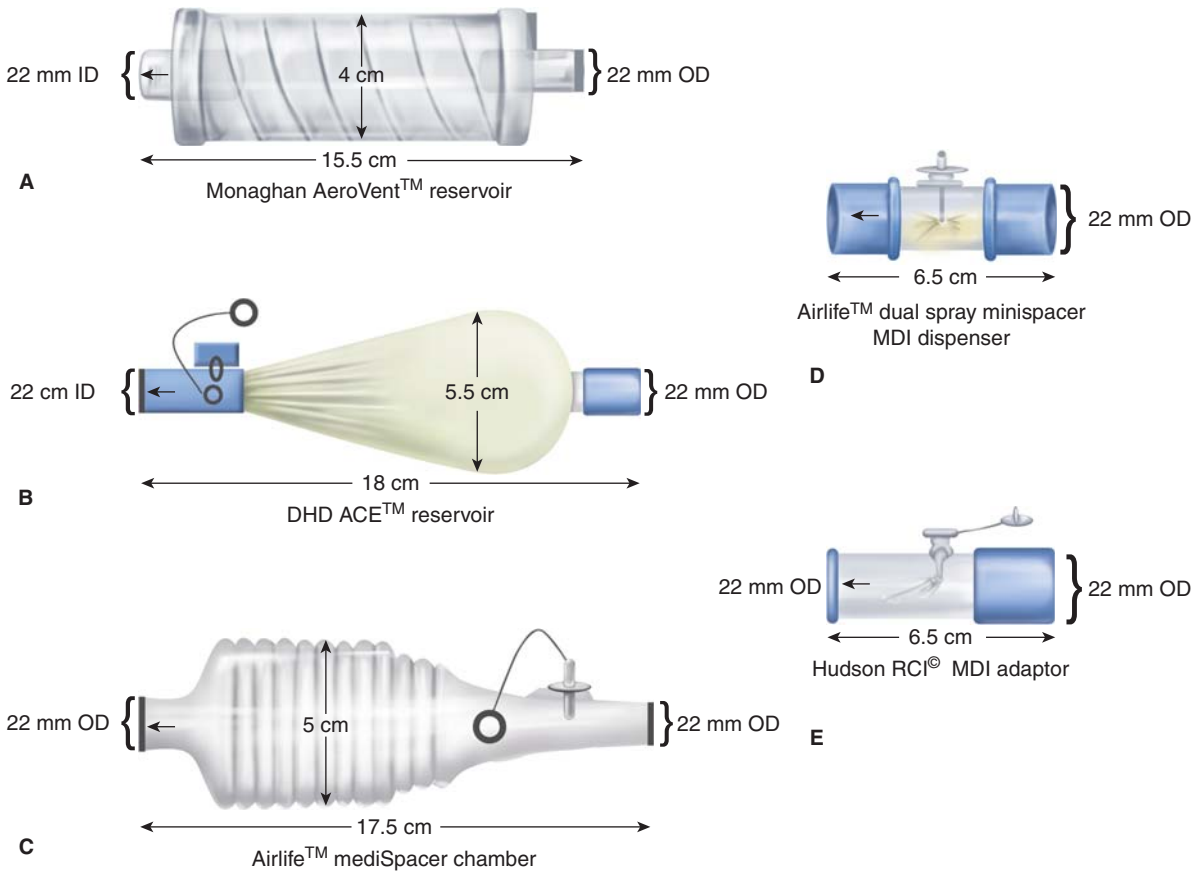

FIGURE 63-3 Commercially available spacers and adapters that are used to connect a metered-dose inhaler (*MDI*) canister in the ventilator circuit. *Top left:* Collapsible spacer chamber. *Middle left:* Aerosol cloud enhancer, wherein the aerosol flume is directed away from the patient. *Bottom left:* Noncollapsible spacer chamber. *Top right:* Bidirectional actuator (mini spacer). *Bottom right:* Inline adapter. *OD*, outside diameter. (Used, with permission, from Rau et al.[203])

a higher efficiency of aerosol delivery than placement closer to the endotracheal tube,[218] probably because the inspiratory limb of the ventilator circuit acts as a reservoir for the aerosol during the exhalation phase. For the same reason, addition of a reservoir between the nebulizer and endotracheal tube also modestly increases efficiency of drug delivery.[219] The nebulizer brand,[157,208] diluent volume, operating pressures and flows, and duration of treatment,[149,157] influence the efficiency of aerosol generation.

Ultrasonic nebulizers are infrequently employed for bronchodilator therapy during mechanical ventilation and there is scant published information about drug delivery with these devices.[160] Moreover, the particle size of aerosols produced by ultrasonic nebulizers in ventilator circuits has not been well characterized. The newer vibrating mesh nebulizers deliver twofold to fourfold higher drug dose than jet nebulizers. In the absence of bias flow, a vibrating mesh nebulizer was most efficient for drug delivery when it was placed 15 cm from the endotracheal tube, whereas in the presence of bias flow (2 L/min) the efficiency of the device was enhanced by placing it at the inlet of the humidifier (i.e., between the humidifier and ventilator).[218]

Synchronizing Aerosol Generation with Inspiratory Airflow. The actuation of a pMDI must be synchronized with the precise onset of inspiratory airflow from the ventilator.[220,221] As short as a 1- to 1.5-second delay between pMDI actuation and a ventilator breath can profoundly reduce the efficiency of drug delivery.[202]

In a ventilator circuit, nebulizers can be operated continuously or intermittently by airflow from the ventilator. Continuous aerosol generation requires a pressurized source of gas (from a wall outlet, pressurized tank, or an air compressor), whereas intermittent operation that is synchronized with inspiratory airflow requires a separate line to conduct inspiratory airflow from the ventilator to the nebulizer. Intermittent operation of the nebulizer is more efficient for aerosol delivery compared with continuous aerosol generation because it minimizes aerosol wastage during the exhalation phase of the breathing cycle.[200,217] The lower driving pressure provided by the ventilator (<15 pounds per square inch [psi]) than that provided by pressurized gas (≥50 psi) could decrease the efficiency of some nebulizers.[222] Aerosol generated by a nebulizer operating at the lower pressure may generate particles whose diameter is larger than the 1 to 5 μm that is optimal for aerosol deposition. When intermittent nebulizer operation is employed, the specific ventilator and nebulizer brand should be tested to determine the characteristics of the aerosol generated and the efficiency of drug delivery.[200]

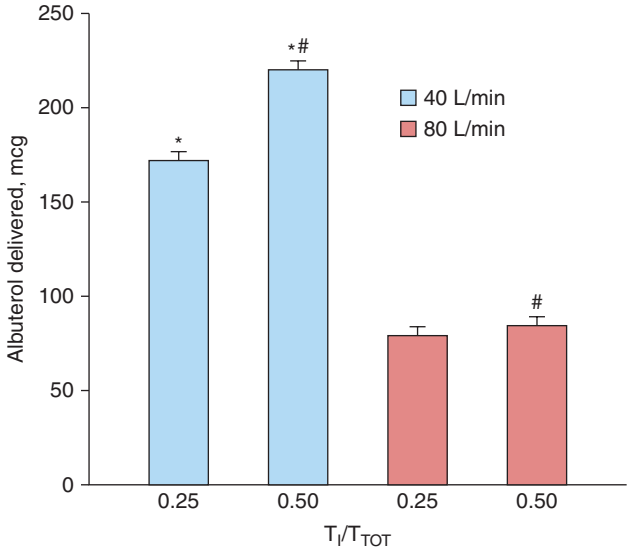

FIGURE 63-4 Comparison of aerosol delivery at different inspiratory airflows and duty cycles (T_I/T_{TOT}) in a bench model of mechanical ventilation. The ventilator delivered a tidal volume of 1000 mL with a constant inspiratory flow of 40 or 80 L/min, and the frequency of breathing was varied to achieve T_I/T_{TOT} values of 0.25 or 0.50 at each inspiratory flow setting. Albuterol delivery to the bronchi was greater with a T_I/T_{TOT} of 0.50 than of 0.25 at inspiratory flows of 40 L/min and 80 L/min. For each value of T_I/T_{TOT}, drug delivery with a slower inspiratory airflow (40 L/min) was almost twice that at the faster inspiratory airflow (80 L/min). *, $p < 0.01$, 40 L/min versus 80 L/min at T_I/T_{TOT} of 0.25 and T_I/T_{TOT} of 0.50; #, $p < 0.01$ T_I/T_{TOT} of 0.5 versus T_I/T_{TOT} of 0.25 at 40 L/min and 80 L/min. (Dhand R. Aerosol delivery during mechanical ventilation: from basic techniques to new devices. *J Aerosol Med Pulm Drug Deliv.* 2008;21:45–60.)

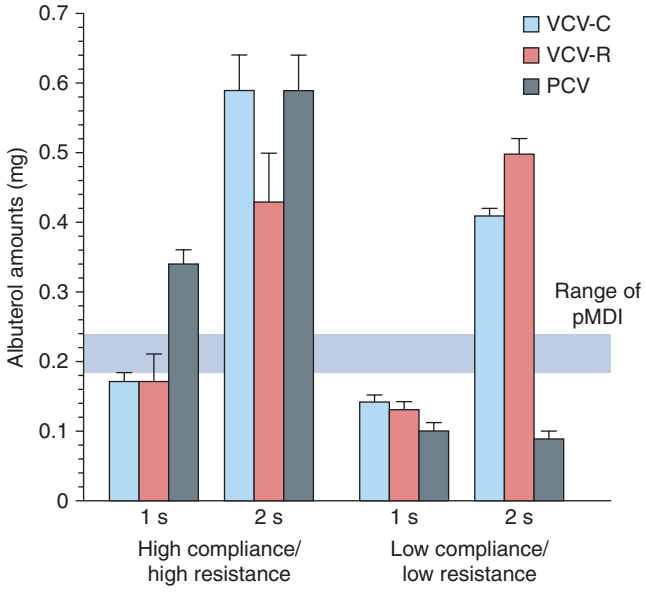

FIGURE 63-5 Comparison of aerosol delivery from a pressurized metered-dose inhaler (*pMDI*) and jet nebulizer in bench models of pressure-controlled and volume-controlled ventilation. The lung mechanics were varied by selecting two settings of resistance and compliance to achieve high or low time constants. For each condition, the amounts of aerosol delivered during inspiratory times of 1 second or 2 seconds were measured. Increasing the duration of inspiration from 1 second to 2 seconds improved the nebulizer efficiency. In the high-compliance/high-resistance setting with 1-second inspiration, nebulizer efficiency was higher during pressure-controlled than during volume-controlled ventilation, whereas the converse occurred in the low-compliance/low-resistance setting with 2 seconds inspiratory time. In contrast, the efficiency of a pressurized MDI (*horizontal purple area*) remained fairly constant under the various conditions simulated in the bench model. Thus, several factors, such as inspiratory time, pattern of inspiratory flow, and lung mechanics, that could influence drug delivery from a nebulizer have minimal influence on drug delivery from a pMDI. *PCV*, pressure-controlled ventilation; *VCV-C*, volume-controlled ventilation with a constant inspiratory flow; *VCV-R*, volume-controlled ventilation with a descending ramp flow pattern. (With kind permission from Springer Science and Business Media: Hess DR, Dillman C, Kacmarek RM. In vitro evaluation of aerosol bronchodilator delivery during mechanical ventilation: pressure-control vs. volume control ventilation. *Intensive Care Med.* 2003;29:1145–1150.)

Ventilator-Related Factors. The characteristics of the ventilator breath have an important influence on aerosol drug delivery. A tidal volume of 500 mL or more (in an adult),[195] longer inspiratory time, and slower inspiratory flows improve aerosol delivery[195,223,224] (Fig. 63-4). An inspiratory flow rate of 30 to 50 L/min is optimal for aerosol delivery; however, slow inspiratory flow rates may increase inspiratory time and by reducing the time for exhalation may have the unintended consequence of increasing auto–positive end-expiratory pressure.[225] Drug delivery is linearly correlated with a longer duty cycle (inspiratory time-to-total time [T_I/T_{TOT}]) for both pMDIs and nebulizers.[175,195,208] Moreover, drug delivery is improved when a pMDI is synchronized with a simulated spontaneous breath compared with a controlled ventilator breath of similar tidal volume.

The inspiratory waveform influences drug delivery from nebulizers, but has much less influence on drug delivery from a pMDI.[226] Unlike pMDIs, nebulizer efficiency could be different during pressure-controlled ventilation than during volume-controlled ventilation (Fig. 63-5).

The breath-triggering mechanism does not significantly influence drug delivery from a pMDI, but use of a flow trigger with a nebulizer could dilute the aerosol and increase the washout of the aerosol into the expiratory limb between breaths.[195,208]

Circuit-Related Factors. Several investigators found that drug delivery to the lower respiratory tract from both pMDIs and nebulizers is reduced by 40% or more in a humidified circuit when compared to a dry circuit (Fig. 63-6).[158,175,200,202,207,208] Circuit humidity increases the size of drug particles generated by a nebulizer.[227] When a pMDI is employed in a ventilator circuit, humidity probably interferes with propellant evaporation so that drug particles remain of a larger size and impaction losses are increased.[212,228]

Heat and moisture exchangers (HMEs) are employed as an alternative to heated humidifiers.[229] The filter in the HME captures the heat and moisture in the exhaled breath and transfers part of it to the air in the following inspiration. The HME filter captures drug particles in the aerosol and

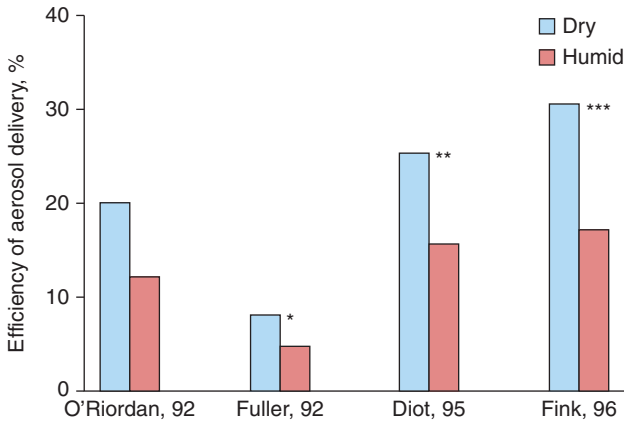

FIGURE 63-6 Effect of humidity on aerosol delivery. The delivery of aerosol to the lower respiratory tract in bench models of mechanical ventilation is reduced by approximately 40% when the circuit is humidified instead of dry. *, $p < 0.05$; **, $p < 0.01$; ***, $p < 0.001$. Studies: O'Riordan et al. 1994, Fuller et al. 1992, Diot et al. 1995, and Fink et al.1996, (Reprinted with permission of the American Thoracic Society. Copyright © 2012 American Thoracic Society. From Dhand R, Tobin MJ. Inhaled bronchodilator therapy in mechanically ventilated patients. *Am J Respir Crit Care Med.* 1997;156:3–10. Official Journal of the American Thoracic Society.)

markedly reduces the efficiency of drug delivery. Therefore, the HME must be removed from the circuit during aerosol treatments. Although placement of a nebulizer between the HME and endotracheal tube could provide adequate drug delivery, backflow of aerosol from the nebulizer could deposit on the HME filter, increase its airflow resistance, and increase the work of breathing for the patient.[230]

The density of the inhaled gas also influences drug delivery. High inspiratory flows employed during mechanical ventilation are associated with turbulence. Inhalation of a less-dense gas, such as a helium-oxygen 70/30 mixture, makes airflow less turbulent and more laminar. The use of helium-oxygen mixtures improved aerosol drug delivery in a pediatric model of mechanical ventilation.[231] In a bench model of adult mechanical ventilation, drug delivery from a pMDI was noted to be 50% higher with a helium-oxygen 80/20 mixture than with oxygen alone (Fig. 63-7A).[232] In contrast, nebulizer operation with helium-oxygen reduced drug output and respirable mass (Fig. 63-7B).[232,233] A practical method to achieve maximum pulmonary deposition of aerosol from a nebulizer during mechanical ventilation is to operate the nebulizer with oxygen at a flow rate of 6 to 8 L/min and to entrain the aerosol generated into a ventilator circuit containing helium-oxygen (Fig. 63-8).[233] Before employing helium-oxygen in ventilated patients, it is important to ensure that the ventilator is compatible with the use of such gas mixtures.[234]

Aerosol impaction on the endotracheal tube poses a significant barrier to effective drug delivery in infant and pediatric mechanical ventilation (endotracheal tube internal diameter 3 to 6 mm),[204,235] with aerosol delivery efficiency being lower with narrower endotracheal tube tubes.[236] In adult mechanical ventilation, there was no difference in nebulizer efficiency with endotracheal tubes of internal diameter 7 mm versus internal diameter 9 mm.[208] Drug losses within the endotracheal tube could be minimized by placing the aerosol generator at a distance from the endotracheal tube instead of being directly connected to it.[196] Removing the right angled elbow connector between the patient Y and endotracheal tube improves aerosol delivery.[175,237] Some investigators attached a long catheter to the nozzle of an pMDI and delivered aerosol directly into the trachea (i.e., beyond the endotracheal tube).[211] With this delivery system, concerns have been raised about catheter blockage and mucosal damage induced by propellants, surfactant, or other constituents of the pMDI formulation.[238]

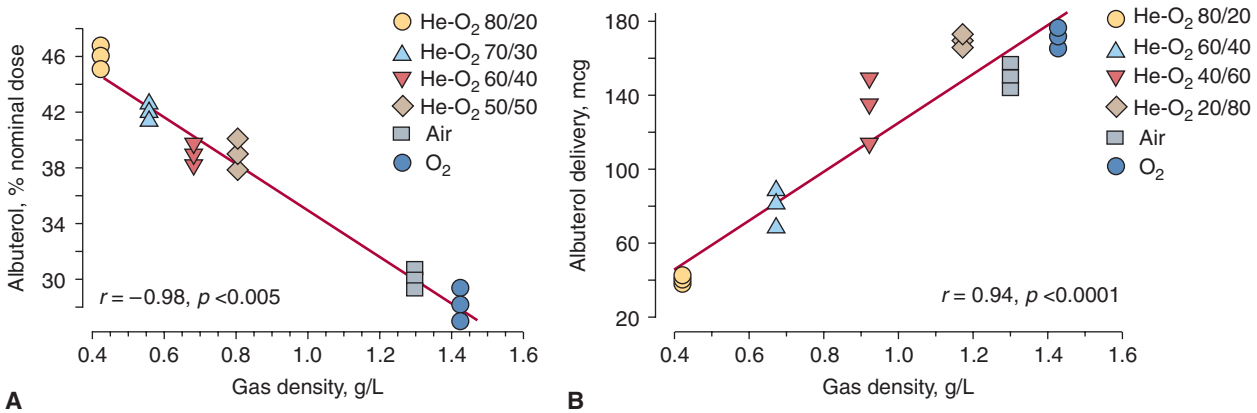

FIGURE 63-7 Effect of gas density on aerosol delivery from a pressurized metered-dose inhaler (pMDI) and jet nebulizer. **A**. Albuterol was administered via a pMDI and chamber spacer in an unheated dry ventilator circuit containing air, 100% oxygen, or several mixtures of helium-oxygen (80/20, 70/30, 60/40, and 50/50). Albuterol delivery from a pMDI (percentage of nominal dose) was inversely related ($r = -0.98$; $p < 0.005$) to gas density. **B**. Albuterol was administered with a jet nebulizer operated at a constant flow of 6 L/min of air, 100% oxygen, or helium-oxygen mixtures (as above) and albuterol output from the nebulizer was measured. Albuterol output from the nebulizer was positively correlated ($r = 0.94$; $p < 0.0001$) with the density of gas used to operate the nebulizer. Improvement in aerosol delivery with helium-oxygen mixtures during mechanical ventilation. *Am J Respir Crit Care Med.* 2001;163:109–114. Official Journal of the American Thoracic Society.)

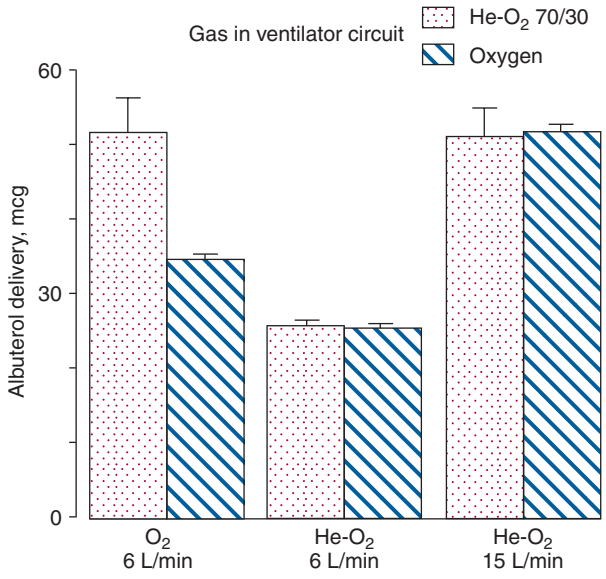

FIGURE 63-8 Effect of gas density and operating flow on aerosol delivery from a nebulizer. A jet nebulizer was operated with 100% oxygen at 6 L/min, helium-oxygen (70/30) at 6 L/min, or helium-oxygen (70/30) at 15 L/min. Drug delivery on filters was measured with the circuit containing helium-oxygen (*stippled bars*) or oxygen (*hatched bars*). Albuterol delivery was greatest when the nebulizer was operated with oxygen and the ventilator circuit contained helium-oxygen. Bars represent standard error (SE). (Reprinted with permission of the American Thoracic Society. Copyright © 2012 American Thoracic Society. Goode ML, Fink JB, Dhand R, et al. Improvement in aerosol delivery with helium-oxygen mixtures during mechanical ventilation. *Am J Respir Crit Care Med.* 2001;163:109–114. Official Journal of the American Thoracic Society.)

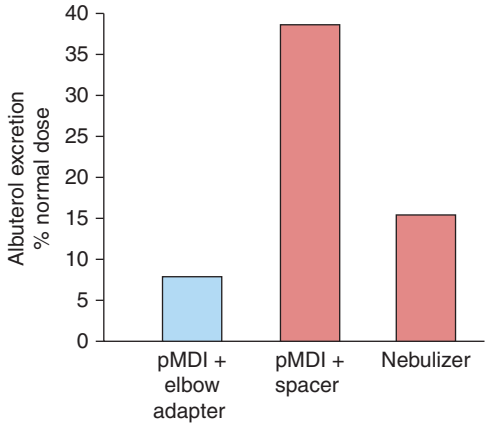

FIGURE 63-9 Comparison of systemic bioavailability of albuterol administered by pressurized metered-dose inhaler (*pMDI*) and right-angle elbow adapter, pMDI and chamber spacer, or jet nebulizer. Urine was collected for 6 hours after drug administration and the amounts of albuterol and its sulfate conjugate determined. The efficiency of the delivery device was determined by determining the percentage of drug excreted. The three delivery systems varied in the efficiency of drug delivery. The pMDI and elbow adapter had the lowest efficiency, the jet nebulizer was intermediate, and the pMDI with chamber spacer had the highest efficiency. (Data from Marik et al.[242])

IN VIVO STUDIES

Several investigators have used radionuclides and measured plasma or urinary drug levels to determine pulmonary deposition of aerosols in ventilated patients.

Radionuclide Studies. In ventilated patients, the pulmonary deposition of nebulized radiolabeled aerosol has been variously reported to be 1.22 ± 0.4%,[194] 2.22 ± 0.8%,[158] 2.9 ± 0.7%,[193] and 15.3 ± 9.5%.[199] Several factors, including type of radiolabel used, nebulizer brand, treatment time, circuit humidity, and methods used to calculate the amount of aerosol deposition,[199,200,208] contribute to the reported variation. With a pMDI and spacer chamber, approximately 6% of the dose was deposited in the lower respiratory tract;[194,214] this value was significantly lower than reported values (10% to 20%) with a pMDI and spacer in nonintubated ambulatory patients.[239,240]

Pharmacokinetic Studies. Unlike nonintubated patients, direct deposition of aerosol in the oropharynx and subsequent enteral absorption cannot occur in ventilated patients. Therefore, estimation of plasma levels of drugs administered by a pMDI should reflect lower respiratory tract deposition. After administration of albuterol with a pMDI and spacer, the area under the concentration-time curve was marginally lower in the patients than in healthy controls.[241] Moreover, measurement of urinary albuterol excretion in thirty ventilated patients with normal renal function showed that albuterol recovery was highest (38%) after administration with a pMDI and chamber spacer, intermediate with a nebulizer (16%), and lowest (9%) with a pMDI and right-angle port connected to the endotracheal tube (Fig. 63-9).[242] These results corroborated previous investigations that found very low efficiency of drug delivery with the adapter connected to the endotracheal tube.[208,209,214] Thus, pharmacokinetic studies show that with an optimal technique of administration, pulmonary drug deposition in ventilated patients is comparable to that achieved in healthy controls.

Pharmacokinetic studies have also been employed to compare the efficiency of drug delivery during mechanical ventilation. Moraine et al measured urinary ipratropium levels after ultrasonic nebulization in ventilated patients, and found no differences in urinary ipratropium levels with the nebulizer placed close to the patient Y or when it was placed before the heated humidifier.[243]

RECONCILING IN VITRO ESTIMATES OF DRUG DELIVERY WITH IN VIVO ESTIMATES OF DRUG DEPOSITION

The wide variation between in vitro[195,207–209] and in vivo estimates[194] of device efficiency can be reconciled by taking into account the effects of humidity in the ventilator circuit,[195] the quantity of exhaled aerosol that is not included in the in vitro measurement,[175] and by correcting for the quenching of radioactivity by the tissues of the chest wall.[214] When these factors are accounted for, in vitro data obtained with humidified ventilator circuits and in vivo gamma scintigraphic studies reveal that approximately

11% of the nominal dose from a pMDI and spacer chamber is deposited in the lower respiratory tract of ventilated patients. This value is remarkably close to values observed with the optimal use of a pMDI without a spacer (10% to 14%) in ambulatory patients.[239,240]

Drug delivery from nebulizers also shows discrepancies between values obtained with bench models versus those obtained by gamma scintigraphy.[158,193,194,219] Miller et al[200] found that accounting for circuit humidity and breath-actuated nebulization could reconcile most observed differences.

Thus, in vitro investigations that accurately simulate the clinical settings could play an important role in determining the performance of various inhalation devices under a variety of conditions encountered during mechanical ventilation.

CLINICAL USE OF BRONCHODILATORS

Bronchodilators Used

Bronchodilators are among the most commonly used drugs in the ICU.[13] In ventilator-supported patients with asthma or COPD, the goals of bronchodilator therapy are to reverse bronchoconstriction, decrease work of breathing, and/or relieve dyspnea. A response has been observed after administration of either aerosolized β-adrenergic[1,9,10,12,21,129,213,215,244–255] or anticholinergic bronchodilators.[129,252,256,257] Inhaled isoproterenol,[244,258] isoetharine,[259] metaproterenol,[2] fenoterol,[245,252] albuterol,[9,10,12,21,213,215,246–251,253–255] and salmeterol[29] produce significant bronchodilation in ventilated patients. The combination of fenoterol and ipratropium bromide was found more effective than ipratropium in ventilated patients with COPD.[260]

Selection of Patients

Ventilated patients with COPD demonstrate a significant decrease in airway resistance after administration of bronchodilators.[12,21,129,215,245,248,250,251,253,254,256,257] Bronchodilators have been successfully used to treat acute bronchospasm in the operating room,[244,258,259] and they are widely used in ventilated patients with severe asthma.[261] In addition, expiratory flow improved after bronchodilator administration in a heterogenous group of ventilated patients.[2] Nebulized metaproterenol reduced elevated levels of airway resistance in patients with acute respiratory distress syndrome.[4,5] Thus, a wide spectrum of patients receiving mechanical ventilation receive bronchodilators.[3]

Bronchodilator Efficacy

ASSESSMENT OF BRONCHODILATOR RESPONSE

The response to bronchodilators depends on several variables: patient airway geometry, degree of airway responsiveness, severity of disease, quantity of secretions, and counterregulatory effects of airway inflammation and other drugs. Most investigators assess response by measuring inspiratory airway resistance. Airway resistance in ventilated patients is commonly measured by performing rapid airway occlusions at constant flow inflation.[262,263] This technique involves performing a breathhold at end-inspiration by occluding the expiratory port. Total or maximal inspiratory resistance (Rrs max) can be partitioned into minimal inspiratory resistance (Rrs min), which reflects "ohmic" resistance of the airways, and additional effective resistance (ΔRrs). The latter resistance represents time-constant inhomogeneities within the lung ("pendelluft") and viscoelastic behavior of the pulmonary tissues.[262,263] Similarly, airway occlusion at end-expiration produces an increase in airway pressure to a plateau value, signifying intrinsic positive end-expiratory pressure.[12] Comparisons of airway resistance and intrinsic positive end-expiratory pressure before and after drug administration are useful for assessing response.

Most ventilated patients with COPD demonstrate a decrease in airway resistance and intrinsic positive end-expiratory pressure following bronchodilator administration.[4,9,12,21,213,215,245,248,250,251–255] That ΔRrs does not decrease significantly after albuterol delivery with a pMDI[12,212,215] suggests that the bronchodilator effect occurs predominantly in the central airways with little effect on viscoelastic behavior or time-constant inhomogeneities in the lung. Moreover, albuterol does not significantly influence the elastic properties of the lung.[12] In contrast, a greater decline in ΔRrs was noted after nebulizer delivery of albuterol and ipratropium bromide.[252] This difference in response between pMDIs and nebulizers could be due to higher drug deposition in peripheral airways with the use of a nebulizer.

In bench models, drug delivery was increased during simulated spontaneous breaths compared to controlled mechanical breaths.[195] In ventilated patients with acute exacerbations of COPD, however, the bronchodilator response did not differ between controlled mechanical ventilation and pressure support.[255] The use of propofol for sedation was a significant confounder of that study because of its known bronchodilator effect.[264]

DOSE RESPONSE TO BRONCHODILATOR ADMINISTRATION IN VENTILATED PATIENTS

Few investigators have examined the dose response to bronchodilators in ventilated patients.[213,215,224,245,254] Most investigators found that the response with the higher doses was no greater than that observed after the initial dose (Figs. 63-10 and 63-11).[215,245] Dose–response curves in stable, ventilated patients with COPD are shallow; when the technique of administration is carefully executed, most patients achieved near maximal bronchodilation with 4 puffs of albuterol.[215] Mouloudi et al[21,250,251,253] showed that, with an optimal technique of administration, alterations in mechanical ventilator settings do not influence

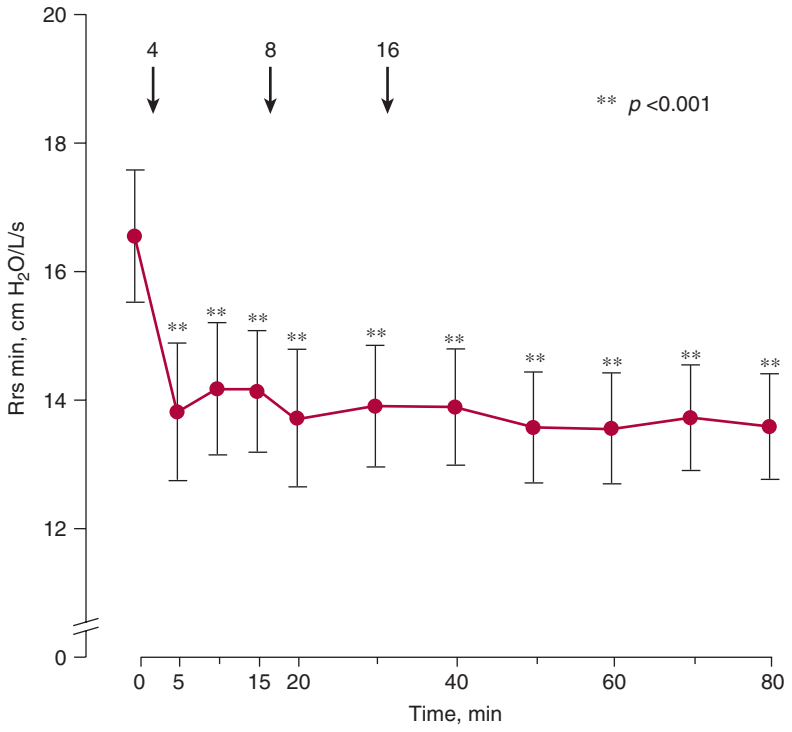

FIGURE 63-10 Effect of albuterol on minimal inspiratory resistance (*Rrs min*) in twelve stable mechanically ventilated patients with COPD. Significant decreases in Rrs min occurred within 5 minutes of administration of 4 puffs of albuterol. The addition of 8 and 16 puffs (cumulative doses of 12 and 28 puffs, respectively) did not achieve a significantly greater effect than that with 4 puffs ($p > 0.05$). Bars represent standard error (SE). **, $p < 0.001$. (Reprinted with permission of the American Thoracic Society. Copyright © 2012 American Thoracic Society. From Dhand R, Duarte AG, Jubran A, et al. Dose-response to bronchodilator delivered by metered-dose inhaler in ventilator-supported patients. *Am J Respir Crit Care Med.* 1996;154:388–393. Official Journal of the American Thoracic Society.)

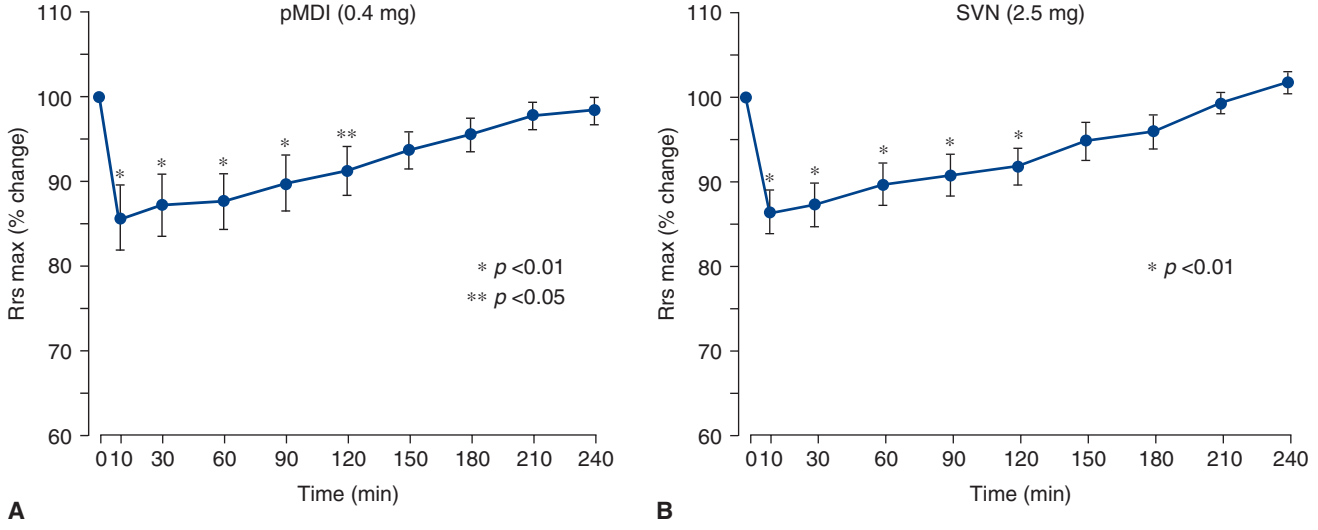

FIGURE 63-11 Effect of albuterol on maximum inspiratory airway resistance (*Rrs max*) in stable, mechanically ventilated patients with COPD. There was a decrease in Rrs max from baseline values within 10 minutes of albuterol administration. **A**. Change in Rrs max from baseline (time 0) after 4 doses of albuterol from a pMDI. **B**. Change in Rrs max from baseline (time 0) after 2.5 mg of albuterol given by nebulizer. Significant reductions in Rrs max were sustained for 2 hours and returned to baseline by 4 hours. The response to albuterol administered by pMDI (0.4 mg) was comparable to that achieved with 2.5 mg administered by nebulizer. Bars represent standard error of mean (SEM). (Used, with permission, from Duarte et al.[254])

the response to albuterol in stable patients with COPD. Patients with acute exacerbations of asthma or COPD may require higher doses.

DURATION OF BRONCHODILATOR RESPONSE

In stable, ventilated patients with COPD, the bronchodilator effect of albuterol is sustained for 2 to 3 hours.[21,254] Thus, in contrast to the four-times-a-day and as-needed albuterol dosing in ambulatory patients, ventilated patients may require dosing every 3 to 4 hours. Two or three times daily dosing may be feasible with salmeterol because its bronchodilator effect is sustained for approximately 8 hours in ventilated patients.[255]

AEROSOL THERAPY IN MECHANICALLY VENTILATED NEONATES AND INFANTS

Infants breathe with a high frequency and low tidal volume. This rapid shallow breathing pattern reduces drug deposition in the lung by limiting the time available for particle deposition. In nonintubated, spontaneously breathing infants, pulmonary deposition of radiolabeled aerosols administered via pMDI and face mask, or nebulizer and face mask, is as low as 0.3% to 2.6% of the nominal dose.[265–269] Several investigators report similar decreases in aerosol delivery in ventilated neonates and infants because of small-diameter endotracheal tubes and ventilator tubing, and the low tidal volumes employed.[235,270,271] Moreover, ventilator modes differ; pressure-limited and time-cycled modes of ventilation are more common, with continuous flow through the circuit and very-short-duty cycles.

In Vitro Studies of Aerosol Drug Delivery in Infants

METERED-DOSE INHALERS

When the pMDI was actuated into a prototype spacer chamber, there was a 10-fold variation (from 0.2% to 2.0% of the nominal dose) in drug delivery to a filter placed beyond the endotracheal tube.[272] Higher values of drug delivery were achieved when the pMDI was actuated before inspiration than after inspiration, and when higher tidal volumes and longer inspiratory times (inspiratory-to-expiratory timing [I:E] ratio 1:1) were employed. The type of spacer employed to actuate a pMDI has a dramatic influence on drug delivery (see Table 63-3).[273–276] In a dry infant ventilator circuit, drug delivery as high as 14.2% was achieved when an AeroChamber MV15 (Monaghan Medical Corp., Plattsburgh, NY) was placed between the ventilator Y and endotracheal tube and the pMDI was actuated at end-expiration.[273] With an ACE spacer in a humidified circuit during infant mechanical ventilation, an HFA-albuterol pMDI formulation gave marginally higher drug delivery than a CFC-albuterol pMDI formulation (5.7% vs. 4.8%, respectively).[276] When a HFA-pMDI was employed with a valved-holding chamber made of electrostatic charge dissipative polymer, aerosol delivery was lower during simulated mechanical ventilation compared to delivery with a manual resuscitation bag or during simulated spontaneous breathing.[277]

NEBULIZERS

Nebulizers have shown uniformly poor efficiency for drug delivery in infants. During simulated infant ventilation, nebulizers deliver less than 2% of the nominal drug

TABLE 63-3: EFFICIENCY OF DRUG DELIVERY WITH A pMDI AND SPACER IN INFANT VENTILATION

First author[a]	Spacer	ET(mm)	V_T(mL)	Mode	Efficiency (%)
Everard	Prototype	3.0	11 to 22	Pressure limited, 30 cm H_2O	1.5 to 2

DiBlasi	HFA-pMDI with AeroChamber Mini/ Spontaneous breaths	2.5, 3.5, 4.0	6 to 60	Mechanical/manual Humidified circuit	3.7 to 13.4[a]

Abbreviations: ET, internal diameter of endotracheal tube; V_T, tidal volume

[a] Values are means of efficiency of drug delivery in various settings. Efficiency of drug delivery was lower during mechanical ventilation compared to manual resuscitation or spontaneous breathing probably because of the effects of high humidity in the circuit during mechanical ventilation.

Source: Data from Everard,[272] Coleman,[274] Avent,[275] Lugo,[276] and DiBlasi.[277]

dose.[273,274,278–280] Many factors influence drug delivery with a nebulizer: type of nebulizer[273,278] and its position in the circuit,[276] intermittent versus continuous nebulization,[280] nebulizer flow,[274] inspiratory time,[274] volume-limited versus pressure-limited ventilation,[276] humidity, and size of the endotracheal tube. Placement of a jet nebulizer in the inspiratory limb of a humidified pediatric ventilator circuit 15 cm from the Y-piece had a lower efficiency of drug delivery compared to placement between the humidifier and ventilator.[167] A vibrating mesh nebulizer achieved twofold to fourfold higher drug delivery than the jet nebulizer.[167] The highest efficiency of drug delivery occurred with the vibrating mesh nebulizer placed at the inlet of the humidifier and operated continuously with a bias flow of 2 L/min in the ventilator circuit. Higher bias flows (5 L/min) reduced the efficiency of drug delivery.[167] In contrast, Turpenin et al found that drug delivery was improved when the nebulizer was placed at the endotracheal tube compared to placement in the inspiratory limb.[281] Moreover, as expected, breath-synchronized nebulization resulted in higher drug delivery than continuous nebulization.[282] The very low efficiency of nebulizers during infant mechanical ventilation, however, means that pulmonary drug deposition would be marginally influenced by altering the ventilator conditions. In fact, underdosing is a concern when a jet nebulizer is employed with settings that have very poor efficiency (as low as approximately 0.1%) for drug delivery.

METERED-DOSE INHALERS VERSUS NEBULIZERS

Few investigators have compared the pMDI to nebulizer efficiency during infant ventilation.[273–276] With optimal technique, the efficiency of pMDIs (approximately 14%) is considerably higher than that of nebulizers (approximately 2%).

In Vitro Studies of Aerosol Drug Delivery in Older Children

In older children, the efficiency of pMDIs and nebulizers improve with increasing age,[270,271] and the factors influencing drug delivery are similar to those in adults.[177]

In Vivo Studies of Drug Delivery in Infants and Neonates

The lung deposition of radiolabeled aerosols in ventilated infants with bronchopulmonary dysplasia was as low as 0.98 ± 0.2% and 0.22 ± 0.1% with a pMDI and spacer or a jet nebulizer, respectively.[283] Minocchieri et al employed a premature nose–throat model to demonstrate that lung deposition was reduced from 61.8 ± 5% to 26.0 ± 1.5% and 9.0 ± 0.8% of the nominal dose at continuous flows of 1, 5, and 10 L/min, respectively.[284] Moreover, placement of the nebulizer closer to the endotracheal tube did not improve the low efficiency of aerosol delivery.[285] In macaque monkeys, pulmonary deposition of ^{99m}technetium diethylenetriamine pentaacetate with a vibrating mesh nebulizer (Aeroneb Pro prototype) was more than 20-fold higher than that with a jet nebulizer (MistyNeb, Airlife Inc., Mountain View, CA).[286]

Clinical Studies

The low efficiency of drug delivery is offset by the smaller size of the lung in infants and children. Compared to a standard 1.3 mcg of albuterol/kg body weight delivered by each actuation from a Ventolin-HFA pMDI in a 70-kg, spontaneously breathing, adult male, the range for spontaneously breathing infants and small children varies from 0.8 to 2.6 mcg of albuterol delivery/kg body weight/actuation with a HFA-pMDI and AeroChamber Plus valved holding chamber.[287] Similar considerations apply for infants and children receiving mechanical ventilation.

Inhaled bronchodilators (β-adrenergic and anticholinergic drugs)[6–10,288–292] are effective in ventilated neonates and infants with acute, subacute, and chronic lung disease. Response to inhaled albuterol was similar to that seen after intravenous administration.[289] Albuterol administered with a pMDI and AeroChamber was found to be more effective than administration with a nebulizer (Fig. 63-12).[10,291] Ultrasonic nebulizers may be as (or more) effective than pMDIs for bronchodilator administration in infants (Fig. 63-12). In addition to monitoring airway resistance and pulmonary compliance, changes in heart rate should be assessed to prevent overdosing. ICSs have been advocated in infants for prevention[293,294] and treatment of bronchopulmonary dysplasia,[295–297] but their efficacy has not been established. In summary, during infant mechanical ventilation, pMDIs appear to be more efficient than jet nebulizers; with a careful technique of administration, one or two doses from an albuterol pMDI

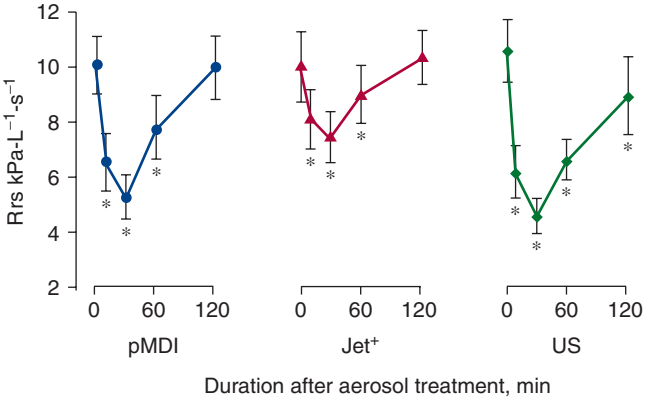

FIGURE 63-12 Total resistance of the respiratory system (*Rrs*) before and at 15, 30, 60, and 120 minutes after albuterol via pressurized metered-dose inhaler (*pMDI*), jet nebulizer (*Jet*), and ultrasonic nebulizer (*US*) during infant ventilation. *, posttreatment Rrs was significantly lower than pretreatment Rrs ($p < 0.0001$). The response to albuterol after administration with a pMDI was greater than that obtained with a jet nebulizer but was comparable to that obtained with an ultrasonic nebulizer. (Used, with permission, from Fok et al.[291])

and spacer chamber should suffice for routine therapy. The aerosol delivery efficiency of vibrating mesh nebulizers is comparable to pMDIs, but the clinical effectiveness of these devices in infants and children needs further study.

TECHNIQUES OF AEROSOL ADMINISTRATION

The optimal techniques for administration of inhaled drugs to ventilated patients are based on the various factors discussed above. The technique employed may have to compromise between the optimum operating characteristics of the device and the patient's condition. For example, although a higher duty cycle increases aerosol delivery,[195,199] it may worsen dynamic hyperinflation in patients with airflow limitation.[225] With this caveat in mind, the technique of administration for pMDIs in ventilated patients is shown in Table 63-4 and that for nebulizers in Table 63-5. The key aspects of the technique with pMDIs are to place an appropriate adapter at a short distance (approximately 15 cm) from the endotracheal tube and to synchronize actuation with inspiratory flow. For nebulizers, it is critical to use the device as recommended by the manufacturer and to place it at a distance from the patient. When these techniques are employed, adequate drug deposition is achieved in the lung[175,195,200] and a significant bronchodilator response is obs erved.[12,21,213,215,224,248,250–255] Most ventilated patients, however, do not show incremental effects with higher drug doses.[215]

Use of Metered-Dose Inhalers or Nebulizers

Nebulizers and pMDIs delivered an equivalent mass of aerosol beyond the endotracheal tube in a ventilator model;[202] in ventilated patients, both devices produced similar therapeutic effects.[246,252,254] When used optimally, pMDIs and nebulizers are equally effective in the treatment of patients with obstructive lung disease.[62]

pMDIs are preferred in ventilated patients because of several problems associated with the use of nebulizers.[155–157,226,232,233] Before using a nebulizer in a ventilated patient, it is imperative to characterize its efficiency in a ventilator circuit, under the typical clinical conditions in which it will be employed.

Unless scrupulously cleaned and disinfected, nebulizers can be a source for aerosolization of bacteria,[298] and thus predispose patients to nosocomial pneumonia.[299] The gas flow driving the nebulizer produces additional airflow in the ventilator circuit, but this is compensated for in most modern ventilators. In contrast, pMDIs are easy to administer, require less personnel time, provide a reliable dose, and do not pose a risk of bacterial contamination. Use of pMDIs rather than nebulizers saves cost and time.[300–302] Costs of bronchodilators have a significant impact on overall costs of care.[302]

In summary, pMDIs offer several advantages over nebulizers for routine bronchodilator therapy. One survey found that most reporting centers (57%) were using pMDIs in neonates and their use had steadily increased since 1988;[303] similar trends are observed in adults.

TABLE 63-4: OPTIMAL TECHNIQUE FOR DRUG DELIVERY BY pMDI IN VENTILATED PATIENTS

1. Review order, identify patient, and assess need for bronchodilator.
2. Suction endotracheal tube and airway secretions.
3. Shake pMDI and warm to hand temperature.
4. Place pMDI in spacer chamber adapter in ventilator circuit.
5. Remove HME. Do not disconnect humidifier.
6. Coordinate pMDI actuation with beginning of inspiration.
7. Wait at least 15 seconds between actuations; administer total dose.
8. Monitor for adverse response.
9. Reconnect HME.
10. Document clinical outcome.

Abbreviations: HME, heat and moisture exchanger; *pMDI*, pressurized metered-dose inhaler.

TABLE 63-5: OPTIMAL TECHNIQUE FOR DRUG DELIVERY BY JET NEBULIZER IN VENTILATED PATIENTS

1. Review order, identify patient, and assess need for bronchodilator.
2. Suction endotracheal and airway secretions.
3. Place drug in nebulizer to fill volume of 4 to 6 mL.
4. Place nebulizer in the inspiratory line 18 in (46 cm) from the patient Y connector.
5. Turn off flow-by or continuous flow during nebulizer operation.
6. Remove HME from circuit (do not disconnect humidifier).
7. Set gas flow to nebulizer at 6 to 8 L/min.
   a. Use a ventilator if it meets the nebulizer flow requirements and cycles on inspiration, *or*
   b. Use a continuous flow from external source.
8. Adjust ventilator volume or pressure limit to compensate for added flow.
9. Tap nebulizer periodically until nebulizer begins to sputter.
10. Remove nebulizer from circuit, rinse with sterile water and run dry, store in safe place.
11. Reconnect humidifier or HME, return ventilator settings and alarms to previous values.
12. Monitor patient for adverse response.
13. Assess outcome and document findings.

Abbreviation: HME, heat and moisture exchanger.

DRUG TOXICITY

Higher doses of β-agonists delivered by a pMDI can cause atrial and ventricular arrhythmias.[304–306] Manthous et al[213] observed sinus tachycardia or supraventricular ectopy after

a cumulative dose of 7.5 mg of albuterol administered by a nebulizer in four of ten patients, and most of the remaining patients developed premature atrial and ventricular contractions with a cumulative dose of 15 mg.[213] Although most investigators have reported no adverse effects following administration of albuterol with a pMDI,[12,129,194,213,214] a dose-dependent increase in heart rate occurs with higher doses.[215] No significant arrhythmias or other serious cardiovascular side effects were observed in ambulatory patients in an emergency department who were treated for acute asthma with up to 16 puffs each of albuterol or fenoterol administered with a pMDI attached to a holding chamber and face mask.[65] Continuous nebulization of β-agonists is effective and safe in nonintubated children[307] and adults[74] with acute severe asthma, but the efficacy and safety of continuous nebulization has not been established in ventilated patients. A few anecdotal reports have described cardiotoxicity secondary to CFCs.[308] Adverse cardiac effects are unlikely to occur with the doses recommended in clinical practice, particularly if there is a short interval between successive doses, because CFCs have a short half-life (<40 seconds) in blood after administration via pMDI in healthy volunteers.[309] With a catheter connected to a pMDI nozzle, however, a substantial portion of the total mass output of the pMDI is delivered directly onto the tracheobronchial mucosa and there is potential for local and systemic toxicity.[238]

Arterial oxygen tension (Pa_{O_2}) may decrease transiently after β-agonist inhalation, probably secondary to pulmonary vasodilation mediated by β_2-receptors.[310,311] In contrast, reduction in Pa_{O_2} was either not seen after inhalation of antimuscarinic agents[312] or was less than the decrement produced by albuterol and salmeterol.[43] The decrease in Pa_{O_2} with albuterol inhalation is transient and small; hence, its clinical significance is doubtful.[43] Significant drops in Pa_{O_2}, however, can occur occasionally,[311,313] and close monitoring may be required in patients with marginal oxygenation.

Blood glucose and insulin levels increase after β-agonist administration, whereas serum potassium levels decrease.[310,314] The clinical importance of these effects is inconclusive; however, in patients with severe airway obstruction fall in serum potassium in the presence of hypoxia has the potential to cause cardiac arrhythmias. A variety of central nervous system effects including anxiety, nervousness, tremor, irritability, insomnia and headaches are associated with use of β-adrenergic agents.

GUIDELINES FOR INHALED THERAPY

Subtle differences in the method of administration can markedly decrease aerosol deposition in the lower respiratory tract.[175,195,202,208,213,226] Routine bronchodilator therapy can be given successfully with assisted modes if aerosol delivery is synchronized with inspiratory flow from the ventilator. Based on the recommendation for use of pMDIs in ambulatory patients, some investigators use a postinspiratory breathhold after aerosol administration.[129,246] With an optimal technique, this maneuver does not influence bronchodilator response in ventilated patients.[250] Mouloudi et al[251,253] have also shown that increasing the tidal volume or using pressure-control (decelerating flow pattern) versus volume-control (constant flow pattern) ventilation did not affect the response to albuterol inhalation with a pMDI. These findings are consistent with other studies showing shallow dose–response curves in ventilated patients.[9,129,215,245,254] Thus, there may be little justification for manipulating ventilator settings to enhance drug deposition in the lung provided an optimal pMDI technique is employed.

Although humidification of the circuit reduces aerosol deposition by approximately 40%,[195,197] bypassing the humidifier is not routinely recommended because it would require disconnection of the ventilator circuit and several minutes would be added to each bronchodilator treatment while waiting for the circuit to become dry. Moreover, when heated wire circuits are employed, there was no reduction in delivery efficiency of albuterol with a pMDI and spacer for up to 60 minutes after turning on the heated humidifier,[315] and after 3 hours of humidifier operation, it took 10 minutes after shutting off the humidifier for aerosol delivery to improve. Even with a humidified circuit, a significant effect is observed with as few as 4 puffs.[215] Bypassing the humidifier may be one method to improve pulmonary drug delivery with more expensive, nonbronchodilator agents. Before such a practice can be routinely recommended, however, studies are needed to document the safety of repeatedly administering nonhumidified gases, albeit for limited periods, to ventilated patients.

BRONCHODILATOR THERAPY DURING NONINVASIVE VENTILATION

Noninvasive positive-pressure ventilation (NIPPV) is being increasingly employed for treatment of patients with acute and chronic respiratory failure.[316] Successful application of NIPPV with a nasal or face mask in patients with acute exacerbations of COPD can often obviate the need for endotracheal intubation and improve mortality.[317–320] Patients with acute or acute-on-chronic respiratory failure who are receiving NIPPV often require inhaled bronchodilators for relief of airway obstruction. One option is to remove the patient from NIPPV and administer bronchodilators by pMDI or nebulizer with a face mask as patients can tolerate brief periods of discontinuation needed for bronchodilator therapy.[321] It is preferable, however, to continue NIPPV without interruption, especially in acutely hypoxic or dyspneic patients.

The delivery of aerosols during NIPPV is complicated by high inspiratory flows that increase turbulence and the associated high inertial forces cause greater particle impaction in central airways.[223,322] On the other hand, application of positive pressure increases tidal volume and

reduces respiratory rate, both of which tend to enhance aerosol delivery.[323] Moreover, increase in expiratory time because of a slower respiratory rate could enhance particle sedimentation and alter the pattern of drug deposition during exhalation.[323] Initial enthusiasm for administration of bronchodilators with intermittent positive-pressure breathing[324] was generated when it was shown that higher plasma levels of albuterol were achieved by this technique compared to administration by pMDI alone. Later studies, however, found that drug delivery to patients with severe COPD and relatively fixed airway obstruction was reduced by administration with intermittent positive-pressure breathing.[325]

The use of continuous positive airway pressure (CPAP) may be more helpful than intermittent positive-pressure breathing in reducing work of breathing in patients with acute bronchoconstriction.[326,327] However, in a bench model, 10-cm H_2O CPAP reduced drug delivery from a jet nebulizer.[328] Mask CPAP is optimally employed with a continuous fresh gas flow that approaches or exceeds the patient's inspiratory flow rate so as to minimize the additional work imposed by a demand valve system.[329] Entrainment of aerosols into the high rates of gas flow used during CPAP dilutes the drug and favors evaporation leading to reduced droplet size, cooling, and hypertonicity,[152] with the potential to produce paradoxical bronchoconstriction. Likewise Chatmongolkolchart et al found that application of CPAP alone, especially higher levels of CPAP, reduced aerosol delivery.[330]

Noninvasive pressure support provides a more sustained boost to inspiratory effort than intermittent positive-pressure breathing by maintaining a constant preset airway pressure.[331] Application of pressure support reduces inspiratory muscle effort and respiratory rate, increases tidal volume and improves arterial blood-gas values.[332,333] Pressure support could also produce more uniform aerosol deposition in the lungs by reversing small airway closure and microatelectasis.[334]

During bilevel ventilation, Faroux et al [335] found that in children with cystic fibrosis, pulmonary deposition of radiolabeled aerosol was increased by the application of 10 cm H_2O pressure support. This study, however, employed a homecare ventilator that does not incorporate a leak port in the circuit and the nebulizer was active only during inspiration. Chatmongkolchart et al[330] found a fivefold variation (between 5% and 25% of the nominal dose) in the amount of albuterol delivered by a jet nebulizer in vitro; delivery was highest (25%) when the nebulizer was close to the patient (between the leak port and patient connection), inspiratory pressure was high (20 cm H_2O), and expiratory pressure was low (5 cm H_2O).[330] Although nebulizer operation during bilevel positive-pressure ventilation does not influence ventilator function,[330] nebulizer operation with bilevel positive-pressure ventilation enhances drug delivery and produces a finer aerosol with a higher proportion of respirable particles compared to nebulizer operation alone.[336] NIPPV, however, did not improve radioaerosol deposition compared to spontaneous breathing in healthy volunteers.[337]

Intrapulmonary percussive ventilation was found to produce a finer aerosol than standard jet nebulization, but pulmonary deposition of radiolabel was much more variable and unpredictable with this technique in healthy volunteers compared to standard nebulizer therapy, and it was not recommended as a mode of aerosol delivery.[338] The use of high-frequency oscillation for radioaerosol delivery was found to reduce total pulmonary drug deposition in normal subjects, and in patients with chronic airflow obstruction, despite a reduction in the size of the aerosol.[339] In normal subjects, the regional distribution of aerosol deposition was unchanged, but in the patients with airflow obstruction a larger proportion of total aerosol deposition occurred in the peripheral lung during high-flow oscillation.[339]

The optimum settings required for maximum drug delivery with a pMDI during NIPPV have not been established. Significant bronchodilator responses occur after albuterol administration with a jet nebulizer or a pMDI in stable patients receiving NIPPV with face mask.[340,341] Nava et al used a homecare ventilator and volume-assured pressure support with dry, unwarmed gas to obtain a guaranteed tidal volume of 10 mL/kg in clinically stable patients with severe COPD.[340] With the pMDI and spacer placed in the inspiratory limb of the ventilator circuit immediately after the patient Y, they found a higher change in FEV_1 after albuterol administration compared to placebo but the effect was comparable to that obtained with a pMDI and spacer during spontaneous breathing.[340] Similarly, Parkes and Bersten employed CPAP at 10 cm H_2O and used nonhumidified compressed gas at a flow rate of 50 L/min with a tight face mask fit in nine stable patients with asthma.[328] Despite reduction in total aerosol delivery, application of CPAP did not affect the bronchodilator response to nebulized albuterol.[328] Patients with acute asthma exacerbations who received albuterol administered during bilevel positive airway pressure ventilation[341] had more rapid and greater improvement in peak expiratory flow than did patients receiving a similar dose by nebulizer alone. It is unclear, however, if this was caused by relief provided by pressure support, or enhanced drug delivery or drug effect produced by NIPPV, or a combination of the two. Both pMDIs and nebulizers could be successfully employed during NIPPV by using the techniques recommended by Hess.[342]

The position of the leak port in the single-arm circuit used for bilevel positive-pressure ventilation influences nebulizer efficiency, but it does not influence pMDI efficiency of drug delivery.[343] Nebulizer efficiency is higher with the leak port in the circuit as compared to a leak port in the face mask.[343] Calvert et al reported that a nebulizer placed between the leak port and ventilator performs with a higher efficiency than placement of the nebulizer between the leak port and face mask.[336] In contrast, Abdelrahim et al found a higher drug delivery with the nebulizer placed between the leak port and face mask than with the nebulizer placed between the ventilator and leak port.[344] The difference in the results of the two studies[336,344] may be explained by the fact that the former investigators placed the nebulizer at a farther distance from the leak port than did the latter investigators.

Moreover, drug delivery with a vibrating mesh nebulizer at either position of the nebulizer was more than twice that delivered by a conventional jet nebulizer.[344]

In summary, delivery of aerosols to patients receiving NIPPV is extraordinarily complex. Several factors related to the type of ventilator employed, the type of aerosol generator and its position in the ventilator circuit, the mode of ventilation, tidal volume, inspiratory flow rate, inspiratory and expiratory pressure settings, circuit humidity, the density of the gas in the circuit, type of mask interface, mask size, and patient characteristics all influence the efficiency of aerosol delivery in this setting. Moreover, the single-circuit design, continuous air flow, and the presence of a leak port further complicate aerosol delivery.

IMPORTANT UNKNOWNS

Despite frequent use of bronchodilators in ventilated patients, their effects on clinically relevant outcomes, such as duration of mechanical ventilation, length of ICU stay, development of ventilator-associated pneumonia, and mortality have not been studied. In fact, few randomized controlled studies have been performed in this patient population.[62] Variations in the methods of administration and assessment of response make it difficult to compare results between various studies.

Further work is also needed to determine whether newer generation of vibrating mesh nebulizers, soft mist inhalers, and dry powder inhalers can be successfully adapted for use during mechanical ventilation.

THE FUTURE

Ventilated patients present a unique opportunity to exploit the advantages of the inhaled route for drug delivery. The past two decades have seen impressive gains in knowledge and understanding of methods to deliver inhaled therapies to ventilated patients. Within the past few years, newer aerosol-generating devices designed for use during mechanical ventilation have become available. These devices are far more efficient than previous jet nebulizers. In the future, further improvements in device design will result in higher efficiency devices that also ensure precision, reliability, and consistency of dosing.

Some modern ventilators have integrated aerosol-generating devices, and this integration should further improve the characterization of aerosols and consistency of drug dosing.

NIPPV is being increasingly employed, especially in patients with acute exacerbations of COPD. Further work is needed to improve our understanding of the factors influencing inhaled drug delivery in this setting. Delivery devices that are designed specifically for mask ventilation would be helpful. Moreover, recent gains in improving aerosol delivery to infants and children will lead to greater clinical application of inhaled therapies in this population.

SUMMARY AND CONCLUSION

Bronchodilator therapy is commonly employed in ventilated patients. Inhaled β-agonist and anticholinergic bronchodilators are widely used, whereas use of theophylline in the ICU has declined significantly. Although ICSs are being employed in ventilated patients, especially in combination with long-acting β-agonists, further investigations are needed to determine the optimal methods of administration, drug dosage, and efficacy; and to assess their risk-to-benefit ratio in this setting. Optimal techniques for employing pMDIs and nebulizers in ventilator circuits have been developed as a result of better understanding of the factors influencing aerosol delivery to the lower respiratory tract of ventilated patients. Important variables that influence aerosol delivery include the type of nebulizer used and its position in the circuit, actuation of a pMDI into an inline chamber spacer, timing of actuation, ventilator mode, tidal volume, circuit humidification, and duty cycle. With proper technique, drug deposition in the lower respiratory tract of ventilator-dependent patients is comparable to that in ambulatory patients. A somewhat higher dose than that used in ambulatory patients is recommended in ventilated patients, mostly to compensate for the effects of humidity in the ventilator circuit. Typically, dose–response curves to bronchodilators in ventilator-supported patients are shallow and the duration of the drug effect is variable. Although both nebulizers and pMDIs are employed for administering bronchodilators in mechanically ventilated patients, pMDIs offer several advantages over nebulizers for routine bronchodilator therapy.

INHALED ANTIBIOTIC THERAPY

64

Jean-Jacques Rouby
Ivan Goldstein
Qin Lu

The incidence of ventilator-associated pneumonia ranges between 8% and 28% in patients receiving mechanical ventilation for more than 48 hours, and between 34% and 70% in patients with acute lung injury or acute respiratory distress syndrome.[1] It prolongs the duration of stay in the intensive care unit and hospital, and increases costs.[2] Associated mortality ranges from 24% to 76%, and appears far greater than the mortality resulting from other nosocomial infections. It may even exceed 85% when high-risk gram-negative bacteria, such as *Pseudomonas aeruginosa* or *Acinetobacter baumannii*, are the causative pathogens.[3] Many studies demonstrate that early intravenous administration of appropriate antibiotics improves the prognosis. Lung deposition of antibiotics, however, administered by the intravenous route is either limited or poorly documented and treatment failure is common, leading to increased dosage and risk of systemic toxicity. Despite antimicrobial therapy and adequate supporting treatment, the mortality rate from ventilator-associated pneumonia remains high, indicating a need for a more effective route of administration. Inhaled antibiotic therapy may represent such an alternative.

RATIONALE

At least three major theoretical arguments support the administration of inhaled antibiotics in critically ill patients with ventilator-associated pneumonia: the very pathogenesis of lung infection that originates in the tracheobronchial tree, the possibility of obtaining high lung-tissue concentrations by bypassing the alveolar–capillary barrier, and the potential for decreasing systemic toxicity.

Deep Lung Infection Originates in the Upper Airways

The normal human respiratory tract possesses efficient defenses against bacteria colonizing the pharynx. The glottis and larynx serve as natural anatomic barriers. The cough reflex, mucociliary clearance, and regional immunity contribute to elimination of invading pathogens and prevention of infection deep in the lungs. Endotracheal and tracheostomy tubes bypass the natural barrier between the

oropharynx and tracheobronchial tree. Bacteria penetrate into the trachea by leakage of infected secretions and/or contaminated gastric contents around the low-pressure cuff of an endotracheal tube.[4] In ventilated patients, deep sedation depresses the cough reflex whereas endotracheal intubation inhibits the ciliary escalator.[5,6] In addition, the internal wall of the endotracheal tube rapidly becomes coated with an antibiotic-resistant bacterial biofilm, which then can become fragmented and disseminated into the deep lung during tracheal suctioning or fiber-optic procedures.[7,8] Consequently, it appears reasonable to hypothesize that antibiotics administered by the inhalational route may reduce bacterial inoculum by stopping the continuous bacterial seeding from the upper airways.

Bypassing the Alveolar–Capillary Barrier May Provide High Antibiotic Tissue Concentrations

Killing bacteria infecting the lung parenchyma requires that an antibiotic achieve a pulmonary concentration at least five times greater than minimal inhibitory concentrations for the infecting pathogen. Reaching concentrations lower than mutant prevention concentrations in the infected parenchyma may trigger the emergence of resistant bacterial strains.[9] When antibiotics are intravenously administered, the alveolar–capillary barrier imposes a difficult-to-cross obstacle, which impairs lung deposition even if lung inflammation increases capillary permeability. Pulmonary vasoconstriction and regional thrombosis, two pathophysiologic abnormalities characterizing severe bronchopneumonia, reduce lung perfusion and tend to impair pulmonary penetration of circulating antibiotics. Major surgery and septic shock are associated with a significant decrease in the ratio between systemic and interstitial antibiotic concentrations (Fig. 64-1). All these factors contribute to markedly reduce the antibiotic concentrations at the site of infection, and may explain failure of intravenous antibacterial treatment.[10,11] During the initial phase of pulmonary infection, some degree of aeration persists within the bronchiolar lumen and alveolar space. Therefore, the early inhalation of antibiotics may represent a unique opportunity to reach bactericidal concentrations at the site of infection. In the presence of severe bronchopneumonia, the existence of the alveolar–capillary barrier and reduced lung perfusion are far from deleterious; instead, they may be beneficial by limiting systemic absorption and reducing systemic toxicity of nebulized antibiotics.

FACTORS INFLUENCING LUNG DEPOSITION

A number of factors influence lung deposition of nebulized antibiotics during mechanical ventilation: aerosol particle size, type of nebulizer, ventilator settings, grade of bronchopneumonia, and lung aeration. A better understanding of the conditions regulating lung deposition and the tremendous growth of technological innovations[12] potentially make the nebulization of antibiotics an attractive alternative to the classic intravenous administration.

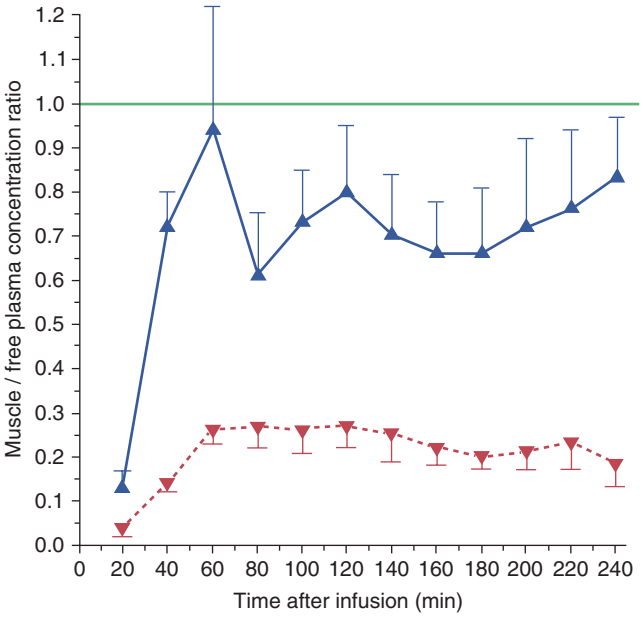

FIGURE 64-1 Time course of the ratio between unbound piperacillin concentrations measured in the interstitial space fluid of skeletal muscle and the concentrations measured in the plasma (mean ± standard error of mean) after administration of a single intravenous dose of 4 g to six septic patients (*inverted triangle dotted line*) and six control healthy volunteers (*triangle solid line*). Piperacillin levels were measured using high-pressure liquid chromatography via microdialysis probes inserted into skeletal muscles. (Used, with permission, from Joukhadar et al.[11])

Aerosol Particle Size

An essential condition for an aerosol particle to reach the deep lung is to ensure that the mass median aerodynamic diameter ranges between 1 and 5 μm.[13] Larger particles tend to impact and attach to ventilator circuits and endotracheal tubes, thereby limiting lung deposition.[14,15] Aerosol-generating devices, such as dry powder inhalers, metered-dose inhalers, jet nebulizers, ultrasonic nebulizers, or vibrating plate nebulizers, all produce particles whose mass median aerodynamic diameter is less than 5 μm. It has to be emphasized that nebulizers that produce the smallest particles require considerably more time to deliver a standard antibiotic dose.[16]

Type and Position of Nebulizers

A nebulizer equipped with a large reservoir is needed for delivering sufficient amounts of antibiotics to the respiratory

system. As a consequence, metered-dose inhalers are not the most appropriate devices for nebulizing antibiotics and should be reserved for inhaled bronchodilators and corticosteroids.[12]

Jet nebulizers produce aerosol particles by superimposing an additional flow on the inspiratory flow that comes from the ventilator. The high-speed turbulent flow that generates the aerosol, however, also promotes particle impaction on ventilator circuits and proximal airways, thereby limiting deposition deep in the lung.

Ultrasonic nebulizers are appropriate for antibiotic nebulization for several reasons: They are generally equipped with a large reservoir; they generate particles whose mass median aerodynamic diameter is less than 5 μm through quartz vibrations; and the aerosol is entrained into the tracheobronchial tree by a low flow, independent of the inspiratory flow coming from the ventilator. The quartz vibration increases the temperature of the antibiotic solution and may alter the chemical structure of the antibiotic molecule.

Recently, vibrating plate nebulizers have been developed and seem appropriate for inhaled antibiotic therapy.[17] The aerosol is generated by a ceramic vibrational element and a domed aperture plate, which has approximately 1000 tapered holes that are electroformed in a sheet. The antibiotic is placed in a reservoir above the domed aperture plate. Powered by an alternating current, the vibrational element expands and contracts causing the domed aperture plate to move upward and downward; this action causes a micropump effect that produces the aerosol.[17] Particle size depends on the aperture diameter that can be changed by the manufacturer to optimize lung deposition. Vibrating plate nebulizers have several potential advantages over ultrasonic nebulizers: At the end of nebulization, the residual volume in the reservoir is negligible; the temperature of the antibiotic solution in the reservoir does not increase, thereby limiting the risk of altering the chemical structure of the antibiotic; the aerosol generation can be synchronized with inspiration, minimizing aerosol waste during exhalation;[18] and the aerosol can be delivered through an intratracheal catheter that can be inserted into a flexible bronchoscope.[19] Both ultrasonic and vibrating plate nebulizers should be placed in parallel with the inspiratory limb before the Y-piece. The ventilator tubing between the nebulizer and the Y-piece serves as a reservoir containing the aerosol generated during the expiratory phase, which is entrained into the tracheobronchial tree during the next inspiration (bolus effect). Ultrasonic nebulizers should be placed 40 cm before the Y-piece to provide enough flexibility; vibrating plate nebulizers, which are less bulky, can be placed 10 cm before the Y-piece. When aerosol delivery is synchronized with inspiration, the vibrating plate nebulizer can be placed between the Y-piece and the proximal tip of the endotracheal tube, thus limiting extrapulmonary deposition.[18] Limiting the nebulization period to a portion of the inspiratory phase, however, significantly increases the time of nebulization, which, in turn, reduces the maximal dose that can be nebulized.

If the nebulizer is placed distally to the endotracheal tube, instead of being directly connected to it, the inner diameter of the endotracheal tube does not markedly influence the efficiency of aerosol delivery.[20]

Ventilator Modes and Settings

During mechanical ventilation, a laminar inspiratory flow provides better distal lung deposition of aerosol particles than a turbulent flow.[21] Turbulence causes wall impaction of particles in the trachea and proximal bronchioles, thereby limiting antibiotic deposition in the lung parenchyma. As a consequence, specific ventilator settings aimed at limiting inspiratory flow turbulence should be implemented during the nebulization phase. In a patient fully adapted to the ventilator, a volume-controlled mode is preferred with the following settings: constant and low inspiratory flow, a minute ventilation limited to 6 L/min, a respiratory frequency of 12 breaths/min, an inspiratory-to-expiratory ratio of 50%, and an end-inspiratory pause that constitutes 20% of the duty cycle to facilitate settling of aerosol particles in the alveolar spaces.[22] Decelerating flows should be avoided[23] as should patient triggering.[24] Inspiratory-to-expiratory ratios less than 50% should not be used because they do not provide enough time for settling of particles in the bronchoalveolar space.[25] These ventilator settings may not provide adequate CO_2 elimination in partially awake patients with acute bronchopneumonia. Consequently, dyssynchrony with the ventilator may result, generating turbulences and impaction of aerosolized particles in the ventilator circuits and the tracheobronchial tree. To provide adequate lung deposition, complete adaptation to the ventilator is required and can be achieved through a continuous infusion of propofol limited to the nebulization period.

Heat, Humidity, and Density of the Carrying Gas

If the gas coming from the ventilator is heated and humidified, distal lung deposition of aerosol particles is markedly reduced.[12,16] Two factors contribute to this undesirable effect: increase in the mass median aerodynamic diameter of aerosol particles[26] and increased deposition in ventilator circuits.[27] If the period of nebulization does not exceed 30 minutes, it is recommended to simply remove the heat and moisture exchanger; the aerosol will provide partial humidification of the inspired gas coming from the ventilator. If the period of nebulization exceeds 30 minutes, then a conventional humidifier should be inserted in the inspiratory limb to avoid damage to the tracheal and bronchial mucosa caused by prolonged administration of cold, dry inspiratory gas. As a result, the aerosol deposition might be reduced by 40%.[12]

Several in vitro studies have shown that reducing the density of the inspired gas, by replacing nitrogen with helium,

increases lung deposition of aerosol particles.[12,28,29] This beneficial effect likely results from helium-induced reduction in flow turbulence, limiting extrapulmonary deposition and tracheobronchial wall impaction of aerosol particles. On the other hand, operating the nebulizer with heliox (helium–oxygen gas mixture) reduces drug output and disposable mass.[30] Thus, it is recommended to operate the nebulizer with a nitrogen–oxygen mixture and to entrain aerosol particles with heliox to maximize lung deposition.[12] These in vitro studies have been confirmed in a recent experimental study performed in mechanically ventilated piglets with healthy lungs: Ceftazidime lung-tissue concentrations following aerosol administration were fivefold to 30-fold higher than after intravenous administration, and increased by 33% when heliox (65%/35%) was used as the operating gas of the ventilator.[31] Unfortunately, this beneficial effect was not confirmed in animals with experimental *P. aeruginosa* bronchopneumonia; presumably, the loss of alveolar aeration resulting from bronchiolitis predominated over the helium-induced reduction in flow turbulence.[31] At present, the routine use of heliox cannot be recommended for nebulizing antibiotics in ventilated patients with infected lungs.

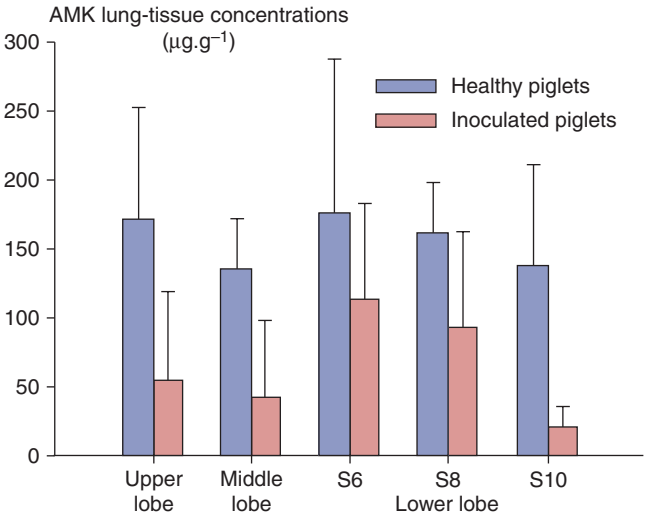

FIGURE 64-2 Amikacin (*AMK*) lung-tissue concentrations (mean ± standard deviation) measured in different pulmonary lobes and segments 1 hour after a second daily nebulization of amikacin 45 mg/kg in mechanically ventilated piglets with healthy lungs (*blue bars*, $n = 5$) and in piglets with infected lungs (*red bars*, $n = 8$), inoculated 24 hours before the first administration with a solution of *Escherichia coli*. In the lower lobe, postmortem specimens were sampled from dependent (segments 6 and 10) and nondependent (segment 8) lung regions. (Used, with permission, from Goldstein et al.[33])

Patient-Related Factors

Experimental studies performed in anesthetized piglets receiving prolonged mechanical ventilation have demonstrated that lung deposition of nebulized antibiotics is significantly greater in animals with healthy lungs than in animals with severe inoculation pneumonia.[32–35] In addition, lung-tissue concentrations of antibiotics were homogeneously distributed in healthy animals, whereas they were heterogeneously distributed in infected animals. As shown in Figure 64-2, dependent lung segments that were heavily infected by *Escherichia coli* had the lowest amikacin lung-tissue concentrations. The loss of lung aeration, the severity and extension of parenchymal infection, and the injury to the alveolar–capillary barrier are the factors that determine lung deposition of nebulized antibiotics.

LUNG AERATION

In patients with ventilator-associated bronchopneumonia, the obstruction of distal bronchioles by purulent plugs[36] may impair lung deposition of inhaled antibiotics, and result in lower pulmonary concentrations than those obtained in patients with healthy lungs. In anesthetized piglets receiving prolonged mechanical ventilation for a severe experimental *E. coli* bronchopneumonia, amikacin pulmonary tissue concentrations were three to thirty times higher after nebulization than after the intravenous administration of an equivalent dose.[33] As shown in Figure 64-3, the degree of lung aeration had the opposite effect in animals receiving intravenous amikacin and in animals receiving nebulized amikacin. The loss of lung aeration tended to increase amikacin tissue concentrations in the intravenous group, whereas the opposite effect was observed in the nebulization group. Very likely, the increased permeability of the alveolar–capillary barrier resulting from severe lung infection tends to promote intravenous amikacin penetration into the lung, whereas the multiple purulent plugs obstructing distal bronchioles tend to impair lung deposition of nebulized amikacin. It should be pointed out that despite the increased permeability of the alveolar–capillary barrier, amikacin lung-tissue concentrations remained hopelessly low after intravenous injection. From these experimental data, it is reasonable to hypothesize that ventilator settings aimed at recruiting nonaerated lung areas, such as positive end-expiratory pressure or recruitment maneuvers, may increase lung deposition of nebulized antibiotics.

SEVERITY AND EXTENSION OF BRONCHOPNEUMONIA

The extension and severity of human lung infection can be evaluated according to an histologic classification proposed in the early 1990s.[36,37] Bronchiolitis is the immediate stage preceding lung infection. It is characterized by the proliferation of polymorphonuclear leukocytes within the bronchial lumen, forming purulent plugs, necrosis, and disruption of the bronchial mucosa. Neutrophilic infiltrates present in alveolar septa and distal bronchioles are characteristic of interstitial bronchopneumonia. The intense proliferation of polymorphonuclear leukocytes into surrounding alveoli characterizes foci of bronchopneumonia and decreases lung aeration. These foci of lung infection

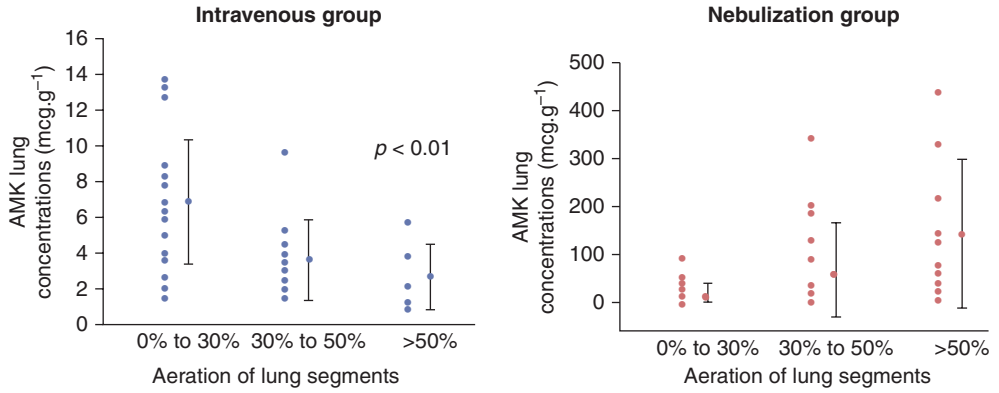

FIGURE 64-3 Amikacin (*AMK*) pulmonary concentrations according to aeration of lung segments (each *dot* represents a single segment) measured in anesthetized piglets mechanically ventilated for a severe *Escherichia coli* bronchopneumonia. In the intravenous group, animals received an intravenous dose of amikacin (15 mg/kg). In the nebulization group, animals received an equivalent dose by the inhalation route (via ultrasonic nebulizer). Lung aeration was quantified on postmortem histologic samples using an image analyzer computerized system coupled to a high-resolution color camera and an optical microscope. (Used, with permission, from Elman et al.[38])

may extend to one or more pulmonary lobules resulting in confluent bronchopneumonia characterized by a severe aeration loss. Pulmonary abscess and purulent bronchopneumonia, the most severe forms of lung infection, are characterized by tissue necrosis, disruption of the normal lung architecture, vascular destruction, consolidation, and complete loss of aeration. In anesthetized piglets receiving prolonged mechanical ventilation for severe inoculation pneumonia, lung-tissue concentrations of nebulized amikacin, ceftazidime, or colistin were markedly higher in pulmonary segments with early stages of bronchopneumonia than in segments with confluent bronchopneumonia and lung abscess.[34,35,38] As shown in Figure 64-4, such differences were not observed when the antibiotic was intravenously administered. These experimental data clearly support the administration of nebulized antibiotics in the early stages of ventilator-associated pneumonia.

INJURY TO THE ALVEOLAR–CAPILLARY BARRIER

A critical factor influencing antibiotic lung deposition is the diffusion through physiologic barriers, such as the bronchial epithelium or vascular endothelium. The normal alveolar–capillary barrier offers high resistance to lung penetration of intravenous antibiotics and systemic diffusion of nebulized antibiotics.[32] Lung infection, as with any type of lung injury, results in increased permeability of the alveolar–capillary barrier, which, in turn, facilitates the diffusion of nebulized antibiotics into the bloodstream.[33,34] Experimentally, amikacin and ceftazidime plasma concentrations are no different after nebulization or intravenous administration in the presence of severe lung infection.[33,34] In addition, systemic bioavailability is markedly increased. In other words, damage to the alveolar–capillary barrier, resulting from the infectious process, facilitates leakage of nebulized aminoglycosides

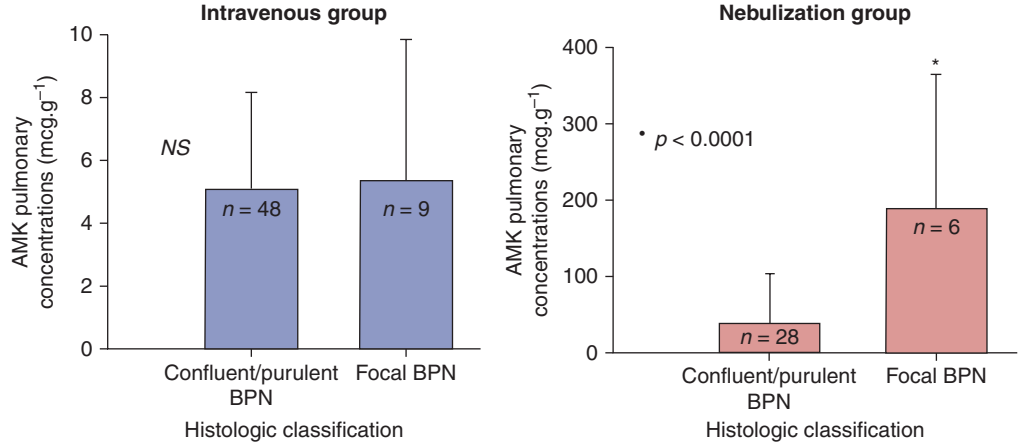

FIGURE 64-4 Amikacin (*AMK*) lung-tissue concentrations according to histologic stages of bronchopneumonia (*BPN*) characterizing lung segments (mean ± standard deviation), measured in anesthetized piglets mechanically ventilated for a severe *Escherichia coli* bronchopneumonia. In the intravenous group, animals received an intravenous dose of amikacin (15 mg/kg). In the nebulization group, animals received an equivalent dose by the inhalational route (via ultrasonic nebulizer). (Used, with permission, from Elman et al.[38])

and cephalosporins toward the systemic compartment, thereby decreasing the tissue concentration and increasing the risk of systemic toxicity. Interestingly, systemic diffusion of nebulized colistin was limited in piglets with inoculation *P. aeruginosa* pneumonia, suggesting a means of decreasing the systemic toxicity of polymyxins.[35]

Efficiency of Aerosol Delivery

In the 1980s, lung deposition of aerosolized antibiotics was assessed using radiolabeled aerosols and gamma-scintigraphy.[39] In the early studies, mechanical ventilation was considered to limit the aerosol lung deposition to less than 5% of the dose placed in the nebulizer.[40] Over the following 15 years, improvements in aerosol technology, as well as an understanding of factors influencing lung deposition during mechanical ventilation, increased aerosol delivery efficiency to 30% to 80%.[15,16,20,32–35] Pneumatic jet nebulizers deliver less than 20% of the initial dose, because of high residual volume, massive deposition of aerosol particles in ventilator circuits and the endotracheal tube, and loss to atmosphere by the expiratory limb.[20] Ultrasonic nebulizers have increased the efficiency of aerosol delivery to 30% to 40%.[32,33] The recent development of aerosol devices using vibrating plate technology, together with synchronizing aerosol delivery to the inspiratory phase, may even increase aerosol efficiency above 70%.[20,34,35] Figure 64-5 illustrates the multiple factors influencing aerosol efficiency and lung deposition of nebulized antibiotics.

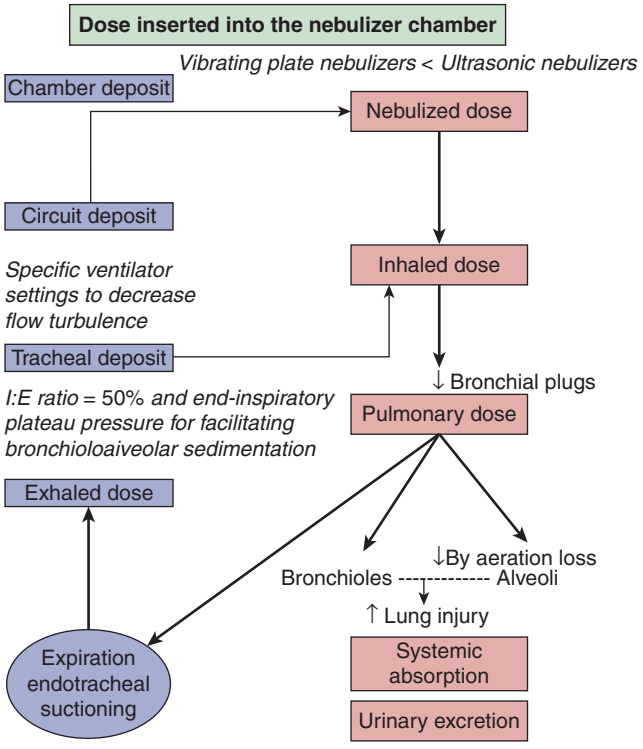

FIGURE 64-5 The mechanisms by which the dose of antibiotic inserted into the nebulizer may differ markedly from the dose delivered to the distal lung. Patient-related factors and medical interventions can interfere with different steps in the nebulization process. (Thin arrows indicate limitation of lung deposition [arrow oriented down] or facilitation of systemic diffusion [arrow oriented up]).

ASSESSMENT OF THE MICROBIOLOGIC RESPONSE

Methods for Assessing Microbiologic Response

In experimental animals, antibacterial efficiency of nebulized antibiotics can be directly assessed by measuring antibiotic lung-tissue concentrations and assessing quantitative bacteriology of postmortem lung-tissue samples.[32–35] Concentrations measured from homogenized lung-tissue samples are representative of antibiotic present in interstitial and cell compartments. Most bacteria do not penetrate into cells and remain in the interstitial space, where antibiotics exert their bactericidal activity by binding to bacterial cell membrane. Therefore, antibiotic concentrations measured from homogenized lung biopsies underestimate "effective" interstitial concentrations, secondary to a dilution factor caused by intracellular components.[41]

In patients with ventilator-associated pneumonia, it can only be assessed indirectly as the regression of clinical, biologic, and radiologic signs of lung infection, and the disappearance of pathogens initially found in cultures of distal pulmonary samples. In ventilated critically ill patients, a number of confounding factors may hamper the clinical evaluation. The bronchial deposition of nebulized antibiotics may render cultures of distal samples falsely negative although the lung parenchyma is still positive. Critically ill patients frequently have several sites of infection, and persisting fever and biologic signs of infection may be related to a persisting extrapulmonary infection.

Antibiotic concentrations representative of the alveolar space can be assessed from a bronchoalveolar lavage. To obtain the antibiotic concentration representative of the epithelial lining fluid, the concentration measured in the aspirated fluid is corrected by a dilution factor, which is derived from the ratio between urea concentrations simultaneously measured in plasma and the bronchoalveolar lavage.[42] Such measurements may fail to provide true representations of antibiotic concentrations at the site of lung infection because of confounding factors such as dilution errors or cell lysis.[42] Of particular interest is a bronchoscopic microsampling method for measuring the antibiotic concentration in bronchial epithelial lining fluid.[43] It consists of introducing, through a bronchoscope positioned in the airways, an inner 1.9-mm polyester fiber rod probe, which immediately adsorbs fluid when placed on a bronchial wall for 10 seconds. Antibiotic concentrations are then measured from the probe without any dilution. To date, this attractive but expensive technique remains limited to research studies.

Microbiologic Response to Concentration-Dependent Antibiotics in Experimental Studies

Most experimental studies of nebulized antibiotics included aminoglycosides[32,33,38,44–46] and polymyxins,[35] families of antibiotics exerting a concentration-dependent antibacterial effect.[32,33,35,38,44–46] With concentration-dependent antibiotics, a single daily nebulization, ensuring high lung-tissue concentrations, is enough to achieve a bactericidal effect at the site of infection for a period of 12 to 24 hours. The postantibiotic effect prevents the regrowth of bacterial strains despite the antibiotic lung-tissue concentrations falling below the minimal inhibitory concentration. After several consecutive daily nebulizations of aminoglycosides, there is no time-dependent tissue accumulation.[47]

In the late 1970s, experimental studies performed in nonventilated mice with *Klebsiella pneumoniae* bronchopneumonia had reported enhanced bacterial killing and higher survival rates when kanamycin was nebulized in comparison to intramuscular administration.[44,45] In spontaneously breathing squirrel monkeys, these investigators demonstrated that nebulized kanamycin efficiently protected against *K. pneumoniae* bronchopneumonia induced by intratracheal bacterial instillation, whereas the intramuscular administration was not protective.[45] Antibiotic clearance curves indicated that nebulized kanamycin remained longer in the lungs and at higher concentrations than intramuscular kanamycin. In the early 1990s, a study performed in spontaneously breathing guinea pigs demonstrated that a combination of aerosolized and intramuscular tobramycin achieved slightly higher survival and total eradication of *P. aeruginosa* compared to nebulized or intramuscular tobramycin alone.[46] Ten years later, an experimental study looked at the antibacterial efficiency of nebulized amikacin in anesthetized piglets ventilated for a severe *E. coli* bronchopneumonia.[33] Twenty-four hours after a massive bronchial inoculation, ventilated animals received equivalent doses of amikacin, either by ultrasonic nebulization or intravenously. Because of a 60% extrapulmonary deposition, 45 mg/kg were nebulized in a single dose and 15 mg/kg administered intravenously. The animals received a second dose after 24 additional hours of mechanical ventilation and were killed 1 hour later, and five subpleural specimens were excised from the upper, middle, and lower lobes. Amikacin lung-tissue peak concentrations were threefold to 30-fold higher after nebulization than after intravenous administration. As shown in Figure 64-6, after two nebulizations and 25 hours of treatment, 71% of lung segments were sterile, whereas cultures of lung segments were comparable in nontreated and intravenously treated animals. In 2010, the antibacterial efficiency of nebulized colistin was assessed in anesthetized piglets ventilated for severe *P. aeruginosa* bronchopneumonia.[35] Twenty-four hours after a massive bronchial inoculation, ventilated animals received equivalent doses of colistin, either by nebulization or intravenously. Because of a 60% extrapulmonary deposition, 16 mg/kg were nebulized in two daily doses and 10 mg/kg administered intravenously in three doses. The animals were killed 1 hour after the third aerosol and the fourth intravenous administration, and five subpleural specimens were excised from the upper, middle, and lower lobes. Colistin lung-tissue concentrations were not detectable following intravenous administration and onefold to 12-fold higher than minimal inhibitory concentrations after nebulization. After three nebulizations and 25 hours of treatment, 67% of lung segments were sterile, whereas 88% of lung segments were positive in nontreated animals and 72% in intravenously treated animals.

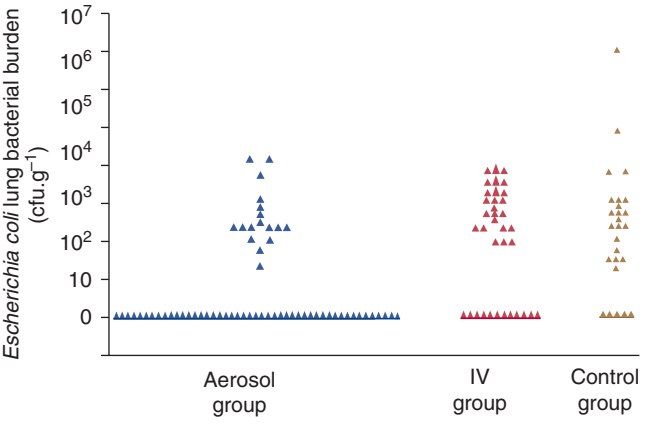

FIGURE 64-6 Lung bacterial burden of *Escherichia coli* (expressed in colony-forming units per gram [cfu/g] of lung tissue) in lung segments of anesthetized piglets mechanically ventilated for severe *E. coli* bronchopneumonia. Postmortem tissue samples were collected 1 hour after the second aerosol or intravenous (*IV*) dose of amikacin, or 48 hours after the bacterial inoculation in the untreated control group. Each triangle refers to a single lung segment. The lung bacterial burden is significantly lower in the aerosol group as compared with the intravenous or control groups. (Used, with permission, from Goldstein et al.[33])

Microbiologic Response to Time-Dependent Antibiotics in Experimental Studies

With time-dependent antibiotics, such as cephalosporins, tissue concentrations have to be maintained permanently above minimal inhibitory concentrations to provide a bactericidal effect. Therefore, aerosols have to be repeated several times a day.

An experimental study looked at the lung-tissue concentrations of ceftazidime administered to anesthetized piglets ventilated for a severe *P. aeruginosa* bronchopneumonia.[31] Twenty-four hours after a massive bacterial inoculation, animals received equivalent doses of ceftazidime either by ultrasonic nebulization or intravenously. Because of a 30% extrapulmonary deposition, 50 mg/kg were nebulized in a single dose and 33 mg/kg administered intravenously. The animals were sacrificed 1 hour later, and five subpleural specimens were excised from the upper, middle, and lower lobes. Ceftazidime lung-tissue concentrations following

nebulization were fivefold to 30-fold higher than after intravenous administration.[31] In a second study performed in the same experimental model, animals received either nebulized or intravenous ceftazidime for 24 hours.[34] Twenty-four hours after a massive *P. aeruginosa* bronchial inoculation, ventilated animals received equivalent doses of ceftazidime, either by nebulization or intravenously. Because of a 60% extrapulmonary deposition, 200 mg/kg were nebulized in eight daily aerosols of 25 mg/kg each, and 90 mg/kg was administered by continuous intravenous infusion. The animals were killed 3 hours after the eighth aerosol and 24 hours after initiation of intravenous administration, and five subpleural specimens were excised from the upper, middle, and lower lobes. Ceftazidime trough lung-tissue concentrations were fourfold higher after nebulization compared to continuous intravenous administration. After nine nebulizations and 25 hours of treatment, 80% of lung segments were sterile, whereas 90% of lung segments were positive in nontreated animals and 70% in intravenously treated animals.

Clinical Response in Human Studies

The experimental studies reported above clearly suggest that aminoglycosides, polymyxins, and cephalosporins have a higher bactericidal efficiency when administered by nebulization as compared to the parenteral route. Beneficial effects of nebulization and endotracheal administration of antibiotics have been repeatedly reported in spontaneously breathing patients with cystic fibrosis.[48] Several human studies have also demonstrated that the endotracheal administration or nebulization of aminoglycosides and polymyxins may prevent bronchial infection and ventilator-associated pneumonia in ventilated critically ill patients.[49–52] The risk of encouraging resistive strains, however, has limited this prophylactic approach.[53] Two studies performed in ventilated patients treated by intravenous antibiotics demonstrated that the addition of endotracheal tobramycin is useful for eradicating the pathogens that cause gram-negative pneumonia.[54,55] In 1992, a comparative pharmacokinetic study, performed in ventilated patients with nosocomial pneumonia, reported high antibiotic bronchial concentrations following the nebulization or the endotracheal administration of 1 g of ceftazidime.[56] In addition, the minimal inhibitory concentrations for 90% of the most important pathogens responsible for nosocomial infections were exceeded by concentrations in bronchial secretions for up to 12 hours after intravenous infusion and for up to 24 hours after endotracheal and aerosol administration.[56]

More than 40 years ago, aerosols of colistin were successfully administered to spontaneously breathing patients with pulmonary suppuration.[57] In the early 1970s, two spontaneously breathing patients with *P. aeruginosa* pneumonia were treated with inhaled polymyxin B, but aerosols had to be stopped because of airway obstruction.[58] Over the last decade, several investigator groups have reported microbiologic response following nebulization of antibiotics to critically ill patients with ventilator-associated pneumonia.[59–70] Most of these studies were retrospective and concerned patients treated by nebulized colistin for ventilator-associated pneumonia caused by multidrug-resistant pathogens.[59,60,62,63,66–69] Three studies were prospective[64,65,70] and two were randomized.[65,70] Most investigators reported "beneficial" effects, either resulting from a combination of nebulized and intravenous antibiotics[59,60,65,65] or from nebulized antibiotics alone.[61–63,67–70] Except for a prospective randomized study published in 2011,[70] ventilator settings were not optimized in these studies and the rationale for choosing the aerosol dose was not given. Clinical response was considered beneficial when aerosol antibiotics were efficient in treating patients whose lungs were infected with multidrug-resistant microorganisms.[60,62,64,65,67,69,70]

In a matched case-control study, aerosolized plus intravenous colistin was not more efficient than intravenous colistin alone for treating ventilator-associated pneumonia caused by multidrug-resistant pathogens.[68] In a double-blind, randomized, placebo-controlled study performed in forty-five critically ill patients with ventilator-associated tracheobronchitis, aerosolized gentamicin or vancomycin administered over the course of 14 days and combined with systemic antibiotics were associated with several benefits[65]: better resolution of ventilator-associated pneumonia, less bacterial resistance, reduced used of systemic antibiotics, and facilitation of weaning from mechanical ventilation. Several limitations, however, preclude drawing firm conclusions from the study: The small number of patients included in the aerosol group ($n = 19$), the small doses used in the aerosol group (gentamicin = 180 mg/day and vancomycin = 180 mg/day), the lack of optimization of ventilator settings during nebulization, and the heterogeneity of clinical and bacterial criteria for determining efficiency of antimicrobial therapy. In a randomized, controlled, phase II trial performed in forty critically ill patients with ventilator-associated pneumonia caused by *P. aeruginosa*, aerosolized ceftazidime and amikacin were compared to intravenous ceftazidime and amikacin.[70] In both arms, antimicrobial therapy was administered over the course of 7 days. Resolution of ventilator-associated pneumonia was assessed by objective criteria based on eradication of *P. aeruginosa* from bronchoalveolar lavage, resolution of clinical signs of sepsis, and lung reaeration on computed tomography. During aerosol administration, ventilator settings were optimized to minimize extrapulmonary deposition and intravenous and nebulized doses were determined so as to deliver comparable amounts of ceftazidime and amikacin in the trachea and pulmonary artery. Aerosol and intravenous antibiotics had a similar efficiency for treating ventilator-associated pneumonia caused by *P. aeruginosa* sensitive to ceftazidime and amikacin. Unlike systemic antibiotics, aerosolized antibiotics were efficient against intermediate strains and they reduced the emergence of resistive *P. aeruginosa*. Because of the small number of patients included, no conclusion could be drawn about the potential benefit of aerosol antibiotics on emergence of resistive strains, duration of mechanical ventilation, length of stay in the intensive care unit, and mortality.

Multicenter randomized trials are required to determine the clinical impact and the indications of nebulized antibiotics, and more specifically their efficiency in ventilator-associated pneumonia caused by multidrug-resistant microorganisms. Apart from potential benefit in patients with ventilator-associated pneumonia, nebulized antibiotics may also prevent microbial biofilm formation on the endotracheal tube internal surface,[74] thereby suppressing a reservoir of infecting microorganisms for the deep lung.[7]

IMPORTANT UNKNOWNS AND ISSUES TO BE RESOLVED

Two major issues must be taken into consideration before nebulized antibiotics can be recommended as an alternative to intravenous anti-infectious therapy in critically ill patients.

Side Effects of Nebulized Antibiotics

Very few complications have been described in patients receiving inhaled antibiotics. Bronchoconstriction, chest tightness, and apnea are the main adverse effects of colistin aerosols.[72,74,75] Hypoxemia may result from aerosol nebulization of any drug, particularly in patients with acute lung injury or acute respiratory distress syndrome. With aminoglycosides, the most common adverse effects are tinnitus, hoarseness, voice alteration, wheezing, cough, dyspnea, and bronchospasm.[73] Nebulized cephalosporins or other antibiotics are usually well tolerated. Cough, nasal congestion, wheezing, taste disturbances, and chest tightness have been reported.[73] Obstruction of the expiratory filter caused by repetitive aerosols of cephalosporin have been reported in ventilated patients with a risk of increased airway pressure and cardiac arrest.[70]

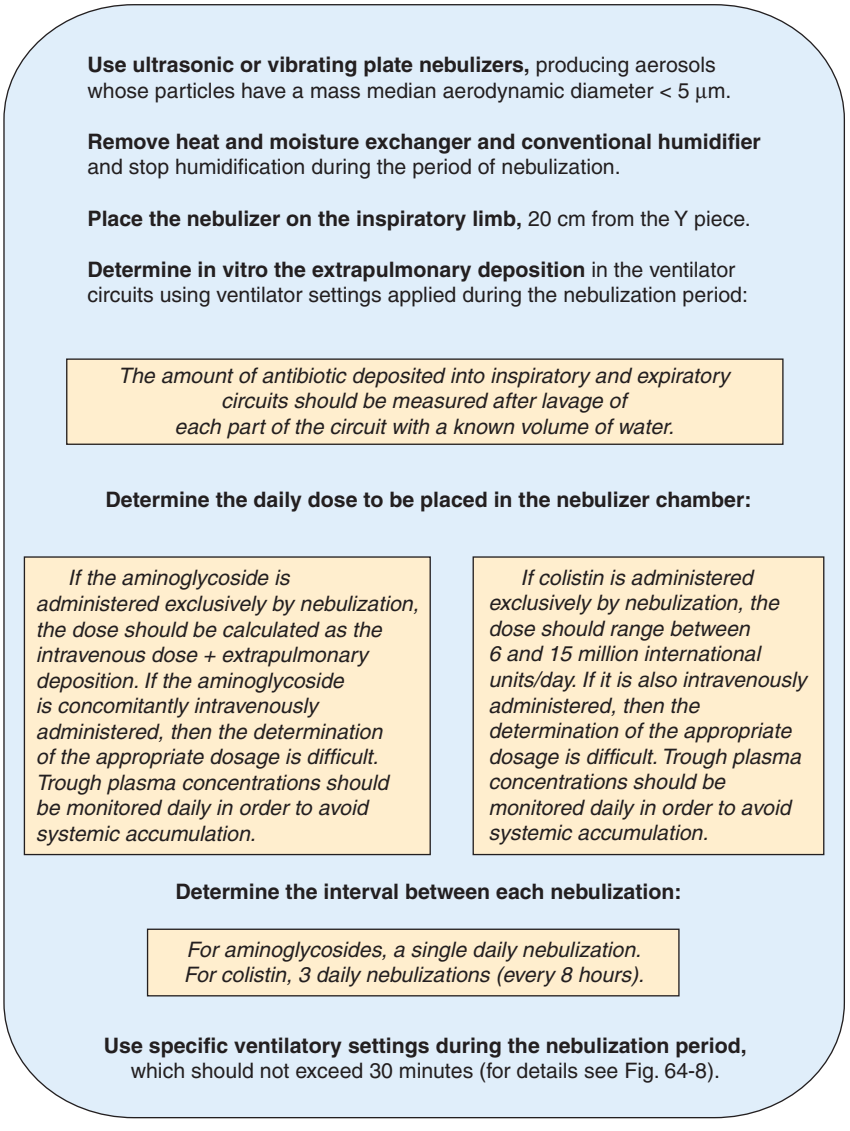

FIGURE 64-7 Guidelines for inhaled antibiotic therapy in ventilated patients.

Another serious potential risk of nebulized antibiotics is the emergence of multiresistant pathogens. Some old studies reported the emergence of resistant strains complicating the intratracheal administration of gentamycin, sisomicin, or colistin for preventing and treating ventilator-associated pneumonia.[49,52,53,76] Other experimental[51] and clinical[77] studies did not find an increase in the incidence of resistant pathogens when polymyxin B or colistin were endotracheally administered to prevent ventilator-associated pneumonia. Interestingly, nebulized antibiotics for treating ventilator-associated pneumonia seem to reduce the emergence of multidrug-resistant strains.[65,70]

Determination of the Aerosol Dose

Different rationales can be adopted for optimizing the aerosol dose. To deliver comparable amounts of antibiotics in the trachea and pulmonary artery, aerosol dose can be determined as intravenous dose plus extrapulmonary deposition. Extrapulmonary deposition can be assessed by rinsing nebulization chamber and the inspiratory and expiratory circuits with saline and measuring antibiotic concentration in the recovered fluid.[31–35,38,70,78] Another rationale is to define the "best" aerosol dose as the dose providing systemic concentrations in the range of those obtained after intravenous administration.[79] Such a rationale requires repetitive systemic dosages and appears difficult to implement in clinical practice. Studies are required to assess the impact of these different strategies on clinical efficiency of inhaled antibiotics.

GUIDELINES FOR INHALED ANTIBIOTIC THERAPY

It is important to recognize that inhaled antibiotics for treating ventilator-associated pneumonia differ in several ways from inhaled bronchodilator therapy for treating bronchospasm in ventilated patients. Nebulized antibiotics must penetrate into the distal lung, whereas bronchodilators only need to reach the bronchial tree. Because antibiotic tissue concentrations in the infected lung parenchyma should largely exceed minimal inhibitory concentrations of causative pathogens, optimizing dosage, an unresolved issue, is more critical for inhaled antibiotic therapy than for inhaled bronchodilator therapy. Great attention must be paid to the period of nebulization: Specific ventilator settings should be used to limit flow turbulence, and a short-acting sedative may be required to avoid flow triggering and dyssynchrony with the ventilator. Figures 64-7 and 64-8 summarize guidelines for delivering nebulized antibiotics during mechanical ventilation.

CONCLUSIONS AND THE FUTURE

Although inhaled antibiotic therapy has been episodically used in ventilated patients for more than 40 years, convincing clinical data are still unavailable to support its routine use. The recent understanding of physical and physiologic factors influencing lung deposition of aerosolized antibiotics together with an impressive growth of new technologies fuel a renewed interest for treating ventilator-associated pneumonia with nebulized antibiotics. In 2012, administration of inhaled antibiotics to ventilated patients should be judged a potentially efficient therapy for treating ventilator-associated pneumonia caused by resistant microorganisms. In critically ill patients with ventilator-associated pneumonia caused by sensitive bacteria, well-conducted phase II trials suggest that inhaled antibiotic therapy is at least equivalent to intravenous antibiotics and may decrease the emergence of resistant strains.[65,70] Multicenter randomized studies should be set up to assess the impact of inhaled antibiotic therapy on mortality, morbidity, antibiotic consumption, and costs in critically ill patients with ventilator-associated pneumonia.

FLUID MANAGEMENT IN THE VENTILATED PATIENT

Andrew D. Bersten

Fluid management during mechanical ventilation is complicated by both the influence of positive-airway pressure on normal homeostatic control of bodily fluids, and the interaction of mechanical ventilation with fluid status. Hypovolemia may lead to hemodynamic intolerance of positive-airway pressure, and fluid overload may result in both impaired gas exchange and respiratory mechanics and deleterious systemic effects. In patients with acute lung injury (ALI) and the acute respiratory distress syndrome (ARDS), positive fluid balance has been associated with both fewer ventilator-free days, and longer intensive care unit (ICU) stay, and with mortality in prospective randomized[1] and observational[2] studies, respectively.

PHYSIOLOGIC CONSIDERATIONS

Fluid Compartments[3]

In the normal adult male, total body water accounts for approximately 60% of body weight. In turn, approximately 40% of body weight is intracellular water and approximately 20% is distributed into the extracellular fluid volume, made up of interstitial fluid (approximately 16%), plasma volume (approximately 4%), and usually negligible volumes of lymph and transcellular fluid (cerebrospinal fluid and pericardial, intrapleural, and peritoneal fluid). Tissues such as brain, kidney, liver, and muscle have high water contents (70% to 80%) but adipose tissue has low water content (approximately 10%). Consequently, women, who tend to have more adipose tissue, have a lower total body water (approximately 50% of body weight). Total body water decreases in the elderly because of a loss of muscle mass.

The extracellular volume is distributed in interstitial fluid and plasma volume, and consists of two compartments. Seventy percent of the volume is rapidly equilibrating (approximately 20 minutes), and the remainder slowly equilibrates (approximately 24 hours) in dense connective tissue and bone. Sodium balance regulates the extracellular volume, whereas water balance regulates the intracellular volume.

WATER BALANCE

Water balance is primarily determined by thirst and the renal action of arginine vasopressin, also termed *antidiuretic hormone,* which is secreted from the posterior pituitary following synthesis in the hypothalamus, in response to a wide variety of stimuli, particularly plasma osmolality. Vasopressin activates V_2 receptors on the basolateral surface of the distal renal tubule and collecting duct, leading to an increase in water permeability, and reabsorption of filtrate, through fusion of aquaporin-2 with the luminal membrane. Vasopressin also reduces water clearance by decreasing renal medullary blood flow, and independently increases the renal medullary concentration gradient by stimulating a urea transporter.[4]

Under normal circumstances, a plasma osmolality of 280 mOsm/kg suppresses vasopressin secretion allowing maximal urinary dilution. As osmolality progressively rises to 295 mOsm/kg, so does the secretion of vasopressin, with an associated reduction in free water clearance. The kidney

TABLE 65-1: FACTORS THAT INFLUENCE VASOPRESSIN SECRETION

Increase Vasopressin Secretion	Decrease Vasopressin Secretion
Plasma osmolality >280 mOsm/kg	Ethanol
Hypovolemia	Drugs
Hypotension	Narcotic antagonists
High-pressure baroreceptors	Phenytoin
Low-pressure baroreceptors	Clonidine
Angiotensin II	Atrial natriuretic peptide
Pain	
Nausea	
Drugs	
Nicotine	
Narcotics	
Barbiturates	
Carbamazepine	
Amitriptyline

Vincristine	
Clofibrate	
Hypercapnia	
Hypoxemia	

can normally concentrate filtrate up to 1200 mOsm/kg under the influence of vasopressin, although this tends to deteriorate with age and renal dysfunction. Table 65-1 lists other stimuli that influence vasopressin secretion. High-pressure stretch receptors in the aortic arch and carotid sinus sense a significant (>10%) fall in blood pressure (BP), leading to an increase in vasopressin release. As vasopressin also causes vasoconstriction through stimulation of V_1 receptors, this is an important homeostatic response in shock,[4] but appears to be reset within 32 hours of sustained hypovolemia.[5] Stimulation of low pressure stretch receptors in the atria primarily results in an increase in both sympathetic tone and renin, and a decrease in atrial natriuretic peptide (ANP), with vasopressin release unaffected until the systemic BP falls.

SODIUM BALANCE

The extracellular volume is primarily regulated through control of sodium balance, which is, in turn, regulated through control of effective plasma volume and its composition. The total body sodium content is approximately 4000 mmol; most of which is found extracellularly, and about half is rapidly exchangeable. Although the standard Western diet contains approximately 150 mmol of sodium per 24 hours, this varies widely and urinary sodium excretion varies between 0.2 and 242 mmol per 24 hours,[6] reflecting a balance between sodium input and output. Although a moderate range of total body sodium content is well tolerated, once effective plasma volume is significantly affected, short-term and longer-term homeostatic responses are initiated.

A fall in effective plasma volume leads to activation of baroreceptors with augmentation of myocardial performance and peripheral vascular tone, and defense of plasma volume through shift of fluid from the interstitium. Longer-term responses include reduced sodium loss by the kidney and sweat glands, through a direct effect of aldosterone. When the baroreceptors are stimulated the increase in sympathetic tone reduces sodium loss through reduced glomerular filtration rate, and through increased tubular sodium reabsorption, both through a direct effect and through the actions of increased renin, angiotensin II, and aldosterone. In addition, ANP is released from the cardiac atria in response to stretch, and directly increases glomerular filtration rate through afferent arteriolar vasodilation, increases renal medullary blood flow, antagonizes vasoconstriction secondary to angiotensin II, and decreases sodium reabsorption by the collecting duct. Dopamine is produced in the kidney following conversion from L-dopa under the action of the cytosolic enzyme L-amino acid decarboxylase present in the proximal tubules.[7] This is upregulated following a high-salt diet, leading to increased urinary sodium loss as dopamine acts to inhibit sodium reabsorption in the proximal tubule,[8] and contributes to the increase in urine output sometimes seen following administration of low-dose dopamine. The renal synthesis of prostaglandins, such as prostaglandin E_2 and prostacyclin (PGI_2), tends to maintain renal blood flow and glomerular filtration rate through vasodilation, and directly increase water and sodium excretion. Consequently, in stressed patients cyclooxygenase inhibitors can precipitate renal dysfunction. Dopaminergic renal vasodilation in part acts through release of PGI_2, because administration of dopaminergic antagonists leads to reduced urinary prostaglandins and loss of dopaminergic vasodilation,[9] perhaps explaining why low-dose dopamine appears to be ineffective in septic ICU patients[10] who already have a prostaglandin-driven kidney.

Influence of Positive-Pressure Ventilation on Fluid Balance

Positive-pressure ventilation and positive end-expiratory pressure (PEEP) raise intrathoracic pressure, resulting in reduced venous return and transmural pressure (see Chapter 36), with consequent complex neurohumoral responses leading to sodium and water retention. Because assisted, supported, and spontaneous modes of ventilation progressively ameliorate the elevation of intrathoracic pressure and its consequences, different ventilator modes variably reduce venous return. Reductions in stroke volume, cardiac output, and BP then lead to stimulation of high-pressure baroreceptors, and altered regional blood flow. Both low- and high-pressure baroreceptor stimulation lead to increased sympathetic outflow, and release of renin, aldosterone, and ANP. Renal denervation does not prevent sodium and water retention.[11] Angiotensin-converting enzyme inhibitors[12] and deliberate hypervolemia,[11] however, reduce sodium and water retention during positive-pressure ventilation.

Right atrial transmural pressure and stretch are also reduced by PEEP and positive-pressure ventilation, and this leads to reduced secretion of ANP,[13,14] with consequent reduction in water and sodium excretion reversed by restoration of venous return with lower body positive pressure. PEEP levels above 10 cm H_2O may lead to an increase in central venous pressure (CVP), and regional venous pressures, which in the kidney contribute to reduced sodium and water excretion, independent of neurohumoral effects.[15]

In summary, various neurohumoral responses to positive-pressure ventilation lead to retention of sodium and water, as a homeostatic response to raised intrathoracic pressure. A major consequence of this response is expanded plasma volume, and a tendency toward systemic and pulmonary edema.

The Starling Equation

The major difference between plasma volume and interstitial fluid is the lower concentration of plasma proteins in the interstitial fluid, typically 40% of their plasma concentration. Although this concentration difference has little effect on the osmotic pressure between these two compartments, it leads to an important difference in oncotic pressure, and 80% of this is attributed to differences in albumin concentration. The normal plasma osmotic pressure is approximately 5500 to 6000 mm Hg, with approximately 28 mm Hg contributed by plasma proteins, despite having an osmolality of approximately 1.2 mOsm/kg.

The Starling equation quantitates the transvascular flux of fluids across the microcirculation (J_v). It is usually written as:

$$J_V = K_{f,c}\left(\left[P_{cap} - P_{int}\right] - \sigma\left[\pi_{cap} - \pi_{int}\right]\right)$$

where $K_{f,c}$ is the capillary filtration coefficient, P_{cap} is the hydrostatic microvascular pressure, P_{int} is the interstitial pressure, π_{cap} is the plasma oncotic pressure, π_{int} is the interstitial oncotic pressure, and σ is the osmotic reflection coefficient. $K_{f,c}$ is determined by both endothelial hydraulic conductance and endothelial surface area, and σ is a measure of protein selectivity. The osmotic reflection coefficient is thought to be 1 in the cerebral microcirculation where the blood–brain barrier effectively prevents protein flux, and approximately 0.7 to 0.8 in the normal pulmonary microcirculation, although this is markedly reduced during lung injury.[14] In a typical systemic microcirculatory bed, the arterial end of P_{cap} is 30 mm Hg and the venous end is 10 mm Hg. Assuming σ equals 1, P_{int} is −3 mm Hg, π_{cap} is 28 mm Hg, and π_{int} is 8 mm Hg, the net driving pressure out of the capillary at the arterial end of the microcirculation will be ([30−3] − [28−8]) or 13 mm Hg, although the effective π_{int} may be a little lower.[16] At the venous end of the microcirculation the net driving pressure into the capillary will be 7 mm Hg, and most of the filtered fluid is reabsorbed, with the lymphatics draining the remainder.

In the healthy lung, P_{cap} is usually assumed to be 7 mm Hg, P_{int} as −8 mm Hg, and π_{int} as 14 mm Hg. Consequently, the driving pressure across the pulmonary circulation is thought to be positive (Fig. 65-1), leading to net filtration of fluid, with lymphatic absorption usually estimated to be approximately 20 mL/hour. The final filtration rate is determined by the capillary surface area, convective forces, and diffusive forces. When P_{cap} is suddenly raised, the filtration rate may increase more than threefold.[16]

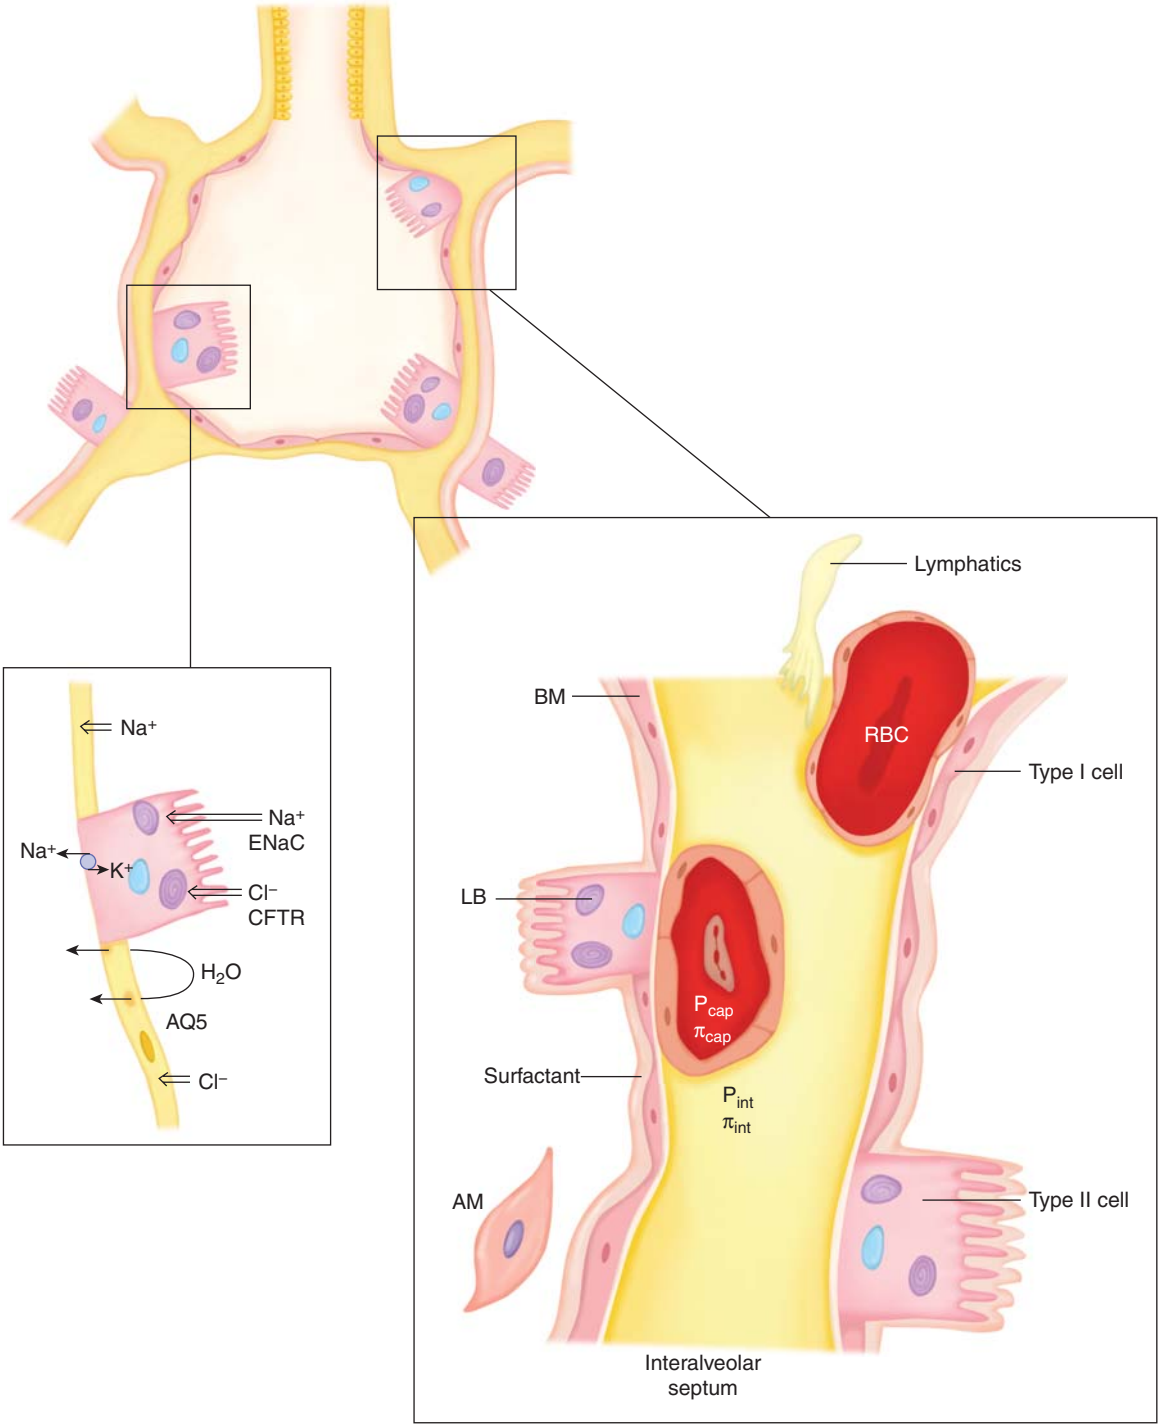
There are a number of safety factors that are thought to help prevent alveolar edema. These include low epithelial permeability (pore size approximately 10% that of the endothelium), low alveolar surface tension reflecting normal surfactant function, active vectorial transport of ions across the epithelium (see Fig. 65-1), and favorable interstitial function and lymphatic drainage (edema fluid moves along a negative-pressure gradient centrally away from the alveolus, while an associated reduction in the negative pressure and dilution of interstitial oncotic pressure reduce filtration).[17] Changes in either Starling forces or these safety factors can lead to pulmonary edema. For example, an increase in P_{cap} is the basis for hydrostatic pulmonary edema; a decrease in P_{int}, as might be seen with an obstructed airway and vigorous respiratory efforts, is thought to cause postobstructive pulmonary edema; although a decrease in σ is the basis for permeability pulmonary edema, concurrent surfactant dysfunction leads to an increase in surface tension and a decrease in P_{int}, also favoring the development of edema.[18–20] Remodeling of the lung parenchyma in chronic heart failure and conditions of persistently elevated P_{cap} such as mitral stenosis allow patients to tolerate a relatively high P_{cap} without developing marked pulmonary edema. Models of chronic heart failure suggest important homeostatic responses including a reduction in $K_{f,c}$, which together with further reduction in surface tension associated with increased surfactant content, can prevent pulmonary edema despite elevated P_{cap}.[21,22]

FLUID TARGETS

In formulating an approach to fluid management in the ventilated patient, a balance between parsimonious and generous fluid therapy needs to be considered. Although this is commonly termed the "dry or wet" approach, and this may be an appropriate general description for particular groups of patients, most clinicians classify fluid therapy as (a) maintenance, (b) replacement, and (c) resuscitation fluids. In general, the tendency of ventilated patients to retain fluids, and the benefits of fluid restriction, argue for the dry approach provided there is due attention to adequate resuscitation. A consensus statement classified fluid restriction as grade IIa evidence in ALI and ARDS.[23]

Maintenance Fluids

The volume of appropriate maintenance fluids in a ventilated patient is usually the most contentious of these parameters. As noted in Table 65-2, approximately 1150 mL of fluid per day should be adequate maintenance in ventilated patients;



P_{cap} +7 mm Hg P_{int} –8 mm Hg

π_{cap} +28 mm Hg π_{int} +14 mm Hg

$\Delta P = [7- -8] - [28-14] = +1$ mm Hg

FIGURE 65-1 Schematic of an alveolus, associated interstitium, and capillary network in the normal lung. Typical pressures involved in fluid flux result in net positive filtration of fluid. The epithelium is both a tight barrier with pore size approximately one-tenth the endothelium, and participates in vectorial ion and water and movement out of the alveolus. Sodium is absorbed at the epithelial surface through a sodium channel (*ENaC*) and actively moved across the basolateral membrane into the interstitium by Na^+,K^+-adenosine triphosphatase (ATPase). *AM,* alveolar macrophage; *AQ5,* aquaporin 5; *BM,* basement membrane; *CFTR,* cystic fibrosis transmembrane conductance regulator; *LB,* lamellar body; P_{cap}, pulmonary capillary pressure; π_{int}, interstitial oncotic pressure; π_{cap}, pulmonary capillary oncotic pressure; P_{int}, interstitial pressure; *RBC,* red blood cell.

TABLE 65-2: TYPICAL FLUID BALANCE IN HEALTHY (NONVENTILATED) SUBJECTS AND VENTILATED PATIENTS

	Healthy Subjects (mL)	Ventilated Patients (mL)
Typical obligatory fluid (water) losses		
Gastrointestinal fluid	200	200
Insensible skin loss	500	500
Humidification of inhaled air	500	0
Urine output	1000	800
Total	2200	1500
Typical fluid (water) intake		
Metabolically generated water	350	350
Water content of food	750	0
Remaining fluid intake	1100	1150
Total	2200	1500

In practice, many clinicians ignore the metabolic production of water, and prescribe 1500 mL of fluid in a ventilated patient.

this amount is less than in nonventilated subjects because all gases are humidified. In practice, metabolic production of water is usually ignored, allowing a total intake of 1500 mL/day; this represents a baseline volume that needs to be reviewed following clinical and biochemical assessment of plasma volume and total body water. Nevertheless, in balance, this volume should be sufficient to generate a urine output of approximately 800 mL/day or 0.5 mL/kg/hour; because the normal daily solute load excreted by the kidney is approximately 600 mOsm, this is easily achieved by the normal kidney with this urine volume by concentrating urine to 700 to 800 mOsm/L. The planned sum of enteral and parenteral maintenance fluids, however, may be less than this because of obligatory fluids given with drug infusions and hydrostatic pressure transducer flush (approximately 3 mL/hour per transducer). Other factors influencing maintenance fluids include the size of the patient, covert losses, such as a diaphoresis, fever that increases fluid loss by approximately 10 mL/kg/day for each degree of temperature elevation, and the ease of supplying adequate nutrition. Although 1500 mL is given as an adequate maintenance fluid volume, many centers use greater volumes, and many patients tolerate greater maintenance fluid volumes.

THE DRY APPROACH

The neurohumoral response to positive-pressure ventilation tends to retain sodium and water, which may lead to both peripheral and pulmonary edema. Daily weights are inconvenient and infrequently performed in ventilated patients. Peripheral edema needs to be carefully sought, and is often evident in the limbs of bedridden patients, and as a wedge-shaped swelling in the flanks. Pulmonary edema is typically detected as dependent crackles on auscultation, but this is a late sign and requires an appropriately placed stethoscope. Other techniques include chest radiographs and measurement of extravascular lung water. In addition to lack of sensitivity, these methods may be troublesome to interpret in disease states such as ALI.

Moderate hypohydration (mean 4.5% loss in body weight) leads to a reversible improvement in lung volume and airflow resistance in normal subjects.[24] Excess fluids may lead to pulmonary edema, which is associated with impaired oxygenation, prolonged ventilation and ICU stay, and difficulty weaning. In both ALI and ARDS,[25] however, and in acute cardiogenic pulmonary edema,[26] extravascular lung water does not correlate with CVP or pulmonary artery occlusion pressure (PAOP). Although the PAOP is an important determinant of the pulmonary capillary filtration pressure, the extravascular lung water is also influenced by permeability and temporal effects. In acute pulmonary edema, empiric treatment with diuretics, nitrates, and ventilator support will often lead to marked reduction of CVP and PAOP before resolution of the pulmonary edema.[26] Indeed, there may be transient hypovolemia secondary to extravasation of fluid in the lung, requiring volume loading.

In ALI and ARDS, extravascular lung water is usually elevated despite normal filtration pressure. Excess lung water portends a worse outcome.[27] Patients with ARDS who achieve a significant reduction in PAOP[28] or total body water, as estimated from weight loss or cumulative fluid balance,[29] are more likely to survive. Prospective, randomized studies report improved oxygenation in hypoproteinemic patients with ALI when a negative fluid balance was produced using furosemide and concentrated albumin;[30] and management of pulmonary edema according to lung water, as compared to PAOP, can lead to a lower cumulative fluid balance, fewer ventilator days, and shorter ICU stay.[31] Prevention of acute left-ventricular failure by diuresis allows weaning in some ventilator-dependent patients with chronic obstructive pulmonary disease.[32] Positive fluid balance is associated with increased mortality in both ALI,[2] and in critically ill patients with acute kidney injury.[33] Liberal fluid management in ALI reduces ventilator-free days and increases ICU stay,[1] with a trend to increased dialysis (14% vs. 10%, $p = 0.06$) consistent with reduced recovery of renal function with fluid overload in acute kidney injury.[33] An important aspect of these data is that the patients were enrolled following the diagnosis of ALI in ventilated patients, and may not apply to the initial resuscitation phase. Taken together, these data suggest that accumulation of excess fluid is common, often difficult to detect, and may be associated with serious adverse events, and mortality.

Replacement Fluids

There is little argument regarding replacement of excess fluid loss. Once the volume becomes significant or contributes to difficulties with fluid balance, it should be replaced. Table 65-3 lists typical electrolyte compositions of gastrointestinal fluids. In the setting of a postobstructive diuresis, it is

TABLE 65-3: COMPOSITION OF GASTROINTESTINAL LOSSES

	Volume (mL)	Na^+ (mmol/L)	K^+ (mmol/L)	Cl^- (mmol/L)	HCO_3^- (mmol/L)
Salivary	500 to 1000	50	20	40	30
Gastric	1500	60 to 100	10	150	30(H^+)
Pancreatic	400 to 1000	140	5	75	115
Bile	400 to 1000	140	5	100	35 to 60
Ileal	1000 to 3000	140	5	70 to 115	30 to 50
Colon		60	70	15	30

As noted above, gastric fluid is usually acidic with an H^+ concentration of approximately approximately 30 mmol/L; this will be markedly reduced by the use of proton pump inhibitors or H_2-antagonists.

common to use 0.45% normal saline with 10 mmol KCl per 500-mL flask; however, greater certainty regarding composition of excess fluid losses can be gained by measuring the electrolyte composition.

Resuscitation Fluids

Critically ill ventilated patients commonly require administration of resuscitation fluids to correct hypovolemia. Underpinning the use of resuscitation fluids is the relationship between increased ventricular preload and increased stroke volume. The trigger for a bolus of fluids often appears fairly obvious: for example, hypotension in a patient with overt bleeding. On other occasions, it may be unclear as to whether a patient will be fluid responsive or whether hemodynamic support is indicated. Yet, early recognition of the need for fluid resuscitation with rapid and titrated administration cannot be underestimated.

CHOICE OF RESUSCITATION FLUIDS

A variety of isotonic and hypertonic fluids have been examined for resuscitation, with varied results. This is often simplified as the "crystalloid versus colloid" controversy. Colloids are fluids with oncotically active contents, such as albumin (molecular weight 66 kDa), which theoretically should ensure that the fluid primarily expands the plasma volume, with little contribution to interstitial volume and edema. If permeability is increased, however, these oncotic substances may also leak across into the interstitium possibly contributing to edema formation. Table 65-4 lists typical electrolyte compositions of commonly used crystalloids and colloids.

Blood and Blood Products. These fluids preferentially expand the plasma volume, and may be indicated for appropriate correction of coagulopathy or maintenance of oxygen carriage and delivery. An important distinction needs to be made between stable and unstable patients when considering transfusion. Data from a large randomized study of stable critically ill patients supports use of a restrictive transfusion policy using a hemoglobin threshold of 7 g/dL, to aim for a target hemoglobin of 7 to 9 g/dL.[34] Although even mild degrees of anemia can result in angina in patients with severe coronary artery disease, observational data of transfusion practice in acute myocardial infarction do not strongly argue for a higher transfusion threshold.[35] In unstable patients a different approach should be considered, and recent recommendations for management of severe

TABLE 65-4: COMPOSITION OF TYPICAL CRYSTALLOIDS AND COLLOIDS

	Osmolality	Na^+	K^+	Cl^-	Organic Anion
0.9% saline[a]	300	150		150	
Hartmann's solution[a]	274	129	5	109	29 (lactate)
Ringer's lactate	272	130	4	109	28 (lactate)
Plasma-Lyte 148	296	140	5	98	50 (acetate, gluconate)
Albumex 4[b]	260	140		128	6.4 (octanoate)
Gelofusine[c]	283	144		120	
Dextran 40 in 0.9% saline	325	150		150	
Dextran 70 in 0.9% saline	306	150		150	
Hetastarch 6% in 0.9% saline	310	154		154	
7.5% saline in 6% dextran 70	2567	1283		1283

sepsis and septic shock suggest a transfusion threshold of 100 g/L during the initial 6-hour resuscitation period.[36]

Crystalloid or Colloid Resuscitation. Comparing colloids and crystalloids for fluid resuscitation in critically ill patients, a recent Cochrane review[37] and a megatrial (total: 6997 patients) of saline versus albumin (SAFE)[38] found no difference in outcome. In the SAFE study more than 60% of the patients were ventilated, and the trigger for fluid loading was based on common clinical grounds and clinician judgment. Although specific groups, such as post–cardiac surgery, post–liver or post–kidney transplantation, and burns were excluded, the data from the SAFE study are widely applicable to critically ill patients.[39] In current practice,[40] there is wide variation in the use of crystalloids and colloids between countries, but colloids are used more often. Crystalloids offer equivalent efficacy, cost, and fewer adverse effects, while colloids offer more rapid volume correction, longer duration of action, reduced risk of pulmonary and interstitial edema, and they may be more appropriate for the clinical setting. Although clinical practice will be influenced by the SAFE study, it seems likely that issues such as patient subgroups, cost and availability, and clinician preference will still influence choice of fluid for volume expansion.

Albumin. Albumin is usually administered as either an isoosmotic solution (e.g., 4% albumin, which has 40 g/L albumin and sodium 140 mmol/L) or as a more concentrated form (e.g., 20% albumin). It appears to be the safest of the commonly used colloids[41] with a reported serious adverse event rate of approximately 1 per 10^6 infusions.[42] Compared to albumin, the anaphylactoid reaction rates of comparable colloids are higher with risk ratios approximately 2 for dextran, approximately 4.5 for hydroxyethyl starch, and approximately 12 for gelatin, with a pooled rate of approximately 9 per 10^5 infusions.[41] In normal subjects, albumin has a metabolic half-life of 16 to 20 days, with a turnover of 12 to 15 g/day.[43] The normal escape of albumin from plasma occurs at about 10% per hour, which is markedly increased during sepsis with 32% of the initial rise following albumin administration lost by 4 hours.[43] Increased catabolism and reduced production of albumin by the liver also contribute to reduced serum albumin levels in critically ill patients. Albumin binds numerous substances such as fatty acids, calcium, thyroxine, amino acids, and hydrogen ions; in addition, many commonly used drugs such as warfarin, phenytoin, midazolam, and antibiotics are highly protein bound.[23] Consequently, hypoalbuminemia may have important physiologic and pharmacologic effects.

Post hoc analysis of the SAFE study suggested that patients with severe traumatic brain injury may have a higher mortality rate with albumin resuscitation (relative risk [RR]: 1.88; 95% confidence interval [CI]: 1.31 to 2.70; $p < 0.001$),[44] and that patients with severe sepsis[45] may have a reduced mortality rate following multivariate logistic regression with adjustment for baseline factors, adjusted odds ratio for death for albumin versus saline was 0.71 (95% CI: 0.52 to 0.97; $p = 0.03$). In patients with severe liver disease and spontaneous bacterial peritonitis, albumin reduces renal dysfunction and mortality.[46] Circulatory dysfunction following paracentesis in cirrhotic patients, defined as an increase in plasma renin activity, is reduced with albumin as compared to gelatin, dextran,[47] or saline,[48] and albumin appears preferable to gelatin for reversal of diuretic-induced hepatic encephalopathy, possibly caused by a reduction in oxidant stress.[49] Finally, albumin and furosemide may have some benefit in hypoproteinemic patients with ALI.[30]

Hydroxyethyl Starch. Hydroxyethyl starch is available in a variety of molecular weights (high, medium, and low: 450 to 480, 130 to 200, and 40 to 70 kDa), C2:C6 ratios (high and low: >8, <8), and molar substitutions (high or low: 0.6 to 0.7, 0.4 to 0.5), which alter their breakdown, intravascular half-life, and in vivo molecular weight.[50] There are, however, significant concerns regarding their safety. The bleeding risk after cardiac surgery may be increased, and starches have been associated with hepatic dysfunction, pruritus, and renal dysfunction;[51] the high in vivo molecular weight[50] is thought to contribute to hyperoncotic renal injury.[52] The newer, smaller, lower half-life starches and volumes less than 1500 mL tend to be associated with few adverse effects,[50] and the starches are commonly used as colloids for resuscitation. There are concerns, however, that even the newer starches increase the risk of renal dysfunction,[53] and their routine use has not been recommended.[54]

Other Colloids. Dextrans are rarely used as volume expanders in ventilated patients because of increases in both bleeding risk and allergic reaction,[41] and possible increased risk of renal dysfunction.[54] They are glucose polymers of either average molecular weight 40 or 70 kDa, with dextran 70 sometimes used to reduce red cell and platelet sludging. Gelatins are a group of volume expanders with a low molecular weight (35 kDa), leading to a half-life of approximately 2 hours. Again allergic reactions are more common, and the main use of gelatins is outside the ICU or for short-lived periods of volume expansion, such as post–cardiac surgery.

Crystalloids. Crystalloids are usually isotonic solutions (e.g., 0.9% saline), but hypertonic solutions (e.g., 7.5% saline) have been increasingly used, particularly in the prehospital management of trauma where this may correct hypotension and reduce cerebral edema. A double-blind, prospective, randomized study, however, comparing 7.5% saline with Ringer lactate solution in 229 prehospital trauma patients, with a systolic BP less than 100 mm Hg and a Glasgow Coma Scale score less than 9, found similar rates for hospital mortality and 6-month neurologic outcome.[55] Large volumes of 0.9% saline, or colloids that contain this electrolyte composition, may lead to a non–anion gap acidosis. An alternative approach is to use balanced crystalloids, such as Ringer lactate (or Hartmann solution), which contain a modest amount of organic anion (e.g., lactate or acetate)

that is metabolized to bicarbonate, and tend to maintain a more normal acid–base state. Various adverse effects, such as increased production of nitric oxide, ALI, hypotension, renal dysfunction, impaired gastric perfusion, nausea, abdominal pain, and bleeding have been attributed to this acidosis.[56,57] Apart from the change in acid–base state, however, there is little evidence of improved clinical outcome with a balanced solution.[58]

Isotonic fluids freely distribute into the extracellular space leading to edema and greater volume requirement than colloids. Although the ratio of crystalloid to colloid needed to achieve the same effect is expected to be at least 3:1, in the SAFE study it was 1.4:1.[38] This was associated with a small but significantly greater heart rate, however, and both lower CVP and transfused volume in the crystalloid arm. In normal subjects, rapid infusion of 0.9% saline at 30 mL/kg over 20 to 30 minutes may reduce forced vital capacity, reduce forced expiratory volume in 1 second,[59] and produce premature airway closure and hypoxemia.[60] Maximum oxygen consumption may also be reduced, possibly because of edema of skeletal muscle and impaired O_2 diffusion.[61] A smaller volume of rapidly infused saline (10 mL/kg), however, only leads to adverse effects in patients with left-ventricular dysfunction.[61] Although there are no direct comparisons of crystalloid with colloid loading, these adverse effects, and the benefits of reducing lung water, argue for care with crystalloids. If a choice is available, it also seems sensible to use a balanced electrolyte fluid, provided there is adequate hepatic function and perfusion to metabolize the associated organic anion.

MONITORING FLUID THERAPY

An excess of body water in relation to sodium is manifest as hyponatremia, and deficiency of water in relation to sodium as hypernatremia, which is often associated with a disproportionate increase of urea relative to plasma creatinine. Factitious results (e.g., hyponatremia in the setting of hyperglycemia) and coexistent disease processes, such as Addison disease, may result in hyponatremia, while sepsis and gastrointestinal blood are other common causes of a disproportionate rise in urea.

Monitoring of both the trigger and response to volume loading can be very useful because excessive fluid therapy can result in adverse events, and only 40% to 72% of critically ill patients increase stroke volume or cardiac output with volume loading.[61] The SAFE study[38] used simple triggers for volume loading, while recent guidelines for management of severe sepsis and septic shock[36] used a lower mean BP threshold (65 mm Hg) and aimed for central or mixed venous oxygen saturation equal to or greater than 70% based on improved survival and reduced organ dysfunction in a randomized study of early goal-directed therapy.[63] Although perioperative mortality may be reduced in high-risk patients with a strategy that targeted increased oxygen delivery,[64] studies in critically ill patients show no benefit[65] or a worse outcome,[66] perhaps reflecting later intervention when organ dysfunction has already been initiated.

Minimally Invasive Methods

CHEST RADIOGRAPHS

In addition to heart size, and the presence of pulmonary infiltrates and pleural effusions, the vascular pedicle width, measured as the horizontal distance between a line dropped from the point where the left subclavian artery leaves the aortic arch to the point where the right main bronchus crosses the superior vena cava, may provide an additional useful measure of volume status. A vascular pedicle width greater than 63 to 70 mm can help distinguish hydrostatic from permeability pulmonary edema,[67] and it falls with negative fluid balance in ALI.[68] A decrease in vascular pedicle width of 5 mm, however, corresponded to a 3.2-L negative balance,[68] suggesting that this technique may not be sensitive enough for acute fluid management decisions, and most patients with permeability pulmonary edema have some signs usually ascribed to volume overload.[67]

DYNAMIC MEASURES

Blood Pressure Variation. Positive-pressure ventilation alters left-ventricular loading conditions leading to both systolic pressure and pulse pressure, and stroke-volume variation during the respiratory cycle, which is predictive of an increase in cardiac output, following a fluid bolus.[69] Validation, however, has mostly been in stable patients without impaired left-ventricular function, and there are important preconditions and caveats. There should be absence of inspiratory or expiratory effort and a stable cardiac rhythm. Because these dynamic measures have also not been shown to be predictive of fluid responsiveness when used with smaller tidal volumes or in the presence of pulmonary hypertension,[69] and respiratory effort is present in many critically ill patients, they have limited applicability. Similar reservations apply to the recently described use of respiratory variations in the preejection period (the time between the Q wave on the electrocardiogram and the upstroke of the arterial pressure waveform)[70] and stroke volume[71] as a measure of fluid responsiveness.

Passive leg raising to 45 degrees results in variable autotransfusion and a temporary increase in venous return, which has been used to test fluid responsiveness. Although the subsequent change in pulse pressure is predictive of fluid responsiveness, the change in cardiac output has a significantly higher predictive value.[72] If patients who increased their CVP by at least 2 mm Hg with passive leg raising are analyzed,[73] then both measures have a higher predictive performance, but again the change in pulse pressure is inferior. An increase in CVP was present in about half of the subjects studied, of whom one-third were fluid responsive, suggesting limited clinical utility.

Ultrasound. Although left-ventricular end-diastolic area is not predictive, echocardiography has been used to assess respiratory variation in the diameter of the vena cava as a measure of fluid responsiveness. In septic patients, a threshold of 36% for superior vena cava collapse during inspiration is both sensitive and specific,[74] and is not correlated with the CVP, but is similar to dynamic pulse pressure changes as a measure of fluid responsiveness. Echocardiography, however, offers the advantage of detection of severe right-ventricular failure, which may lead to false-positive results with pulse pressure variation. Respiratory changes in inferior vena cava diameter also appear promising, but may be invalidated by raised intraabdominal pressure.[75] Because both techniques require similar conditions to those needed for BP variation measures, they may not be widely applicable in the ICU. Lung ultrasound has been promulgated as a measure of subpleural interstitial pulmonary edema,[76] which may reflect PAOP when permeability is normal and in the absence of rapid changes in filtration pressure.

Parameters derived from the esophageal Doppler, such as the heart-rate corrected time to peak flow (a preload measure) and the descending aortic flow, may be used to predict volume responsiveness. A number of studies have used the esophageal Doppler to guide perioperative fluid management; fewer complications and shorter hospital stays were associated with greater fluid administration.[77] The use of this technique, however, appears limited in most ventilated ICU patients; they will not tolerate an esophageal probe without additional sedation. A fixed 70% of the aortic blood flow is assumed to pass to the descending aorta, and patients with irregular cardiac rhythms, an intraaortic balloon pump, or esophageal disease are usually excluded. Although good agreement of esophageal Doppler with thermodilution cardiac output has been reported,[78] others have found substantial variability.[79,80]

Invasive Measures

CENTRAL VENOUS CATHETER

The CVP is determined by the venous return and right-heart function. It is increased by many factors, including high levels of PEEP and decreased venous capacitance; it does not correlate particularly well with right or left end-diastolic volume in critically ill patients. Although a number of studies have not found the CVP predictive of volume responsiveness,[62] it may still be a useful measure.[81] Above a CVP of 12 mm Hg, few patients are volume responsive, and changes in the CVP may be helpful. An unchanged CVP after volume loading is suggestive of volume responsiveness, whereas a large increase is not. Similarly, the absence of a fall in CVP with spontaneous respiratory effort suggests lack of volume response.[81] Rivers et al[63] used a target CVP of 8 to 12 mm Hg, and continuously measured the central venous oxygen saturation in their goal-directed group with a target of equal to or greater than 70%. Under normal conditions, a mixed venous oxygen saturation of 75% corresponds to an intracellular partial pressure of oxygen (P_{O_2}) of 11 mm Hg, but this falls to 0.8 mm Hg at a saturation of 50%. Consequently, central venous access may be useful in determining fluid responsiveness or the need for other means of augmenting cardiac output.

Transpulmonary thermodilution is a technique that allows intermittent and continuous measurement of cardiac output, and closely agrees with pulmonary artery thermodilution measurement.[82] Additional measures include extravascular lung water and global end-diastolic volume, which is a measure of the total volume of the four heart chambers, and may be a useful preload measure.[83] However, concern has been expressed about the accuracy, including thermally silent areas as a result of hypoxic pulmonary vasoconstriction, of the extravascular lung water measure.[84,85] In addition to central venous access, this technique requires insertion of a thermodilution arterial catheter, which is usually inserted via the femoral artery although it can be inserted via the brachial artery. Although it is a promising technique, it does increase the risk of complications, and requires further investigation.

PULMONARY ARTERY CATHETER

Although the PAOP should be a measure of left-ventricular preload, it correlates poorly with left-ventricular end-diastolic volume in critically ill patients, and is a poor marker of volume responsiveness. Measurement of the PAOP requires insertion of a pulmonary artery catheter, which may allow measurement of a number of variables, including cardiac output, pulmonary artery pressure, mixed venous oxygen saturation, and right-ventricular volumes; numerous derived variables can be subsequently calculated. The accuracy and interpretation, however, of some of these data have been questioned, and serious complications from the catheter and its insertion are well described. Retrospective analysis found that use of the pulmonary artery catheter in critically ill patients was associated with increased mortality, hospital stay, and costs despite careful adjustment for severity.[86] A more recent prospective observational study found that there was a marked increase in postoperative events.[87] Nevertheless, data measured by the pulmonary artery catheter can be extremely useful in particular patients, and central venous oxygen saturation,[63] a surrogate for mixed venous oxygen saturation, may be an important end point for resuscitation.

Mortality, morbidity, and complications are not influenced by the presence of a pulmonary artery catheter in patients with shock and/or ARDS.[88,89] Although high-risk surgical patients may have a higher rate of pulmonary embolism,[90] this was not confirmed by the ARDS Network trial comparing pulmonary artery with central venous catheter guided management in ALI.[89] Apart from more insertion-related arrhythmias with the pulmonary artery catheter, this large trial did not confirm the suggestion of more complications. In the subgroup of surgical patients, randomization to the pulmonary artery catheter group was associated with

increased fluid administration and fewer ventilator-free days,[91] suggesting that interpretation and consequent management decisions have a greater influence on outcome than does the catheter itself.

CONCLUSION

As both physiologic measures and outcome are influenced by fluid management, an integrated approach is essential to the management of ventilated patients. The tendency to retain sodium and water, the adverse effects of pulmonary and peripheral edema, and improved outcomes from both observational and randomized clinical trials argue for a parsimonious approach to maintenance fluids, provided there is adequate resuscitation. Although colloids appear as safe as crystalloids, there may be particular circumstances in which one is preferable, even though it remains unclear whether balanced salt solutions improve clinical outcomes. Dynamic measures of fluid responsiveness, such as respiratory variations in BP, are superior to static measures, such as an isolated CVP or PAOP reading, but common clinical conditions often render these data invalid. Perhaps, more important than the choice of fluid, or assessment of fluid responsiveness, is the definition of integrated pathways that can be simply applied to patient care.

THE ETHICS OF WITHHOLDING AND WITHDRAWING MECHANICAL VENTILATION

Michael E. Wilson
Elie Azoulay

To save the lives of critically ill patients, intensivists utilize sophisticated technologies to support vital organs until treatments reverse underlying medical conditions. Most patients recover from the acute event, a few die rapidly, and the remainder fail to improve and remain dependent on life-sustaining treatments. In this last group, the chance of recovery changes from one day to the next, and questions often arise about the appropriateness of continuing life support, especially mechanical ventilation.[1]

Over the last half century, health care professionals in intensive care units (ICUs) have been forced to make decisions for patients who remain dependent on mechanical ventilation with death in the short term as the only possible outcome.[2] In these patients, continued treatment in the hope of cure is rarely the best option.[3] Mechanical ventilation may be prolonged beyond the point of beneficence, robbing patients of their dignity and families of their right to honest prognostic information and an opportunity to prepare for bereavement. The best option here is a decision to forego life-sustaining treatment.

Because respiratory failure, shock, and coma are common reasons for ICU admission, mechanical ventilation is the most widely used life-sustaining treatment in the ICU.[4] Thus, mechanical ventilation is also the most common target of a decision to forego life-sustaining treatment.[5–10] Although most patients are successfully weaned off the ventilator, a few die while on the ventilator or immediately after weaning.[11] Ideally, a decision to forego life-sustaining treatment, which consists of moving from curative care to comfort care, should be based on the patient's wishes.[12,13] When the issue of comfort care arises, however, fewer than 5% of patients are able to participate in decisions, and knowledge of their preferences is usually unavailable.[14,15] Therefore, concern that curative care may be harmful is often voiced first by the ICU team, which then broaches the issue with the family or surrogate decision maker. Thus, barely a few years after the creation of ICUs, intensivists realized that, in addition to fighting death, their duties included the daunting task of accepting and managing death. This task requires (a) identifying situations in which all hope of recovery is lost and life-prolonging treatments become death-prolonging treatments, which should be withdrawn or withheld; (b) promptly initiating a continuous process of family care based on sensitive and straightforward information and communication; and (c) improving the ability to manage death, via epidemiologic studies of practices, interventional studies of end-of-life

strategies, and continuing education aimed at honing the information and communication skills of all ICU professionals. Warding off death and restoring self-sufficiency have been the main goals of intensivists for decades; now, ICU professionals are becoming acutely aware that they must develop a professional approach to dying patients, learn what makes a "good death," and provide dying patients and their families with support, reassurance, comfort, dignity, and freedom from guilt.

The literature on end of life in the ICU comprises epidemiologic studies (descriptive, deductive, or quantitative) and qualitative studies of theoretical concepts that allow subtle interpretations of structures, experiences, roles, interactions, and perspectives. This review provides an interpretation of published data on limiting mechanical ventilation and other life-supporting treatments in patients dying in the ICU. Its goal is to help readers understand and organize the decision-making process within an ICU team and to ensure that decisions are implemented so as to give the patient a "good death" and families bereavement support.

FUNDAMENTAL ISSUES OF ETHICS

The field of bioethics, born in the late 1960s, rests on four fundamental ethical principles (beneficence, nonmaleficence, autonomy, and distributive justice) and describes a spectrum of patient–physician relationship styles ranging from paternalism to autonomy (Fig. 66-1).[16] The four fundamental ethical principles guide decisions in the ICU management of dying patients and their families. Regarding beneficence and nonmaleficence, we discuss studies that address the specific needs and expectations of dying patients. We then briefly contrast paternalism and autonomy, and argue that the long-standing controversy opposing these two models should give way to emphasis on the shared decision-making model. We also discuss the double-effect principle accepted by the U.S. Supreme Court, Society of Critical Care Medicine recommendations, and international consensus in the support of the use of sedation and analgesia to relieve symptoms, provided death is not intended, although it may be foreseen.[17–20] The unresolved debate regarding the relative merits of terminal extubation and terminal weaning for taking dying patients off the ventilator is mentioned. Regarding justice, we do our utmost to convince the reader that cost considerations are irrelevant to a decision to forego life-sustaining treatment.

In a study by Singer et al,[21] patients identified five domains of quality end-of-life care: adequate relief from pain and anxiety;[22] avoiding inappropriate prolongation of dying; achieving a sense of control; relieving burden; and strengthening relationships with loved ones. When a patient is dying, intensivists must make it clear that they are dedicated to providing optimal care throughout the dying process;[23] to treating the patient with respect and dignity; and to relieving pain caused by physical, emotional, social, and spiritual factors.[24,25] Patients fear to be abandoned. They should be assured that the doctor is and will remain on their side, stopping useless interventions, and providing treatments that ensure comfort.[26] Encouraging family and friends to be present at all times is another component of this effort to ensure beneficence; however, some family members may be unbearably distressed by having to spend long hours with

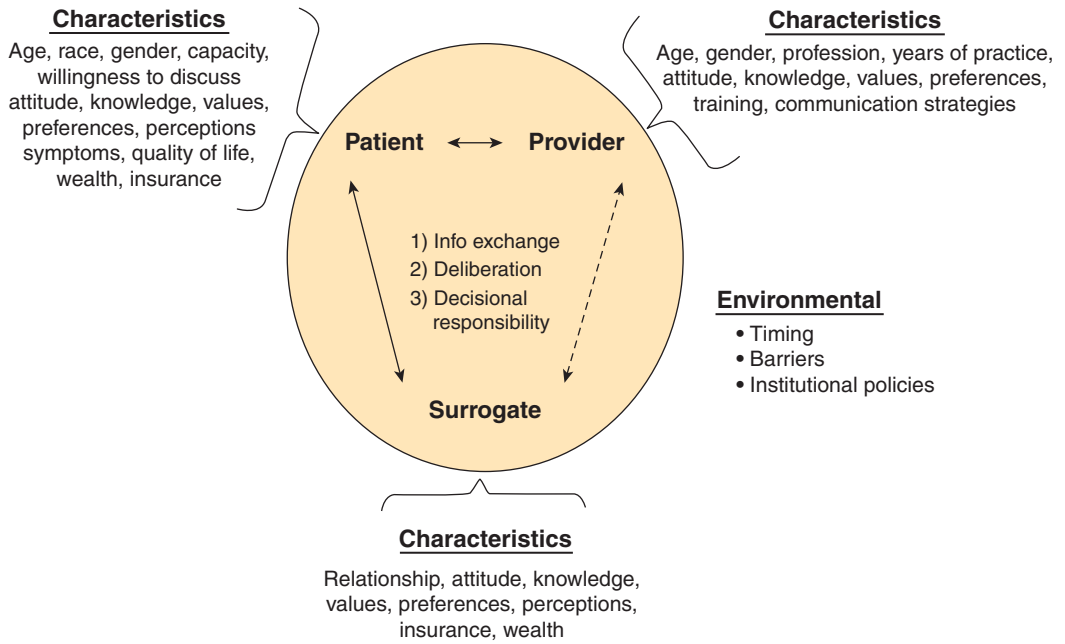

FIGURE 66-1 Conceptual framework of a patient–physician interaction. (Adapted, with permission, from Heyland DK, Rocker GM, Dodek PM, et al. Family satisfaction with care in the intensive care unit: results of a multiple center study. *Crit Care Med*. 2002;30:1413–1418.)

their dying relative. The presence of a chaplain, chosen by the patient and family, and access to religious rites should be encouraged.[27]

After years of heated debate opposing autonomy and paternalism, a model in which decision making is shared with family members is gaining precedence (Fig. 66-2). This model upholds patient autonomy[28] without forcing family members to be involved in decisions they do not want to make[29] or are not ready to make.[30] The shared decision-making model stands in sharp contrast to paternalism, in which the physician shields the patient, making decisions alone so as to protect the patient and family from the potentially harmful effects of making painful decisions.[13] Because most ICU patients are unable to make decisions,[31,32] sharing in a decision to forego life-sustaining treatment shifts to the family members.[12] Attempting to wake ICU patients so that they can participate in decisions in the name of autonomy clashes violently with the principles of beneficence and nonmaleficence.[33] Beneficence requires that family members be empowered to understand the patient's situation,[34] to identify and meet their expectations,[35,36] and to gain awareness of possible anxiety or depression that might impair their decision-making capabilities.[37] Under no circumstance should anxiety or depression in family members be used to justify benevolent paternalism; on the contrary, communication with families must receive close attention as a means of empowering families to share in decisions.[12] Reports from Canada, Sweden, and the United States describe sharing discussions and decisions as rational[38] and as crucial to family satisfaction.[39–42] In addition, studies of family outcomes several weeks or months after the death of a patient in the ICU have highlighted major difficulties and profound inadequacies in information.[27,43–45] Finally, nonmaleficence in this setting requires intensive communication with families if needed; a multidisciplinary approach can be used, or external ethical advice obtained, with the objective of empowering families to achieve their own goal (whether this is sharing in decisions or leaving decisions to the intensivists) and of convincing families that comfort care is preferable over aggressive interventions.[46–48] When family members have not received optimal information, involving them in the decision-making process probably carries a risk of subsequent posttraumatic stress and abnormal grief reactions.[30]

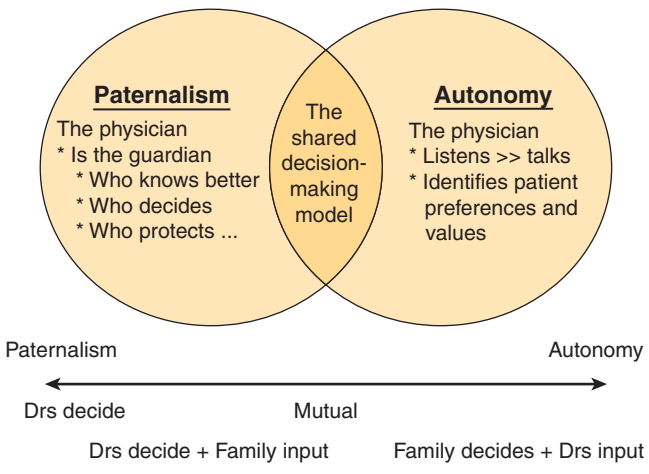

FIGURE 66-2 The shared decision-making model.

The SUPPORT (Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments) studies showed a high rate of unacceptable pain in dying patients.[49,50] When withholding or withdrawing mechanical ventilation is in order, clinicians have the duty to emphasize comfort and to relieve pain and anxiety in their patients. Opioids and anxiolytics remain the reference treatment for these symptoms.[17–20] Opioids may hasten death by inducing respiratory depression,[51] but this risk is legally and ethically acceptable.[19,52–54] In contrast, use of high-dose opioids to cause death by a person making the decision alone is not consonant with optimal end-of-life care. This is voluntary euthanasia and is illegal, even in The Netherlands, Belgium, and the states of Oregon and Washington, where patients can request and obtain the assistance of a physician to commit suicide.[19,52] Because it is the physician's intention that separates opioid use to relieve pain and anxiety from opioid use to hasten death, the line between the ethical and the unethical, the legal and the illegal, is subjective.[18,55] Although some physicians may tend to use higher doses to ensure patient comfort, this practice cannot be likened to euthanasia.[56] Nevertheless, eliminating ambiguity from end-of-life decisions can be extremely difficult.[57]

The optimal method for taking dying patients off the ventilator remains actively debated. The controversy consists of advocates of terminal weaning, in which volumes, respiratory rate, and fractional inspired oxygen concentration (FI_{O_2}) are reduced gradually, versus proponents of terminal extubation with sedation,[58] which restores the normal appearance of the patient but carries a risk of respiratory secretion accumulation with asphyxia and gasping.[59,60] Terminal weaning is perceived as less active and therefore less distressing for health care professionals; furthermore, the family members are spared the ordeal of witnessing gasps, which they interpret as suffering.[61] In addition, extubation may wrongly suggest to the family that the patient is better and no longer needs the ventilator.[61] Opponents of extubation for ventilation withdrawal have pointed out that even patients who survive extubation remember the weaning period as a time of stress, discomfort, loss of hope, and extreme fear.[62]

Cost considerations[63] have entered into the treatment-limitation debate on the grounds that using ineffective treatments in one patient may deprive another patient of lifesaving treatment or ICU admission, thereby violating the principle of distributive justice.[64] Guidelines[65] suggest that elderly patients and patients with chronic conditions (cancer, hematologic malignancies, or chronic obstructive pulmonary disease) should be denied ICU admission or should receive a decision to forego life-sustaining treatment earlier than other patients. Whether the principle of distributive justice applies to a decision to forego

life-sustaining treatment is controversial, and the relevance of the cost/efficacy concept to ICU management has been challenged.[66] Denying ICU admission to a seriously ill patient for cost-containment reasons makes little sense, because other resources will then be used for the patient elsewhere, sometimes for a longer period and to the detriment of patient comfort.[67] Furthermore, patient-centered care allows the patient to die with dignity, free of pain and anxiety, while placing the family in optimal conditions for preparing the bereavement process.[64,68,69] Interventional studies of intensive communication with families of patients dying in the ICU found cost savings related to conflict prevention[70,71] that diminished the use of ineffective treatments.[46–48,72]

TERMINOLOGY

Five mutually exclusive categories of a decision to forego life-sustaining treatment have been defined. The first category is the do-not-resuscitate order for cardiac arrest. The second category comprises a decision to forego life-sustaining treatment in patients who are in a chronic vegetative state. Third is the decision to withhold a potentially beneficial treatment (e.g., mechanical ventilation, catecholamine administration, or dialysis). Fourth is withdrawal of life-sustaining treatment. The fifth category involves active induction of death (administration of a treatment that results in death). Do-not-resuscitate orders are not relevant to the present chapter. We do not discuss patients in a chronic vegetative state, because they raise specific issues whose resolution relies on concepts that do not apply to other ICU patients. Neither do we deal with euthanasia (injection of a lethal substance), which has been used in the past but is no longer an acceptable component of end-of-life care in ICU patients. Euthanasia does not constitute care, virtually never involves a rational collegial decision-making process, leaves anxiety and pain unrelieved, and fails to respect the dignity of the patient and family. We believe that euthanasia should be banned from ICUs and all other places where medical care is delivered.

EPIDEMIOLOGY OF THE DECISION TO FOREGO LIFE-SUSTAINING TREATMENT IN THE INTENSIVE CARE UNIT: GEOGRAPHIC, CULTURAL, AND RELIGIOUS VARIATIONS

In most countries, most deaths in the ICU are preceded by a decision to forego life-sustaining treatment.[6,7,9,40,56,73–81] In addition, the incidence of decisions to forego life-sustaining treatment may be increasing over time.[82,83] In patients discharged alive from the ICU, a decision to forego life-sustaining treatment taken in the ICU influences hospital survival.[84] In practice, withholding mechanical ventilation precedes or occurs concomitantly with withdrawal of all other life-sustaining treatments.[10,73] Withholding and withdrawal occur within 3 days after ICU admission, and the patient usually dies within the next 24 hours.[85] There is widespread agreement that there is no ethical difference between withholding and withdrawal,[86] although withdrawal has been described as more difficult for intensivists[74] and is not used in some countries.[73]

TABLE 66-1: VARIATIONS ACROSS COUNTRIES IN THE INCIDENCE OF DECISIONS TO FOREGO LIFE-SUSTAINING TREATMENTS AND IN FAMILY INVOLVEMENT IN THESE DECISIONS

Wide variation exists regarding the incidence of decisions to forego life-sustaining treatment (Table 66-1).[87] These variations across countries and cultures have been identified in studies comparing practices,[88,89] studies of responses to ethical scenarios,[74,90] and descriptive studies.[7,9,10,73,75,78,82,91–105] The Ethicus study described the variable practices to forego life-sustaining treatments in thirty-seven ICUs in seventeen European countries (Table 66-2). In southern Europe, the proportion of deaths after unsuccessful resuscitation was greater than in the rest of Europe. In northern Europe, the time from a decision to forego life-sustaining treatment to death was shorter.[73] These data confirm the considerable variability in approaches to bioethical issues in Europe.[88,106]

Additionally, the role given to the patient's and family's opinion in the decision to forego life-sustaining treatment also varies widely, although compassion and respect for the patient are universally recognized as crucial.[12,13] Some differences may be explained by the fact that in the late 1980s the United States adopted a model based on patient autonomy and self-determination,[96,107] whereas other countries kept a paternalistic model in which the physician

alone determines the appropriate level of treatment intensity.[7,9,74,90,91,108,109] Evidence, however, suggests that variability exists within a given country, with some physicians in traditionally paternalistic countries involving patients and families in the life support decision making process, and vice versa.[75,78,82,94]

Religious beliefs of both patients and providers are reported to influence the attitudes of intensivists towards life support decisions.[88,110,111] The Ethicus study identified variations across religions with Jewish, Greek Orthodox, and Moslem physicians more likely to withhold therapy, and Catholic and Protestant physicians more likely to withdraw therapy. Time to first therapy limitation also varied from 1.6 days for Protestant physicians to 7.6 days for Greek Orthodox physicians.[73,112]

Variable ICU admission rates and policies may influence the variable incidence of decisions to forego life-sustaining treatment. The SUPPORT study group found that half the patients with chronic diseases were in the ICU within the 3 days preceding death and that one-third of patients spent at least 10 days in the ICU during the hospitalization that preceded death.[50] In 1995, 20% of deaths in the United States or Canada occurred in the ICU.[113,114] In other countries, ICU admission policies are more restrictive,[102,115–117] so that comparisons are inherently biased. Predictors of increased end-of-life ICU utilization include age, number of comorbidities, hospital type, number of available hospital beds, and lack of outpatient to inpatient continuity of care.[118–120] The high incidence of in-hospital and in-ICU deaths, which has emerged over recent decades in industrialized countries, must be considered under the harsh light of data showing poorer quality end-of-life care in hospitals and ICUs as compared to home hospice care,[121,122] in addition to minimal gains in survival.[123] Important differences also exist among race. In the United States, black and Hispanic patients are more likely to die in an ICU[124] and incur 30% to 50% more health care expenditures in the 6 months preceding death than white patients,[125] even after control for variables such as geography and socioeconomic status. Additionally, there is limited evidence that white patients who prefer intensive end-of-life care are more likely to receive it than are black patients with the same preference.[111]

LEGAL DECISIONS TO DATE

The courts recognize that withholding or withdrawing life-sustaining treatment and giving palliative care are legal. In the United States, the ethical principle informing laws that allow decisions to forego life-sustaining treatment is autonomy, manifesting as informed consent from the patient or family, who can also refuse treatment withholding or withdrawal.[14,19,52,126] Among European countries, The Netherlands was the first to allow euthanasia and physician-assisted suicide.[106] Belgium followed suit in 2002.[127,128] Nevertheless, in neither country does the law deal specifically with patients receiving life support in the ICU.[129] In France, the Senate has passed a law authorizing physicians to let patients die if they are kept alive only through artificial means, treatment is futile, and death is imminent.[130]

After the advances in mechanical ventilation achieved in the 1970s and 1980s, the notion that mechanical ventilation should at times be withheld or withdrawn was deeply disturbing to many intensivists. By the 1980s, however, intensivists could no longer deny that life-sustaining treatment merely prolongs the dying process in some patients.[22,86,107]

The confusion that exists between ethical concepts and legal concepts is frequently disconcerting to intensivists. From both the ethical and legal points of view, a decision to forego life-sustaining treatment is acceptable only when it constitutes an expression of the patient's personal autonomy, that is, when it is made with the informed consent of a competent patient or, when the patient is incompetent, based on knowledge of the patient's wishes. All adults have the right to accept or refuse treatment and to define their preferences and values.[28,33,131,132] This right does not end when an ICU patient becomes mentally incompetent, and it can be exercised by the patient's surrogate decision maker.[14,52] In 1990, the U.S. Supreme Court upheld the withdrawal of life-sustaining treatment at a patient's request;[131] more recently, it stated that decisions to forego life-sustaining treatment in ICUs did not constitute physician-assisted suicide or euthanasia.[133] These rulings apply to all fifty states, in theory at least. Furthermore, the Supreme Court has ruled that physicians cannot use futility

as a basis for making a decision to forego life-sustaining treatment of their own accord. Nevertheless, the Supreme Court issued detailed recommendations on palliative care, acknowledging that sedatives and analgesics may be given, when needed, to alleviate the symptoms of a dying patient, even when this is expected—but not intended—to hasten death (the doctrine of double effect).[19]

The information above relates to the law. Physicians must comply with the laws of their country. A medical decision, however, may be legal yet unethical. We believe that the confusion between ethical principles and legal obligations that exists in the minds of many physicians can distort the decision-making process. When decisions to forego life-sustaining treatment are entirely based on standardized criteria, which comply with the law but ignore the specific factors characterizing each individual patient,[134] they may produce deleterious effects, ranging from loss of opportunity to treat to administration of useless treatments. Furthermore, the confusion between ethical and legal obligations may hinder openness in communicating decisions; for instance, physicians may be reluctant to record the nature and implementation of a decision to forego life-sustaining treatment in the patient's medical record.[135]

When decisions to forego life-sustaining treatment are made, fewer than 5% of patients are able to participate in the discussions or decisions.[136] In addition, patient preferences are usually not known.[20] Consequently, intensivists have turned to families as the primary partners for initiating a decision to forego life-sustaining treatment. The patient may be represented by a surrogate decision maker holding a durable power of attorney for health care; if the patient has not designated a surrogate, the intensivists discuss decisions with family members. The person representing the patient is asked for advice in some countries[130,137] and for decision-making input in others.[19,138] Whether the information on patient wishes used to make a decision to forego life-sustaining treatment in patients receiving mechanical ventilation should be obtained from family members has been challenged. Many families do not understand what is at stake;[139] have no knowledge of the patient's wishes;[140] want, but do not have, written instructions from the patient;[141] have opinions that disagree with patient wishes;[142] and, most importantly, suffer a burden of stress and anxiety that may impair their decision-making capacities.[37]

Advance directives have been suggested as a means of allowing patients to remain in control of their care, even when they have lost their decision-making capacity, as is the case for intubated patients in the ICU.[143] Unfortunately, a complex set of reasons[144] impairs the effectiveness of advance directives in ensuring that patient wishes are honored[145] and that treatments given in the ICU or wards are changed in accordance with patient instructions.[68,146] In addition, patients may change their minds over time, so that advance directives may no longer reflect their wishes at the time decisions to forego life-sustaining treatment are made.[68,144–147] Interestingly, a 1990 survey among members of the American Thoracic Society found that one-third of respondents provided care that contradicted the wishes of patients and surrogates, and that more than 80% unilaterally made and implemented a decision to forego life-sustaining treatment, at times over the objections of patients and surrogates.[92] Finally, the SUPPORT investigators found that 10% of older inpatients with serious illnesses received care they did not want[49] and that advance directives or families' wishes were often disregarded.[50] Having a specifically trained nurse talk to the patients, families, physicians, and other hospital staff members failed to improve compliance with patients' wishes.[50]

THE DECISION-MAKING PROCEDURE: HIGH COMPLEXITY, HIGH STAKES

Evaluating the prognosis is the key issue: When continuing mechanical ventilation and other aggressive interventions that may ensure recovery from the acute life-threatening event that prompted ICU admission, full care must be provided, without which the patient may suffer a loss of chance. Therefore, intensivists must be able to identify those patients whose chances of recovery are virtually nonexistent. For these patients, aggressive care, far from inducing benefits, prolongs the dying process, puts the patient's dignity in jeopardy, and hinders the bereavement process for family members. Clearly, the stakes are extraordinarily high for all concerned with the decision, who must achieve a consensus about what to do and how to do it.

Because decisions to forego life-sustaining treatment force patients, families, and health care professionals to stand very close to the line that separates killing from allowing patients to die, they carry a destructive power that must be acknowledged and kept under control. To this end, intensivists have worked on developing decision-making procedures that maximize objectivity, legitimacy, serenity, and agreement among all those involved. Two main factors govern a decision to forego life-sustaining treatment: the imminence of death and the patient's wishes regarding life support. The first factor was investigated by pursuing two avenues concomitantly: one consisted in defining futility, a concept based on clinical experience, and the other in developing mortality-prediction tools based on physiologic disturbances or organ failures. These efforts were intended to assist in objectively identifying situations that warrant a decision to forego life-sustaining treatment; however, they failed to reduce the complexity of the decision-making process. The second factor, patient wishes, faced a major obstacle: The inability of most patients to express their wishes at the time a decision to forego life-sustaining treatment is considered.[10,20,73] To ensure that patient wishes would nevertheless be honored, three approaches were suggested: advance directives, formal designation of a surrogate decision maker holding a durable power of attorney, and family participation in decisions.

Predicting mortality has relied chiefly on severity scores developed in the United States and Europe[148–151] to characterize patients (based on age, chronic morbidities, recruitment type, and severity of each organ involvement) and to constitute homogeneous patient groups (i.e., groups with a similar risk of hospital death). These scores have proved useful for measuring the performance of ICUs (via determination of the standardized mortality ratio [SMR]) and for establishing homogeneous patient groups for inclusion in therapeutic trials. Their poor calibration and discrimination, however, make them unhelpful for predicting the risk of death in the individual patient. Furthermore, because these scores are determined at a single point in time (ICU admission) and developed in a given population, they fail to reflect changes in organ failures over time[152,153] or advances made in the management of a specific condition.[154] Therefore, mortality-prediction scores are of no assistance in deciding when treatment withholding or withdrawal is appropriate.

Futility is a concept that was widely used to determine that a decision to forego life-sustaining treatment was appropriate. The patient-benefit-centered view defines futility as use of interventions that are unlikely to benefit the patient.[155] We prefer the definition suggested by Schneiderman et al in 1990: "When physicians conclude (either through personal experience, experiences shared with colleagues, or consideration of published empiric data) that in the last 100 cases a medical treatment has been useless, they should regard that treatment as futile," and "if the likelihood of functional recovery after a proposed course of therapy is less than 1%, then physicians may assert the prerogative to withdraw therapy without the consent of the patient or surrogate decision maker."[156]

The concept of futility has been fiercely criticized. Its opponents argue that the definition of futility is neither clear nor reproducible, the concept is clearly intended to increase the power of the physician while undermining patient autonomy, treatment data do not necessarily apply to an individual patient, the 1% cutoff is not supported by scientific evidence, and the use of futility allows physicians to make decisions unilaterally.[157,158] The futility debate ultimately condenses into a conflict in which patients or families and physicians disagree about the patient's right to receive a treatment that is highly unlikely to succeed. The futility concept fails to acknowledge the huge amount of excellent work done by ICU professionals to involve families in the decision-making process and to recognize the emotional and social problems raised by family participation in decision making.[29,30] Rather than speak of the physician's right to withhold or withdraw treatment, we should speak of the physician's duty to prepare the ICU team and the family for a clearly identifiable shift from curative care to care aimed at optimizing patient comfort and dignity while alleviating distress in the family members.[159] ICU teams must move beyond the futility debate toward a position firmly rooted in a care, an ethic that gives a meaningful role to all staff members (physicians, nurses, and other health care professionals) in organizing the decision-making process with the patients and families, while interfacing with health care institutions, third-party payers, and, the general public.[160]

FACTORS ASSOCIATED WITH DECISIONS TO FOREGO LIFE-SUSTAINING TREATMENT

As discussed in the previous section, the two main factors that should influence decisions to forgo life-sustaining treatments are patient preferences and the imminence of death (poor patient prognosis). An assessment of prognosis usually takes into account factors such as patient age, previous health status (cognitive function, self-sufficiency, and chronic morbidities), time spent in the ICU, severity at ICU admission, and worsening organ failure despite ICU management.[7,9,11,73] Nevertheless, these factors may be overshadowed by events or perceptions that develop during an ICU stay,[161] such as dependency on catecholamines and intensivists' perceptions that the prognosis is poor and the condition irreversible.[10] Thus, multiple factors exist and may compete with one another, clearly indicating a need for a rigorous and collegial decision-making process based on consensus-building centered on the patient's and family's preferences.[9,108,162,163] Several studies show that intensivists pay close attention to quality of life.[7,9,74,92,94] Nevertheless, there is evidence that intensivists underestimate the quality of life of their patients, and that quality of life does not influence patient preferences regarding the intensity of treatment received in the ICU.[163]

Studies have found that the frequency and nature of decisions to forego life-sustaining treatment vary with the personal characteristics of physicians and with their experience.[28,164] As pointed out above, religious beliefs and cultural background play a role. In addition, physician gender,[89] specialty,[165] time working in ICUs,[166] working in private versus public institutions,[167] and teaching status of the hospital[78] influence practices regarding end-of-life care. It should be noted that participating in decisions to forego life-sustaining treatment and caring for dying patients has been associated with higher rates of burnout syndrome and conflict in the ICU.[168,169] Conflict increases job strain,[168] and burnout syndrome has been associated with high employee turnover rates, absenteeism, and poor communication with families, all of which may impact the quality of a decision to forego life-sustaining treatment.[169]

Christakis et al identified four major sources of bias affecting the nature of treatments withdrawn from patients in whom a decision to forego life-sustaining treatment had been made.[170] These biases may have clinical, social, and ethical consequences. Intensivists were more likely to withdraw treatments supporting organs that failed for chronic or "natural" reasons than for iatrogenic reasons, treatments started recently, and treatments whose withdrawal would result in immediate death, although when the diagnosis was

uncertain, they preferred treatment withdrawals that resulted in delayed death. Similarly, Asch et al found that intensivists preferred to withdraw treatments that were expensive, scarce, and invasive.[171] The incidence of decisions to forego life-sustaining treatment increases with ICU stay duration, indicating that intensivists respond rationally to persistent or worsening organ failures by adapting their management strategy.[20] Thus, Cook et al identified several time-dependent factors associated with withdrawal of mechanical ventilation: dependency on catecholamines, the physician's prediction of a low likelihood of surviving the ICU stay or a high likelihood of poor cognitive function, and physician perception that the patient did not want life support.[10]

Recent data on prolonged mechanical ventilation in ICU patients showed a high rate of major dependency among survivors.[172–174] Asch et al reported that treatment withdrawal in the ICU usually occurs in the following order: blood products, dialysis, catecholamines, mechanical ventilation, parenteral nutrition, antibiotics, infusions, and enteral nutrition.[175] Whereas Cook et al found that mechanical ventilation was often stopped at the same time as dialysis or catecholamines,[10,176] others reported that mechanical ventilation was sometimes continued after the withdrawal of dialysis and catecholamines.[7,9] In France, nutrition and hydration are rarely withdrawn.[7,9] Thus, even when a decision to forego life-sustaining treatment is made, the sequence of withdrawals is influenced by multiple, complex, nonclinical factors that may seem irrelevant. These factors may be ethical, social, religious, or related to family preferences.[94] In one study, the same intensivists made contradictory decisions about the same clinical scenarios at different points in time.[177] Similarly, our group and others have shown that making a decision to forego life-sustaining treatment influences survival independently of all other factors known to affect survival, indicating that a decision to forego life-sustaining treatment depends in part on setting-specific characteristics that are difficult to identify.[178–180]

WHO DECIDES?

End-of-life management of ICU patients can be artificially distinguished into two phases. The first phase is making the decision to forego life-sustaining treatment by building a consensus that treatment must move from curative interventions to palliative (comfort) care.[26] Ideally, this consensus is achieved using the shared decision-making model recommended by Society of Critical Care Medicine in 2001 and an international consensus conference in 2003.[17,18] In this model, the decision to forego life-sustaining treatment is made by a well-organized team in which physicians and nurses communicate openly, provide relevant medical information, elicit patient values and preferences, explore the family's preferred role in the decision process, and achieve a consensus that is most consistent with the patient's values and preferences.[181] From the beginning of the decision-making process, the family members participate, either by bearing witness to the patient's wishes or by explaining their own wishes.[12]

Although the current goal standard of decision making is a consensus shared by health care providers and surrogate decision makers acting in the patient's best interest, diverging opinions often emerge, and conflict may be inevitable.[168] A previous conflict, inadequate information, or economic restrictions imposed by managed care may lead families to view a decision to forego life-sustaining treatment with distrust.[182] When such conflict occurs, physicians should refrain from unilaterally enforcing their own decision over the objections of the family.[183] On the contrary, physicians should intensify communication with families,[3] initiate a process of negotiation,[96,184–186] seek external advice, or show families that the decision is consistent with institutional policies and recommendations issued by learned societies.[136,187] Physicians should must be aware that their own value judgments may be different than those of the patient, surrogates, and other members of the health care team such as nurses.[188,189] Although surrogate decision makers fulfill a vital role in the decision-making process, as many as one-fourth of all deaths in the ICU occur in patients without decision-making capacity and without a surrogate decision maker. Few guidelines exist to guide a decision to forego life-sustaining treatment in such circumstances, and wide variability exists in how health care teams address a decision to forego life-sustaining treatment in this patient population, often without institutional oversight.[190]

The second phase in the end-of-life management of ICU patients consists in implementing the decision to forego life-sustaining treatment. This requires an organized strategy relying on both human and technological resources to meet the expectations of patients and families. ICU teams must learn this approach, if needed with the help of palliative care teams or consulting ethicists, where available.[17,18,20,46,71,162,184,187,191–195]

This phase may last a few hours to a few days. Support must be provided not only to families, but also to ICU staff members, who should be confident at all times that comfort care is preferable over the use of sophisticated technologies that prolong life artificially.[196] The ICU team may need to orchestrate the dying process by adjusting the treatment to the needs of the family (e.g., maintaining mechanical ventilation unchanged until the entire family is ready or a family member arrives from a far-away location).[196,197]

Making and implementing a decision to forego life-sustaining treatment that is in the patient's best interest, especially in the setting of complex negotiation, is a clinical procedure that must be learned, practiced, refined, and evaluated, just as are other ICU skills.[191] Physicians must take into account both ethical principles and the dignity of patients and families.[192,198,199] Because decisions to forego life-sustaining treatment are often irreversible and associated with imminent mortality, it is imperative that ICU physicians be trained and evaluated in assessing and implementing decisions to forego life-sustaining treatment, and in providing support to dying patients and their families.[40,193,198,200–204]

THE INTENSIVE CARE UNIT HEALTH CARE TEAM: A KEY ROLE IN COMMUNICATING WITH FAMILIES OF DYING PATIENTS

Several studies have sought to identify the needs and expectations of families of ICU patients.[35,36,39,41,205–207] The specific needs of families of dying patients have been investigated in studies of the overall long-term impact on families of the ICU experience and bereavement,[27,43–45,208,209] in studies of interventions (the presence of families during resuscitation or involvement of families in decisions),[30,210] and in studies of the impact of family conferences on the decision to forego life-sustaining treatment process.[200,211] Families have stated that a pain-free death was a key priority,[49] and that they often perceived information as quantitatively or qualitatively inadequate. For instance, some families complained that they did not know the cause of death. These data have been used to identify specific needs of families of patients dying in the ICU (Tables 66-3 and 66-4).[18,20] Keenan et al found that families had seven major needs directly related to the decision-making process: that the process be well explained; that it proceed as expected; that the patient be comfortable; that the discussion be initiated by a member of the ICU team; that the family and friends be prepared for the decision; that the family be allowed privacy during implementation of the decision to forego life-sustaining treatment;[212] and that the family be given opportunities to voice concerns and to make special requests.[208] Others have emphasized the importance of meeting the spiritual and religious needs of patients and family members.[27,213,206,214]

Meeting these needs empowers and motivates families to participate in the process of deciding to forego life-sustaining treatment. Burdens weighing on families should not be construed as reasons to exclude families from decision making.[12] Conversely, involving families at all costs without previously providing them with information and with psychological and social support may lead to severe residual disorders, including severe persistent guilt and abnormal bereavement.[30,210] Thus, sharing decisions with families is intricately linked with a procedure of intensive communication that supports and guides the family at the time of the decision to forego life-sustaining treatment.[46–48,187,195,215] The reasons justifying a decision to forego life-sustaining treatment and, subsequently, the specific implementation modalities are discussed, usually during family conferences attended by members of the family and members of the ICU team (physicians, nurses, and social workers).[162] Informal conversations, however, at the bedside or in the hallway or waiting room are also useful and may involve a smaller number of people (often the intensivist and the patient's spouse). Nevertheless, formal family conferences are invaluable for strengthening communication between the family and the ICU team. They should be offered as often as needed, and at least once for each family.

During the conferences, the ICU team members are familiar faces for the family members, and the physician leading the conference starts by introducing each person. Each conference is prepared by the ICU team to establish a consensus among staff members[201,216–219] as a prerequisite to the development of a consensus with the family.[20,185,186,217] Regular decision-making and debriefing meetings of physicians and nurses are essential to ensure that all team members understand one another's points of view.[12] Similarly, because resident physicians receive insufficient training in ethical principles,[220] informal discussions between residents and senior ICU physicians should be encouraged to improve residents' confidence in withdrawal decisions. Residents should also be encouraged to participate in family meetings.[221] During family conferences, the word "death" should be used and the manner in which the patient will die should be explained to the family members, with emphasis on patient comfort. The ICU staff must allow the family members to speak and to vent their emotions, but they must also anticipate questions the family members cannot bring themselves to ask.[200,211] Studies show not only that inadequate information is a source of dissatisfaction among families of patients dying in the ICU, but also that targeted interventions aimed

TABLE 66-3: TEN MOST IMPORTANT NEEDS OF FAMILIES OF CRITICALLY ILL DYING PATIENTS

1. To be with the person
2. To be helpful to the dying person
3. To be informed of the dying person's changing condition
4. To understand what is being done to the patient and why
5. To be assured of the patient's comfort
6. To be comforted
7. To express emotions
8. To be assured that their decisions were right
9. To find meaning in the dying of their loved one
10. To be fed, hydrated, and rested

TABLE 66-4: A DOZEN NEEDS OF THE FAMILY IN THE SETTING OF CRITICAL ILLNESS

1. To have questions answered honestly
2. To know specific facts about what is wrong with the patient
3. To know the prognosis for recovery
4. To be called at home about changes in the patient's status
5. To receive information from the physician (at least) once daily
6. To receive information in understandable language
7. To believe that hospital personnel care about the patient
8. To be assured of the patient's comfort
9. To be comforted
10. To express emotions
11. To find meaning in the death of their loved one
12. To have the opportunity to eat, drink, and sleep

Source: Used, with permission, from Prendergast et al.[20]

at improving communication may be ineffective.[50,215,222–228] In addition, clinicians lack training in techniques that help families consider decision sharing, express their opinions, and cope with the attendant burden.[192,220,229,230]

A key objective of the family conference is to assure family members that the patient's wishes will be honored, although the patient is incompetent.[192] Neither families nor health care professionals know how to predict patients' wishes regarding a decision to forego life-sustaining treatment in the ICU.[139,141,147,219,231] In practice, the physicians must first ask the family whether the patient has expressed wishes about end-of-life care. If the patient has expressed wishes, then the family members describe them and use substituted judgment to participate in a decision to forego life-sustaining treatment. When nothing is known about the patient's wishes, the best interests of the patient guide the decision-making process. Placing the patient's wishes at the center of the discussions and negotiations ensures that decision making is of high moral and ethical quality despite the absence of patient participation.[186] Surrogate decision makers should receive active support from the ICU team.[46] Furthermore, by making it clear that families speak for their loved one and not for themselves, this approach should minimize feelings of guilt secondary to involvement in a decision to forego life-sustaining treatment.[232]

For most decisions to forego life-sustaining treatment, a consensus is achieved rapidly with the family.[82] In difficult cases, a process of negotiation should be initiated to convince the family that the patient cannot survive and that the patient's best interests govern decisions.[233] It may be possible to continue life support for an interval time so as to help the family understand that the patient's condition is irreversible. Compassion and understanding must sustain the relationship with families. Families are often dissatisfied with the level of communication, but are unable to express their dissatisfaction because they do not wish to provoke an open conflict. Intensive communication is the only road leading from a potential battle of diverging opinions to a consensus in which the family accepts, probably with pain and sadness, that the best care available for their loved one is discontinuation of aggressive artificial treatments and continuous painstaking attention to comfort. This awareness that treatments must be withheld or withdrawn is acquired via a multifaceted process whose components are cognitive (understanding the information and trusting the ICU team), emotional (believing that the patient is not being abandoned but has reached the end of his or her life),[20] and interpersonal (protecting the family and friends from long-term harm related to participation in decision making).[209,234] At this stage, lifting restrictions on visiting hours and encouraging participation in patient care (washing, massaging, pain relief treatment, and so on) provides families with a sense of comfort, intimacy, and utility. Family members have a strong desire for opportunities to communicate with the patient (by touching, speaking, looking at photos, and listening to music). The health care professionals must respect the silence, rituals, emotions, and religious practices of each family. Again, everything must be done to minimize feelings of guilt.

IMPORTANT UNKNOWNS

Despite considerable advancements made in the past 20 years, significant barriers to optimal decision making regarding life support and end-of-life care in the ICU still exist. In a recent survey, nursing and physician directors of ICUs in the United States reported major barriers in the following areas: clinician training in effective communication with patients and patients' families, as well as with the medical team; competing demands for clinician time; unrealistic patient and family expectations about prognosis; inability of patients to participate in treatment decisions; and disagreements within families about goals of care.[235] Despite a general consensus on basic principles that should guide the delivery of end-of-life care in the ICU, numerous studies show that the implementation of these principles is lagging. Many ICU physicians are unaware of patient wishes,[236] physicians do not document patient preferences,[237] many patients still die in moderate or severe pain,[50] and half the families experience inadequate communication with physicians.[34] Physicians do not discuss basic prognosis for survival in one-third of all family conferences[238] and lack basic communication skills, such as showing empathy[207]and responding to family members' emotional cues.[239] Additionally, many physicians are reluctant to give a recommendation regarding decisions to forego life sustaining treatment, even when directly asked to do so by surrogates.[240] Families with limited English proficiency may be at risk for further communication deficiencies.[241] Various solutions to the aforementioned barriers have been proposed,[235] and these solutions form the emphasis of current investigations.

THE FUTURE

In the future, intensive multidisciplinary programs and early incorporation of palliative care into ICU management should be encouraged so as to improve information and communication. Multidisciplinary teams could either handle communication with families of dying patients or assist the ICU staff members and teach them palliative care strategies. Data from the literature strongly support a heavy emphasis on palliative care.[242,243] By facilitating prognostic information and promoting communication with patients and families, huge efforts on the part of investigators have been successful in identifying patient preferences and wishes regarding treatment intensity. A program of intensive palliative care offered to dying ICU patients holds promise as a means of improving communication at a time when openness is crucial.[47,48,187,242,243] Nevertheless, the generalizability and feasibility of this strategy require evaluation in a range of countries and cultures.[50]

SUMMARY AND CONCLUSION

Mechanical ventilation is the life-sustaining treatment most often used in the ICU. Most patients are successfully weaned off the ventilator. A few, however, cannot recover from their disease, remain dependent on the ventilator, and have a very high likelihood of death in the short term. In this situation, intensivists must engage in the complex process of deciding to withdraw mechanical ventilation. These patients must be offered the best possible death. We must remain at their side and on their side, keeping them comfortable at all times, while encouraging family involvement in decisions and care, if they so wish, welcoming family members in the ICU as partners rather than as visitors, alleviating their guilt, and helping them to prepare for the bereavement process.

Over the last 20 years, several descriptive studies have provided detailed epidemiologic data on practices and changes to practices over time, as well as on targets for improvement. Qualitative studies have helped us to understand the complexity of the decision-making process, to recognize that upholding ethical principles requires more than compliance with the law, and to distinguish intentions from practices. The results of these studies indicate a need for major improvements in end-of-life care for ICU patients, most notably regarding our skill in communicating, imparting information, and organizing and implementing treatment withholding and withdrawal. Further knowledge of the decision-making process and of the individuals involved in it will help to improve our end-of-life practices, rest our decisions to forego life-sustaining treatment on ethical principles, and validate the shared decision-making model by studies of outcomes in family members long after the ICU experience. Serving the principle of autonomy requires not only that a patient's wishes be honored, but also that the family be able to proceed through the bereavement process with the least possible guilt, remorse, and regret. Thus, our end-of-life practice should be tailored to the specific characteristics of each region and culture, each clinical situation, each patient, each family, and each ICU professional.

ECONOMICS OF VENTILATOR CARE

Shannon S. Carson

One of the most urgent targets for improved efficiencies in inpatient hospital care is critical care services. Between 2000 and 2005, critical care medicine beds increased in the United States by 6.5% (from 88,252 to 93,955), and occupancy rates increased by 4.5%.[1] In that period, critical care costs per day increased by 30.4% (from $2698 to $3518). In 2005, critical care medicine accounted for 13.4% of hospital costs in the United States and consumed 0.66% of gross domestic product. Patients requiring mechanical ventilation are among the largest consumers of critical care resources, and hospitals often experience financial losses in providing care for them. As many as 2.8% of hospitalized patients in the United States received mechanical ventilation in 2005, representing 2.7 episodes of mechanical ventilation per 1000 population.[2] Estimated national costs were $27 billion. This chapter reviews the economic implications of mechanical ventilation. Basic principles of health economics are reviewed to provide a framework for interpreting health economic analyses related to mechanical ventilation. Actual costs of mechanical ventilation are addressed, followed by a discussion of whether mechanical ventilation is cost-effective. Finally, strategies for cost containment are reviewed.

BASIC PRINCIPLES OF HEALTH ECONOMICS

The goal of *health economics* is to ascertain the highest level of efficiency in providing health care.[3,4] A key assumption in this field is that health resources are a finite commodity. In such a system, a series of questions should be answered regarding any new or current medical intervention:

- Is the intervention effective relative to other available therapies?
- How much does it cost relative to other available therapies?
- From whose perspective are the costs being considered?
- How widely will the intervention be utilized?

Measured approaches to answering these questions allow health care systems to select medical therapies based upon evidence rather than assumptions, commercial marketing, or bias. Economic analysis has become a standard component of decision making for health systems in countries such as the United Kingdom or Australia, where health care policymaking is centralized on a national level. In countries

such as the United States, delivery of health care is much less regulated, and many practitioners and most patients have unbounded access to any available therapies. Few physicians in the United States, however, are able to practice without significant awareness of the resource implications of their decision making. One goal of recent health care reform efforts in the United States is cost control, and it is highly likely that third-party payers will increase efforts to balance available services with more efficient delivery. The formation of Accountable Care Organizations, in which providers are incentivized to organize care delivery in a way that improves quality and outcomes and reduces costs, is mandated in the recent Affordable Care Act.[5] Other delivery reform initiatives include pay-for-performance measures,[6] expansion of medical homes, bundled payments, and value-based purchasing. Consequently, a basic understanding of how the efficiency of various health care practices is defined is becoming essential to the practicing clinician. The following section outlines some of the common definitions and methodologies employed in health economic analysis.

Costs

When considering the cost of therapies, the unit price of a drug or piece of equipment is often the basis of discussion in the clinical setting, especially if the analysis is being performed in the interest of the physician or hospital. Payers may have a broader view, especially if they are responsible for health care costs after hospital discharge. Patients and society view the cost of illness from an even larger perspective that includes a longer time horizon. Ideally, economic analyses determine the true costs that are accrued from the beginning of a patient's disease to the long-term outcome for the patient. These costs are categorized as direct medical costs, direct nonmedical costs, and indirect costs.[3,4,7]

DIRECT MEDICAL COSTS

Direct medical costs are expenses for the provider of a service. These can include *variable costs* such as physician labor, drug costs, or use of diagnostic or therapeutic equipment.[8] Variable costs are not generated unless the service is provided. An important subgroup is *direct variable costs,* which are defined as variable costs excluding staff salary and equipment costs.[9] Nursing labor and equipment are usually considered *fixed costs,* as nurse salaries must be paid regardless of bed occupancy, unless staff are laid off. Another form of fixed costs that is more removed from medical practice is *overhead costs,* which include general operations of the hospital or clinic such as utilities, leases, capital improvement, insurance, and administrative overhead or taxes.

DIRECT NONMEDICAL COSTS

Direct nonmedical costs include costs incurred by the patient that are not related to care provided by the physician or hospital. These costs may include emergency transportation to the hospital, transportation and lodging for the patients' family, and domestic help and rehabilitative services after discharge. Although these costs are difficult to measure, they can have an important impact on the patient and their perception of the benefits of care.

INDIRECT COSTS

Indirect costs include the overall financial burden of illness to the patient. This can include loss of wages and benefits as a consequence of missed work or loss of earnings and unpaid care provided by family members. This, too, is difficult to measure, but it has substantial impact on the well-being of the patient and family.[10–13] Indirect costs for the patient can ultimately affect direct costs for a health system. If economic burdens on the patient decrease access to resources, affect medical adherence, and result in incomplete recovery, then recurrence of hospitalization or even critical illness can result.

MEASURING COSTS

One of the greatest challenges in health economic analysis is accurate measurement of relevant costs. Many hospitals have adopted sophisticated cost-accounting systems that assign a specific cost to each service based on hospital expenses.[8] Expenses can be determined from either the hospital's acquisition costs or the service-specific relative-value units based upon the Center for Medicare and Medicaid Services Resource-Based Relative Value Scale. Overhead costs are assessed internally and assigned to each department.

Most hospitals increase the patient charge for many services above acquisition costs and expenses to help pay for services that are otherwise inadequately reimbursed. Because this practice can vary according to different payment plans, hospital *charges* are often an inappropriate surrogate for hospital *costs.*[14] Large studies involving patients under a single-payer such as Medicare can adjust charges using a standard cost-to-charge ratio to gain acceptable estimates of costs, but this is less reliable with more heterogeneous groups of patients and payers.

As nursing time, monitoring costs, physician costs and certain laboratory and radiology ordering practices are linked to a patient's presence in an intensive care unit (ICU), ICU length of stay is considered by many to be a reliable and convenient surrogate for ICU costs. In one frequently cited model that is based on the relative costs per day of hospital admission, 4.5 units are assigned to the first day of each ICU stay, 2.5 units for each additional ICU day, and 1 unit for each non-ICU day after the first ICU discharge.[15]

For comparisons between institutions, length of stay can be confounded by differences in ICU admission criteria, nurse-to-patient ratios, presence of intermediate care or "stepdown" units, and transfers to other acute care facilities. To standardize resource use between different ICU settings, instruments such as the Therapeutic Intervention Scoring System (TISS) can be used.[16] The TISS instrument assigns

TABLE 67-1: TYPES OF ECONOMIC ANALYSES

Type	Comparisons	Result	Advantages/Disadvantages
Cost-Minimization	Costs of therapies with similar efficacies	Cost difference	Few therapies have similar efficacies for multiple outcomes
Cost-Benefit	Monetary value of costs and benefits of therapies	Cost/monetary benefit	Therapies for different conditions and outcomes can be compared, but it is difficult to place a monetary value on clinical outcomes such as death or quality of life
Cost-Effectiveness	Therapies with efficacies measured using similar clinical outcomes	Cost/clinical outcome (e.g. life-years saved)	Utilize clinically relevant outcomes. Analyses using different outcomes cannot be compared
Cost-Utility	Therapies for which mortality and quality of life are important outcomes	Cost/QALY	Different therapies with different efficacies can be compared; includes patient-centered outcomes; difficult to comprehend

Abbreviation: QALY, quality-adjusted life-years.

weights to seventy-six ICU interventions based upon the severity of illness associated with the need for each intervention. Intensity of ICU care can then be assessed by comparing the added weights or TISS scores between intervention groups, and costs can be standardized by applying a specific cost to each service.

Cost data for economic evaluations can come from multiple sources, but the most common approach is to collect cost data prospectively during clinical trials.[17,18] Utilizing cost data from a single, large clinical trial has the advantage of uniform methodology, but it may not be generalizable if the trial involved highly selected patients managed in ways that are not standard to the typical clinical setting. When clinical trial data are not available, cost and outcome data can be derived from cohort studies. With this approach, sensitivity analyses to account for clinical variability and potential biases in the cohort studies are particularly important. A combined approach that begins with data from a large clinical trial and adds multiple scenarios that account for clinical variability is useful.

Types of Economic Analyses

Economic analyses function to provide more than just a description of the costs of a therapy. Their role is to compare costs between therapies relative to the benefits or efficacies of those therapies. Table 67-1 describes the four primary types of economic analyses.[3,4,17] Cost-effectiveness analysis, the most useful approach to economic analysis, is described in more detail below.

COST-EFFECTIVENESS ANALYSES

Cost-effectiveness analyses use standard clinical measures such as life-years gained or quality of life units rather than monetary units to assess benefit. Outcomes are expressed as a ratio of cost to measure of benefit, for example, cost per life-year gained. Cost-effectiveness analyses are easy to understand for clinicians and have the advantage of not having to assign a monetary value to outcomes. Consequently, they are the most common type of economic evaluation performed. They can, however, only compare the costs of therapies that have a common clinical outcome.

COST-UTILITY ANALYSES

An important and common subgroup of cost-effectiveness analysis is cost-utility analysis, which is performed when therapies are likely to have an impact on quality of life as well as mortality. The level of well-being for a given health state (*utility,* rated from 0 for worst health or death to 1 for best health) is multiplied by the amount of time spent in that health state. The resulting index is called a *quality-adjusted life-year* (QALY). For example, a therapy that results in a health state valued at 0.5 for 2 years would yield 1 QALY. Utilities can be measured by interviewing participants of a clinical trial, or predetermined values measured in similar groups of patients can be utilized. Results of a cost-utility analysis are expressed as cost per QALY. Results of selected cost-utility analyses related to mechanical ventilation and ICU care are listed in Table 67-2.

The advantages of cost-effectiveness analyses are that costs and benefits of different therapies involving different types of patients can be compared, and outcomes beyond survival are factored in. The disadvantage is that many clinicians have difficulty understanding the complexity of the studies, and the models can involve numerous assumptions that vary across patient populations. Therefore, strict guidelines[19] must be followed in conducting the studies to ensure transparency in how utilities are assigned, and rigorous testing in the form of sensitivity analyses should be performed to determine how variability in clinical factors could affect results of the models.

Cost-effectiveness analyses can aid decision making by providing data on how much therapies cost relative to the outcomes that are achieved, particularly if one therapy has greater benefits than the alternative, but the costs are greater as well. Cost-effectiveness analysis is not a cost-containment tool. Instead, it should be considered a method to improve

TABLE 67-2: COST-EFFECTIVENESS OF SELECTED MECHANICAL VENTILATION-RELATED INTERVENTIONS

Intervention	Cost/QALY
Mechanical ventilation for respiratory failure related to pneumonia or ARDS[28,86]	$29,000 (estimated 2-month survival > 70%) $44,000 (estimated 2-month survival 51%–70%) $110,000 (estimated 2-month survival ≤ 50%) $32,000 (age < 65 years) $46,000 (age > 75 years)
ICU care for patients with acute respiratory failure *without* chronic lung disease[27]	$11,970[a]
ICU care for patients with acute respiratory failure *with* chronic lung disease[27]	$14,365[a]
Mechanical ventilation to treat acute respiratory failure[87]	€1391[a]
Prolonged mechanical ventilation (>21 days) after acute illness[30]	$82,411 $60,967 (estimated 1-year survival > 50%) $101,787 (estimated 1-year survival ≤ 50%)
Lung-protective ventilation protocol in patients with acute lung injury[52]	$11,690
ICU care for patients with acute renal failure[27]	$30,625[a]
Activated Protein C for severe sepsis[88]	$27,400 (APACHE II ≥ 25) >$100,000 (APACHE < 25)
Ultrasound screening for deep vein thrombosis in ventilated patients with femoral vein catheters[89]	$12,793
Lung transplantation compared to standard care[90]	$44,000 (assuming 10-year survival) $204,000 (assuming 5-year survival)
In-hospital cardiopulmonary resuscitation	$215,000

[a]Analysis did not include costs after hospital discharge.

Abbreviations: ARDS, acute respiratory distress syndrome; *ICU*, intensive care unit; *QALY*, quality-adjusted life-years.

value. The analyses may not always lead to decreased costs for a health care system, especially when underutilized services that increase cost but improve value are identified and encouraged.[20] In most Western health systems, an incremental cost per QALY of less than $20,000 is strong evidence for adoption of a therapy. Incremental costs per QALY of between $50,000 and $100,000 provide moderate evidence for adoption. If the incremental cost per QALY is greater than $100,000, the therapy may not be considered cost-effective, although more recent recommendations raise that boundary to a range of $183,000 to $264,000.[21] These boundaries of cost-effectiveness are somewhat arbitrary however. Ultimate decision making must take into account other factors such as seriousness of the health condition, availability of alternatives, and number of patients who would receive the therapy (total budgetary impact).[3,22]

COSTS OF MECHANICAL VENTILATION IN THE INTENSIVE CARE UNIT

The average total cost of hospitalization for a critically ill patient ranges from $14,135 to $32,253, depending on the study methods and patient population.[23,24] This is nearly three times the cost of a hospitalized patient managed on the medical or surgical floor. Two-thirds of the costs associated with critically ill patients are accrued during their stay in the ICU. For those whose length of stay in the ICU is more than 5 days, as much as 80% of their hospital costs are accrued in the ICU. Hospital costs for ICU patients who require mechanical ventilation is significantly higher than for nonventilated patients in the ICU (e.g., $47,158 vs. $23,707 in one study).[23] It is important, however, to understand that the difference in cost between ventilated and nonventilated patients is a factor of higher illness severity rather than the cost of providing mechanical ventilation.[25]

Maintaining a mechanical ventilator accounts for less than 5% of direct ICU costs for a ventilated patient.[9] A ventilator includes a one-time cost of $20,000 to $45,000 for the hospital plus nominal maintenance charges, and it is used for a number of years. A respiratory therapists' time ranges from $70 to $130 per day depending on local salary and staffing levels, and administrative costs are a smaller factor. Rather than the mechanical ventilator itself, the major contributor to variable costs for a ventilated patient is the nursing effort assigned to the patient (Table 67-3).[26,27] The nurse-to-patient ratio for acutely ill, mechanically ventilated patients is usually 1:1 or 1:2.

One study assessed the fraction of total costs attributable to variable and direct-variable costs for mechanically ventilated patients at an urban teaching center.[9] The average total cost for each patient was $69,472. Costs were highest during the first 2 days of intensive care and decreased significantly

TABLE 67-3: COSTS OF MANAGING INTENSIVE CARE UNIT PATIENTS BY HUMAN AND CAPITAL COMPONENTS

Component	% Component Cost	% Total Cost

thereafter (Fig. 67-1). Only 18.4% were direct-variable costs (costs not attributable to overhead, staff, or equipment). Direct-variable costs were highest for the blood bank (44%) and pharmacy (48%), and lower for radiology (8%) and respiratory care (3%).

Is Mechanical Ventilation Cost-effective?

Thorough economic analyses of mechanical ventilation have been limited because of difficulties in applying adequate study methods in this complex patient population. One high-quality study, however, addressed the question of cost-effectiveness of mechanical ventilation in severely ill patients who required mechanical ventilation for pneumonia or acute respiratory distress syndrome (ARDS).[28] In the analysis, patients were stratified based upon likelihood of 2-month survival (Table 67-4). The incremental cost per QALY of providing mechanical ventilation to these patients was $29,000 for low-risk patients (>70% estimated survival), $44,000 for medium-risk patients (51% to 70% estimated survival), and $110,000 for high-risk patients (≤50% estimated survival). Sensitivity analyses that increased mortality and costs to twice the baseline estimates resulted in incremental costs per QALY that were still less than $80,000 for low-risk and medium-risk patients. In another cost-utility analysis from France,[27] cost-utility ratios for ICU care of patients with acute respiratory failure were estimated to be $11,970 for patients without chronic lung disease and $14,365 for patients with chronic lung disease (see Table 67-2). This analysis did not include costs of care following discharge, so it is relevant only from the hospital's perspective.

These data suggest that mechanical ventilation for patients with acute respiratory failure as a consequence of pneumonia or ARDS meets standard criteria for cost-effectiveness

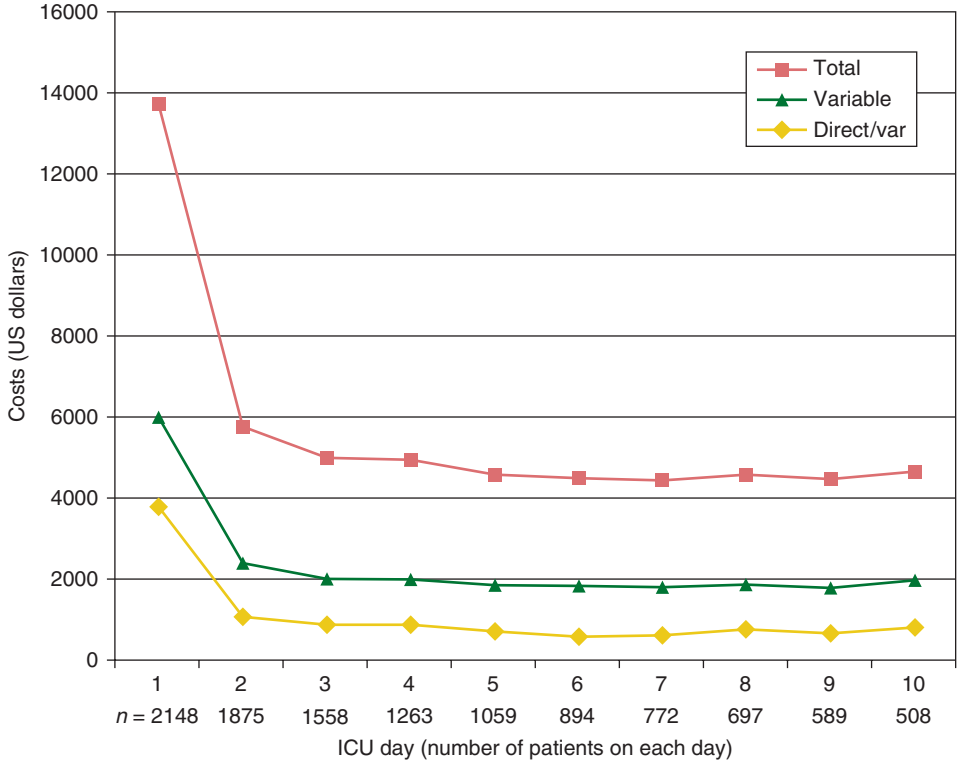

FIGURE 67-1 Mean costs by ICU day for patients receiving mechanical ventilation. Mean total (*Total*), variable (*Variable*), and direct-variable (*Direct/var*) costs by day for each ICU admission. (Used, with permission, from Kahn et al.[9])

TABLE 67-4: COSTS OF MECHANICAL VENTILATION FOR PATIENTS WITH ACUTE RESPIRATORY FAILURE SECONDARY TO PNEUMONIA OR ACUTE RESPIRATORY DISTRESS SYNDROME

	>70% Estimated 2-Month Survival	51% to 70% Estimated 2-Month Survival	≤50% Estimated 2-Month Survival
Hospital costs	$59,096 ± $64,336	$70,130 ± $85,300	$59,310 ± $54,590
Physician costs	$5,034 ± $6,705	$6,162 ± $5,264	$6,474 ± $7,426
Costs through the year after discharge	$22,037 ± $44,847	$18,772 ± $42,253	$11,994 ± $34,475
Annual costs after first year	$18,265 ± $48,078	$13,053 ± $26,519	$28,102 ± $86,998
One-year survival	0.62	0.39	0.21
Cost per QALY	$29,000	$44,000	$110,000

Patients were enrolled in the SUPPORT (Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments) trial. Index hospital costs were derived from hospital charges using Medicare cost-to-charge ratios. Physician costs and costs of hospitalization after the index hospital discharge were estimated from Medicare financial data. Two-month survival estimates were determined at the time of diagnosis of acute respiratory failure.

Abbreviation: QALY, quality-adjusted life-year.

Source: Used, with permission, from Hamel et al.[28]

for all but the highest-risk patients. It may be reasonable to assume that mechanical ventilation for patients with conditions that afford better prognoses, such as asthma, chronic obstructive pulmonary disease (COPD), or routine postoperative patients, will be similarly cost-effective, and mechanical ventilation for patients with worse prognoses, such as pulmonary malignancies or hematologic malignancies, may be less cost-effective. Of course, it is rather difficult to apply these principles in bedside practice. When resources are available, mechanical ventilation should be utilized according to how the expected benefit matches the patient's wishes for invasive care.

Costs of Prolonged Mechanical Ventilation

Patients who require more than 7 days of mechanical ventilation represent only 10% of ICU patients, but they consume up to 40% of ICU resources.[29] More than 20% of those resources are consumed after the seventh day of ventilation. In 2005, patients requiring prolonged mechanical ventilation ranked third in summative inpatient charges by diagnostic group and first in diagnostic charges per patient.[30] The number of patients in the United States requiring at least 7 days of mechanical ventilation has been increasing steadily since 2000, and by 2020, the number is projected to double.[31] This is projected to require an absolute increase of over 2.1 million mechanical ventilator days, 3.2 million ICU days, and 6.5 million hospital days over year 2000, at a total inflation-adjusted cost over $64 billion.[32]

Health care costs associated with prolonged ventilation remain high even after patients are liberated from mechanical ventilation and discharged from the hospital. Readmissions occur in up to 40% of patients within a year, and total health care costs that accrue for patients during the year after discharge are almost as high as their index hospital costs because much of their time is spent in institutional care such as nursing homes or rehabilitation facilities.[33] In one single-center cohort study, prolonged ventilation patients who survived their acute hospitalization experienced a median of four transfers between different care centers, and 74% of days alive were spent in institutional care (Fig. 67-2).[34]

One-year survival of patients requiring prolonged ventilation ranges from 23% to 50%.[35,36] Considering their poor long-term outcomes and very high costs, the question inevitably arises as to whether or not prolonged care for these patients is cost-effective. In one economic analysis, investigators measured the cost-effectiveness of mechanical ventilation beyond 21 days compared to withdrawal of life-sustaining therapies as a hypothetical comparison.[30] They determined that providing prolonged mechanical ventilation cost $82,411 per QALY. Cost-effectiveness ratios were most sensitive to variation in age, hospital costs, and probability of readmission (Fig. 67-3).

CONTROLLING COSTS OF MECHANICAL VENTILATION

From the perspective of patients and society, mechanical ventilation results in significant and sometimes catastrophic charges, especially when provided in the ICU of an acute hospital. From the hospital perspective, more than half of the patients managed in the ICU generate costs that are greater than the average payment in the Medicare Diagnostic Related Group (DRG) system, leading to financial losses for the hospital.[24]

To control costs associated with mechanical ventilation, a patient's time on the ventilator and in the ICU should be limited as much as safely possible. Strategies to reduce duration of mechanical ventilation include prevention of intubation, efficient management of the ventilated patient, and withholding or withdrawal of mechanical ventilation in terminally ill patients (Table 67-5).[25] For the hospital, savings can be achieved by transfer of the ventilated patient to lower-intensity sites of care. It should be noted that none of these strategies will significantly reduce overall costs if they merely shift costs from one cost center to another (e.g., from an ICU

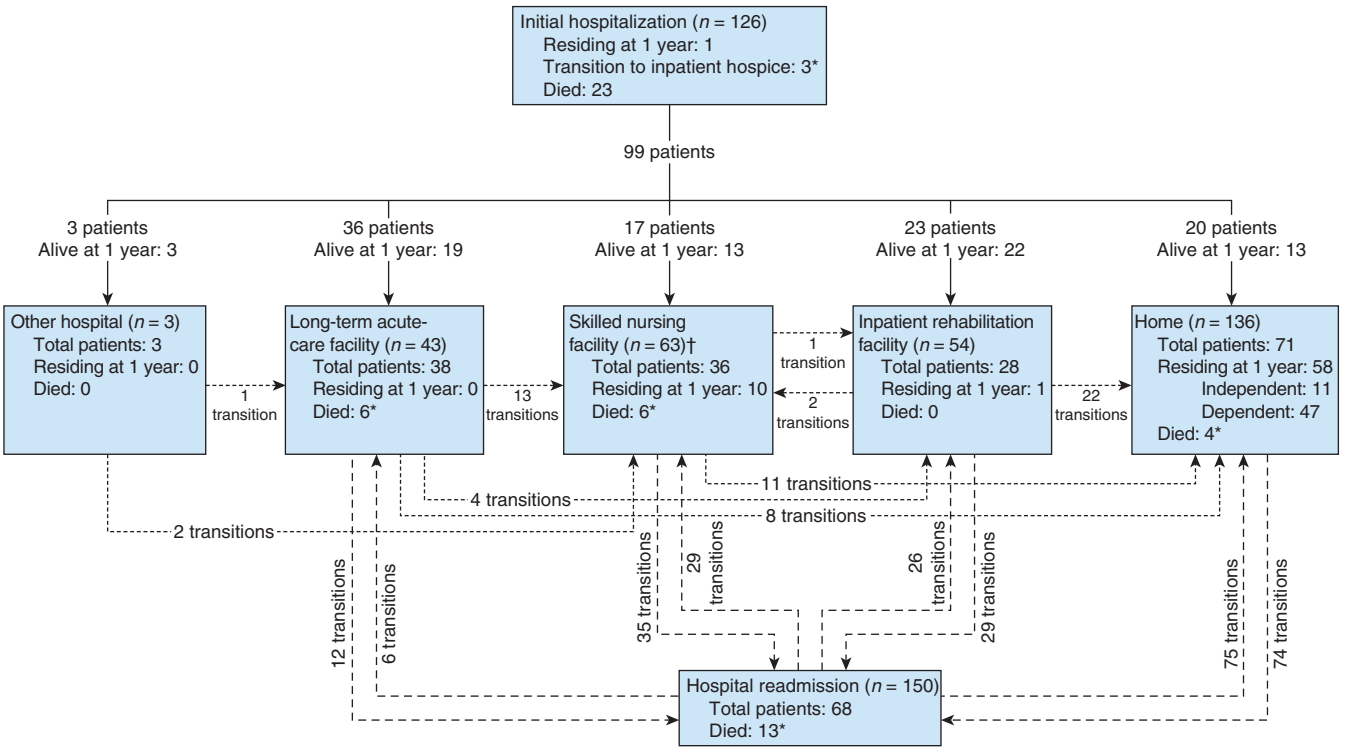

FIGURE 67-2 Trajectories of care over the first year after discharge for a cohort of patients requiring prolonged mechanical ventilation in a U.S. tertiary care hospital. *Arrows* between locations indicate both the direction of patient transitions and the total number of patients transferred between locations over 1 year. *Solid lines* represent initial transitions between the hospital and other locations. *Dashed lines* represent subsequent hospital readmissions and discharges involving postdischarge care locations. *Dotted lines* represent transitions among postdischarge care locations, including home. Each box summarizes the total numbers of both readmissions and patients admitted, as well as how many patients remained or died in each location of care at 1 year. *, Seven transitions to inpatient hospice and death not shown (three from the acute hospitalization and one each from home, long-term acute care facility, skilled nursing facility, and hospital readmission); †, one transition from skilled nursing facility to skilled nursing facility not shown. (Used, with permission, from Unroe et al.[34])

to a weaning facility).[8] Furthermore, one less day of mechanical ventilation and ICU care does not amount to savings relative to the average daily cost of ICU care, but rather to the last day of ICU care, which is much lower than the average daily cost.[9] And, finally, most of the costs associated with a day of mechanical ventilation are fixed costs rather than variable costs or direct-variable costs (see Fig. 67-1). Therefore, reducing time on a ventilator only lowers costs significantly if it leads to fewer days in the hospital and reductions can be sustained across enough patients over enough time to allow for closure of ICU beds and hospital beds.[8,37] With these caveats in mind, some strategies to reduce costs of care for the ventilated patient are discussed below.

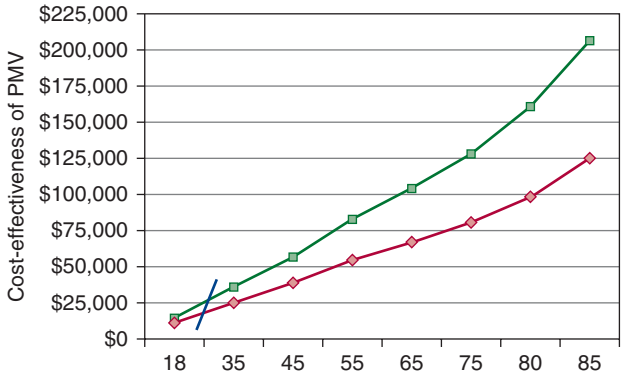

FIGURE 67-3 Incremental costs per life-year (*red line*) and incremental costs per quality-adjusted life-year (*green line*) of prolonged mechanical ventilation (*PMV*). (Used, with permission, from Cox et al.[30])

Prevention of Intubation

One effective means of preventing mechanical ventilation in the ICU is to intervene with appropriate resuscitative efforts before respiratory failure occurs. Early recognition and intervention for conditions that will predispose patients to respiratory failure such as sepsis, cardiogenic pulmonary edema, or acute bronchospasm may reverse processes enough to avoid intubation. Rapid response teams can facilitate early interventions, but some models require significant additional staff and may not improve hospital survival.[38–40] Protocols for early goal directed therapy in septic shock may reduce ICU resource requirements,[41] but confirmation of early findings await results of ongoing clinical trials. Perioperative clinical

TABLE 67-5: COST-CONTAINMENT STRATEGIES FOR MECHANICAL VENTILATION

Accepted strategies
Prevention of intubation
Rapid response teams
Noninvasive mechanical ventilation
Efficient management practices
Daily screening and performance of spontaneous breathing trials
Daily interruption of sedative infusions
Use of short-acting sedatives
Early mobilization
Prevention of ventilator-associated pneumonia
Prevention of intravenous catheter-related infections
Intensive care unit (ICU) organization
Critical care trained medical director
Closed ICU format with full-time intensivist coverage
Nurse-driven sedation protocols
Nurse-driven or therapist-driven weaning protocols
Flexible nurse staffing
Continuous medical education
Continuous quality improvement
Telemedicine
Transfer to lower-intensity sites of care
In-house respiratory care units
Long-term acute care hospitals or regional weaning centers
Acute rehabilitation hospitals with mechanical ventilation capabilities
Skilled nursing facilities with mechanical ventilation capabilities
Home mechanical ventilation
Unproven strategies
Withholding or withdrawing mechanical ventilation from terminally ill patients
Advanced directives are uncommon and do not influence practice
Very poor prognoses are often not evident until well into the ICU course
Cost savings are reduced if the patients require continued hospitalization for palliative care

management pathways have benefitted from fast-track anesthesia, and enhanced care in postanesthesia care units have greatly reduced the need for ICU care in cardiac, thoracic, and head-and-neck surgical patients.[42–45]

NONINVASIVE MECHANICAL VENTILATION

Noninvasive ventilation for acute respiratory failure secondary to severe COPD exacerbations decreases the likelihood that a patient will need intubation.[46,47] This is associated with significantly lower hospital mortality and decreased ICU and hospital length of stay. Noninvasive ventilation has also been shown to decrease likelihood of intubation in patients with congestive heart failure without shock or ischemia, patients with community acquired pneumonia if they have underlying COPD, patients with acute-on-chronic respiratory failure associated with obstructive sleep apnea, and in immunocompromised patients who have early ARDS.[48]

Avoiding intubation does not eliminate all of the costs associated with mechanical ventilation. Noninvasive ventilation in the setting of acute respiratory failure still requires a significant investment in respiratory therapist time in addition to equipment and administrative costs. More importantly, if the patient requires monitoring in an ICU, the actual cost savings will be reduced.[49] Many hospitals manage patients with acute respiratory failure requiring noninvasive ventilation on a stepdown unit or hospital floor that has lower nurse-to-patient ratios than in an ICU. Although achieving some cost savings, this approach should be implemented only if well-trained staff and sufficient monitoring are available to be able to respond to patients who fail noninvasive ventilation. Utilization of noninvasive ventilation in patients with less-severe COPD exacerbations would result in financial losses because it requires a higher level of monitoring than standard therapy and does not improve outcomes.[50]

Efficient Management Practices

Because decreasing time on the ventilator and time in the ICU is the mainstay of cost reduction for mechanical ventilation, recent clinical trials have focused on these issues as important outcomes. Use of normal tidal volumes (6 mL/kg predicted body weight) in patients with acute lung injury or ARDS rather than tidal volumes of 12 mL/kg of predicted body weight results in fewer ventilator days in addition to lower mortality.[51] As a result, it is a proven cost-effective therapy.[52] Daily screening for readiness to wean and initiation of spontaneous breathing trials does reduce ventilator days by 1.5 days compared to usual care.[53] Similarly, daily awakening of patients receiving continuous infusions of sedatives can decrease ventilator days by 2.4 days compared to usual care.[54] Use of a short-acting sedative rather than long-acting sedatives can reduce ventilator days as well, in part by reducing delirium.[55,56] These practices by themselves have a negligible impact on mortality, and total hospital costs are not dramatically impacted by a few less days of ICU care. But when these practices are applied in combination, long-term survival of patients can be significantly improved, indicating clear benefit.[57] Early mobility protocols are an extension of this concept of animating the ventilated patient to enhance cognitive and physical function.[54,58,59] Because some of these practices have not been standard care at many medical centers, clinicians have been slow to adopt them for their daily routine. Practice guidelines and nurse-driven or therapist-driven protocols have been very useful in these settings to change practice.[60–63] A meta-analysis evaluating the benefit of instituting formal weaning protocols indicated that they can result in decreased duration of mechanical ventilation and ICU stay, especially in surgical units, but mortality and hospital length of stay are not greatly affected.[64]

Individual practices that decrease time on the ventilator may decrease the risk of ventilator-associated pneumonia.

Ventilator-associated pneumonia can occur in up to 30% of ventilated patients, depending on the type of ICU. It is associated with longer time on the ventilator and longer ICU stays.[65] Ventilator-associated pneumonia may also result in higher patient mortality, although the attributable mortality of ventilator-associated pneumonia remains uncertain.[66] Therefore, prevention of ventilator-associated pneumonia is likely to be important for minimizing costs.[67] Early tracheostomy is another practice that is associated with fewer ventilator days and fewer days in the ICU. Most studies, however, do not demonstrate a mortality benefit, and not all studies result in fewer hospital days.[68–70] None of the clinical trials assess the additional costs associated with tracheostomy placement and care, or how discharge disposition is affected (e.g., discharge to a nursing home rather than home because of tracheostomy care needs). Early tracheostomy remains an ongoing area of clinical research, with the largest challenge being accurate identification of patients who are likely to proceed to prolonged ventilation so that unnecessary tracheostomy can be avoided.

Intensive Care Unit Organization and Staffing

A dedicated critical care-trained medical director is essential to maintaining an efficient ICU, and a closed ICU organization with intensivists managing all aspects of patient care is the ideal. The rationale for maintaining high-intensity ICU staffing (mandatory intensivist consultation or a closed ICU setting) is supported by multiple studies in the literature, although none of them are randomized trials. A systematic review of studies comparing high-intensity staffing to settings with no intensivists or only elective intensivist consultation revealed a pooled estimate of relative risk for hospital mortality of 0.71 (95% confidence interval, 0.62 to 0.82).[71] Although some studies noted greater use of ICU interventions, such as mechanical ventilation or pulmonary artery catheters, in the closed ICUs, high-intensity staffing reduced ICU length of stay in fourteen of eighteen studies, including the two studies using case-mix adjustment. Importantly, the degree of illness severity increased for many of the ICUs when they adopted high-intensity staffing, suggesting that dedicated intensivists achieve more appropriate use of ICU resources. Although the closed ICU model is the norm in Europe and Australia, only 30% of ICUs in the United States have adopted such forms of organization.[72] This proportion may increase as quality initiatives by various health consortiums and industry groups have identified 24-hour intensivist coverage for ICU patients as an important priority.

Although a closed ICU model is advocated for better outcomes, there are limited data to clarify the best ratio of intensivists to patients. Furthermore, there will be an insufficient number of available intensivists in the United States to staff all ICUs in a closed model for the foreseeable future.[72] Therefore, another relevant question is what type of clinicians, besides intensivists, provide the most efficient care. As a result of decreased availability of resident trainees, a number of models involving hospitalists, nurse practitioners, and physician assistants are being evaluated.[73,74] Another approach is to utilize evolving technologies in telemedicine. This expensive technology can be associated with improved hospital mortality and decreased ICU stay if there is broad physician acceptance, and if the intervention is focused on adherence to evidence-based practices and enforcement of daily patient goals.[75,76]

Withholding or Withdrawing Mechanical Ventilation in Terminally Ill Patients

Up to 12% of health care expenditures and 27% of Medicare expenditures are spent on patients during the last year of their lives.[77,78] For Medicare patients who die, 40% of their Medicare expenses are generated during the last month of their life. Seventy percent of their total expenses are spent on inpatient care. Dying patients often endure a period of critical illness before their death. Limiting ICU care for patients at the end of their life might seem like an obvious target for reducing ICU resource consumption and limiting health care costs, but realizing true cost savings in practice has been very difficult to accomplish for a number of reasons.[37,79]

Advance directives are relatively uncommon and often countermanded in the setting of acute respiratory failure if palliative measures are not already in place. The SUPPORT (Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments) trial[80] and other studies have demonstrated that interventions to make physicians more aware of patient prognoses and preferences for end-of-life care do not alter outcomes or result in reductions in resource use. Once patients have been intubated, early withdrawal of support for those with the worst prognoses could potentially result in cost savings, but only if it resulted in death in a much shorter period of time than would have occurred with continued care. Prolonged palliative care in an inpatient setting would significantly reduce any incremental cost savings.

One study of an intervention to improve communication of prognosis and goals of care highlights the difficulties of achieving true cost savings from interventions that reduce ICU length of stay. In a before-and-after study design,[81,82] investigators found that implementation of regular, structured family meetings emphasizing clinical milestones by the ICU team reduced median ICU length of stay from 4 to 3 days. ICU mortality rates also decreased, which the authors attributed to earlier triage of severely ill patients who were likely to die, with subsequent admission of less severely ill patients. So in effect, more efficient use of ICU beds in the care of severely ill patients did not result in any change in fixed ICU costs, because less-severely ill patients who were previously managed on the general wards were admitted to the ICU as more resources became available.

Transfer to Lower-Intensity Sites of Care

For critically ill patients, the highest intensity of care usually occurs within the first few days of ventilation. As gas exchange and hemodynamics improve, the level of nursing required to manage them decreases. As long as they remain in an ICU, however, the associated nursing commitment and costs remain substantial. When the lengths of stay extend beyond approximately 14 to 21 days, hospitals begin to assume considerable financial losses. Therefore, hospitals are quite motivated to find less-intensive sites of care for these patients.

Options for lower-intensity sites of care for patients requiring prolonged ventilation include (a) stepdown units or dedicated respiratory care units within the acute hospital, (b) transfer to separate acute care hospitals dedicated to weaning patients from mechanical ventilation such as regional weaning centers, long-term acute care hospitals (LTACs) or specialized rehabilitation hospitals, (c) transfer to skilled nursing facilities that offer ventilator care, or (d) discharge to home with home ventilation.[83] When ventilated patients are transferred from the acute ICU to stepdown units, some variable cost-savings are achieved primarily because of lower nurse to patient ratios. Prolonged weaning of weak patients demands a high degree of therapist monitoring, and aggressive physical rehabilitation during weaning is felt to be important for good outcomes. Therefore, in well-managed weaning units, savings in nursing costs are balanced by additional expenses for respiratory therapists and physical and occupational therapists. Custodial care of ventilated patients in skilled nursing facilities that does not include active weaning or rehabilitation is less expensive on a daily basis, but complete failure to wean patients results in higher long-term costs.

Hospitals realize the largest cost savings and open the most ICU beds by transferring ventilated patients to freestanding weaning hospitals, such as LTACs. These financial and resource incentives have driven considerable growth in the largely for-profit LTAC industry in the United States, resulting in an 8.8% increase in the number of LTAC hospitals per year between 1997 and 2006.[84] The number of patients transferred to LTACs for prolonged ventilation increased from 10,389 in the period between 1997 and 2000 to 30,877 between 2004 and 2006. It should be emphasized that transferring a ventilated patient to a freestanding weaning facility will result in cost savings for the hospital, but not necessarily for the health care system. Recent analyses sponsored by the Center for Medicare and Medicaid services have indicated that for patients transferred to LTACs, costs for the total episode of care (hospital and LTAC) were significantly higher than for similar patients whose total episode of care was managed completely at the acute care hospital. Whether this is secondary to additional costs and complications of transfer, less efficient management at the LTACs, or selection bias in the analysis, it certainly suggests that transferring patients to LTACs may ultimately result in cost shifting rather than overall cost savings.

THE FUTURE

Continued advances in technology will increase the gap between what critical care medicine can do and what is economically feasible to do. The formal application of health economics to guide decision making in the delivery or organization of critical care is in its early stages. Economic analysis will become more influential as providers become more familiar with its benefits and its limitations. Investigators can improve upon limitations by applying better methodology, especially relating to measurement of costs across various levels of care. Increasing sophistication of clinical information systems and inclusion of economic components in the design of clinical trials will provide higher quality data.[17,18] Investigators are continuing to refine quality-of-life assessments, and better understanding of long-term outcomes of critically ill patients is an area of growing research interest. More research into the behavioral aspects of medicine including social and professional expectations for distribution of resources will provide guidance to societies and health plans on how to utilize the data from economic analyses.[85]

Economic pressures and financial constraints will continue to have a beneficial effect on efficiency of care in the ICU by reducing waste and redundant services. ICU directors, however, need to exercise caution in the persistent drive for efficiency. Overly aggressive measures to discharge patients from the ICU and maintain high occupancy of only severely ill patients can worsen outcomes. For example, discharges from the ICU at night and ICU admissions during periods of peak occupancy and high nursing workload are associated with higher hospital mortality. From the perspective of society and health care systems, savings generated from reductions or restrictions in critical care services are justified only if those savings are invested in more effective services elsewhere in the system.

SUMMARY AND CONCLUSIONS

The high costs of critical care services will always make this area of medicine a target for cost containment. Patients requiring mechanical ventilation consume a disproportionate share of hospital resources, especially those requiring prolonged ventilation. Despite the costs, mechanical ventilation for patients with acute respiratory failure meets current standards for cost-effectiveness except for patients with the highest likelihood of short-term mortality. Strategies to reduce hospital costs are directed toward decreasing the duration of mechanical ventilation. These strategies include prevention of intubation by rapid response to illness and noninvasive ventilation when indicated, efficient evidence-based management practices, and optimal ICU organization including continuous quality improvement. Economic analyses will assume a greater role in decision making related to mechanical ventilation as investigators include cost and quality-of-life components in the design of clinical trials and as providers gain a better understanding of how to utilize the data.

LONG-TERM OUTCOMES AFTER MECHANICAL VENTILATION

Margaret Sutherland Herridge

When the first edition of this book was published in 1994, the standard metric of outcome after critical illness was 28-day all-cause mortality. Since that time, there has been a revolution in the way we view critical illness, its treatment, and its lasting effects both for the patient and the family caregiver. The dramatic rise in the number of longer-term outcomes reports published over the past 5 to 10 years clearly reflects this point. It is now apparent that most patients who have survived an episode of severe critical illness requiring mechanical ventilation will sustain some compromise in physical function related to intensive care unit (ICU) acquired weakness and a myriad of other physical disabilities.[1–5] This acquired disability may be permanent.[5] Patients may also sustain an important new or incremental decline in neuropsychological function, including neurocognitive impairments, and neuropsychiatric or mood disorders.[6–8] The constellation of muscle, nerve, and brain dysfunction[3,9–13] may permanently alter disposition for those who were previously independent and who, post-ICU, now require assisted living or comprehensive care.[1] ICU-acquired morbidity may result in an additional cost burden in health care utilization that is similar to patients with chronic disease,[1,5,13–14] and this traumatic life event may completely erode the reserve of family members and they may also acquire new mood disorders.[15–18]

This chapter reviews the literature on physical and neuropsychological outcomes after critical illness and highlights important emerging data that link patient characteristics, burden of comorbid disease, and ICU practice patterns to acquisition of new morbidity. In addition, newer data on psychological disability in family caregivers and models of rehabilitation and intervention after critical illness are discussed. To date, the outcomes literature has been dominated by reports on survivors of acute respiratory distress syndrome (ARDS), but there are emerging data on other vulnerable patient subgroups, such as the frail elderly and the chronically critically ill. Outcomes in these populations add insight to the current understanding of the diversity in post-ICU disability and also are discussed. The chapter concludes with a commentary on a proposed framework for a continuum of rehabilitation for patients and families after critical illness.

PHYSICAL MORBIDITY AFTER CRITICAL ILLNESS

The current state of the outcomes literature suggests that the greatest short-term morbidity after critical illness is diminished physical health-related quality of life as a consequence of ICU-acquired weakness.[3,5,9,10,13,19–22] Reports from long-term follow-up studies suggest that by 5 years, patients complain less of physical disability and more of a decline in general health, diminished vitality, and mood disorders.[5] The finding of compromised physical quality of life has been robust across many studies since the early 1990s, as discussed in detail below. An understanding, however, of the specific determinants of this reported decrease in physical function was not well known until more than a decade later.

Patients with acute lung injury and ARDS represent some of the most complex critically ill and long-stay ICU patients and have been the most rigorously studied group of ICU survivors to date. More than 100,000 patients survive acute lung injury and ARDS every year[24] and their outcomes dominate the review that follows. The emerging outcomes literature on the chronically critically ill, elderly, and sepsis patient populations adds nuance and depth to our understanding of the spectrum of disability and is also included.

Physical Function and Health-Related Quality of Life

Health-related quality of life is a set of causally linked dimensions of health, including biologic/physiologic, mental, physical, social function, neurocognitive, and health perception.[21] Measures of health-related quality of life have emerged as important patient-centered metrics of recovery from critical illness. These questionnaires provide ease of administration and ready interpretability with published normative data for comparison, although fail to yield crucial details about the exact nature of any reported disability. Without this insight or more detailed understanding, the investigator is left to blindly hypothesize about the etiology of the reported disability and limits her or his ability to construct appropriate interventional or rehabilitation programs.

There is emerging evidence that the degree of disability acquired after critical illness and resultant health-related quality of life is variable and relates to differences in premorbid functional status, burden of comorbid illness, and nature and duration of critical illness.[1,3,4] Although there is some heterogeneity across different study samples of patients with ARDS, there is less variability in reported health-related quality of life among this group than in general populations of critically ill patients.[24] The following is an overview of the literature on ARDS health-related quality of life and these data highlight the consistent signal of diminished physical function reported up to 1 year after severe lung injury, and also the controversy that still continues about the relative contribution of pulmonary disability to functional decline after ARDS and severe critical illness. In 1994, McHugh et al were the first group to prospectively evaluate the relationship between pulmonary dysfunction and functional disability in patients with ARDS.[19] They noted that scores for the Sickness Impact Profile (a generic quality-of-life measure of the subject's self-perceived physical and psychological condition) rose substantially to 3 months postextubation with only minimal further improvement to 1 year. Using a lung-related Sickness Impact Profile score, only a modest proportion of the patients' overall physical dysfunction was attributed to pulmonary difficulties. Weinert et al[20] documented functional impairment in a cohort of lung injury survivors using the Medical Outcomes Study 36-item short-form health survey (SF-36) and reported the largest decrements in role-physical and physical-functioning domains, which patients attributed to global disability.[25] Similar observations were made by other groups who inferred that disability in their patients with ARDS was secondary to pulmonary dysfunction in the absence of any direct pulmonary measurement[26] or through administration of pulmonary disease-specific measures and this failed to differentiate between pulmonary and extrapulmonary disability.[22] Others have made comparisons to control populations of patients with known pulmonary disease (e.g., cystic fibrosis), but after health-related quality-of-life measures had been disaggregated, symptom burden was seen to be related to musculoskeletal or constitutional issues.[10] In the context of outcome evaluation after a trial comparing higher versus lower tidal volumes during mechanical ventilation, some have demonstrated very modest abnormalities of pulmonary function, which correlate with reduced function on health-related quality-of-life metrics, and maintain that there is an important relationship between pulmonary and functional outcomes in ARDS survivors.[28]

In 2003, Herridge et al reported on 109 ARDS survivors at 3, 6, and 12 months after ICU discharge and captured function as distance walked in 6 minutes, pulmonary function, and health-related quality of life using the SF-36. The investigators also did a detailed in-person interview and physical assessment as part of each follow-up visit. In their relatively young patient sample (median age: 45 years), with few comorbidities and who had been working full time before their critical illness, 6-minute walking distance was 66% at 1 year and pulmonary function was normal or near normal. They noted that the major morbidity after ARDS and sepsis was muscle wasting and weakness.[3] In-person evaluation of patients and the collection of multiple outcome measures led the investigators to different conclusions about the major contributors to morbidity after severe lung injury and also facilitated the generation of a catalogue of physical disabilities that contribute to poor health-related quality of life (Fig. 68-1).

Impaired physical function is a robust observation across different studies, countries, and investigators, and may persist for years after ICU or hospital discharge and be irreversible (Fig. 68-2).[4,5] Health care costs generated by relatively young, previously working patients in an ARDS cohort followed to 5 years were higher than predicted for this age group and comparable to patients with chronic disease (Fig. 68-3). It was not expected that this patient group would not fully recover from their critical illness in terms of physical functioning, emotional outcomes, or quality of life, and this finding has significant public health ramifications.

RISK FACTORS FOR POOR FUNCTIONAL OUTCOME AFTER CRITICAL ILLNESS

The ARDS outcomes data are instructive because most of these study samples involved younger patient groups with few or no premorbid conditions. It was a surprising and striking observation that these patients did not fully recover

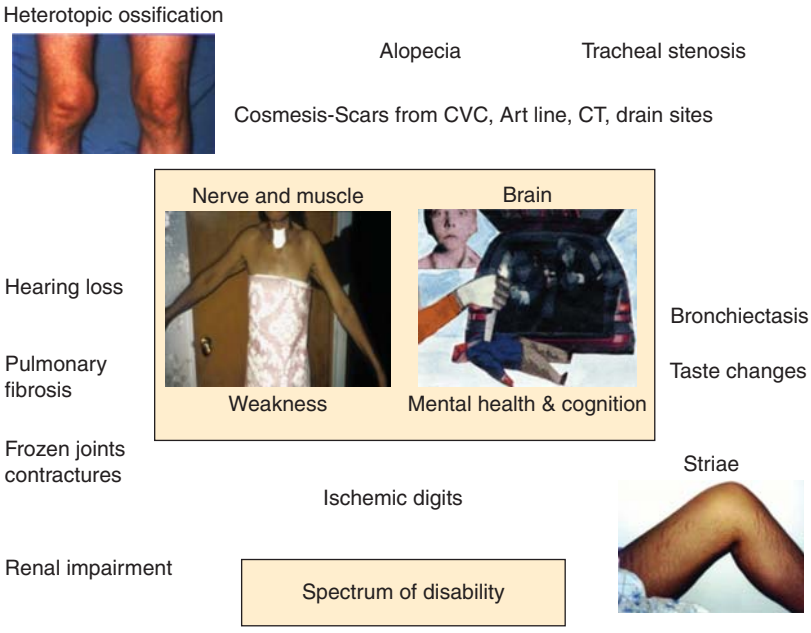

FIGURE 68-1 The spectrum of disability in survivors of critical illness. Brain, muscle, and nerve are the major morbidities; others are less common.

and had important and persistent morbidity for years after their critical illness. These data establish that there is a physical and neuropsychological "cost" to a severe episode of critical illness, and that most patients, particularly those in more vulnerable groups, such as patients requiring prolonged mechanical ventilation, patients with a significant burden of comorbid illness, and the elderly, may suffer even greater functional decline and require dependent care as a result of their critical illness.

Studies on survivors of prolonged mechanical ventilation have helped in elucidating important risk factors for outcome and change in disposition. Chelluri et al evaluated factors associated with mortality and quality of life in 817 patients 1 year after prolonged mechanical ventilation.[28] The median age of their patients was 65 and 1-year survival was 44%. Those patients surviving their ICU stay had fewer comorbidities, lower severity of illness scores, and less premorbid dependence in activities of daily living. Fifty-seven percent of surviving patients needed caregiver assistance at 1 year of follow-up. A French study by Combes et al evaluated 347 patients receiving mechanical ventilation for equal to or greater than 14 days.[29] Factors associated with death in the ICU included age greater than 65 years, preadmission New York Heart Association functional class of equal to or greater than 3, preadmission immunocompromised status, septic shock at ICU admission, need for renal replacement therapy in the ICU, and nosocomial septicemia.

Unroe et al evaluated the trajectories of care and resource utilization for 126 patients with a median age of 55 years who also required prolonged mechanical ventilation. These patients had, on average, two comorbid conditions, and most were not working, retired, or disabled at the time of ICU admission. At 1 year, only eleven patients (9% of the cohort) were alive and without functional dependency. Patients with poor outcomes were older, had more comorbid conditions, and were more frequently discharged to a post–acute care facility. The mean cost per patient was $306,135 (standard deviation [SD]: $285,467) and total cohort cost was $38.1 million, for an estimated $3.5 million per independently functioning survivor at 1 year.[1]

Iwashyna et al noted persistent reduction in functional status after sepsis and critical illness, again echoing the theme of acquired disability after critical illness. Among older patients (median age: 77 years), they observed a high rate of new functional limitations in those who had no limits before their episode of sepsis (mean: 1.57; 95% confidence interval [CI]: 0.99 to 2.15). In patients with reductions in activities of daily living before sepsis, they noted an important further decrement in function. Neurocognitive and physical decline persisted for at least 8 years after the episode of sepsis and altered patients' ability to live independently.[4]

The impact of increased age, however, on outcomes after critical illness remains somewhat controversial. Some studies report higher mortality with advanced age[30] and others do not.[31,32] Khouli et al[33] recently evaluated 484 patients, who were age 65 years and older, and administered an health-related quality-of-life instrument to the patient or proxy at ICU admission and 6 months after hospital discharge. One-third of these patients died within 6 months of hospital discharge. Independent predictors of death at 6 months were: number of days during the 30 days before hospitalization that the patient felt their "physical health was not good," a higher Acute Physiology and Chronic

Health Evaluation (APACHE) II score, and chronic pulmonary disease. This same group also found that the oldest survivors (age 86 years) had worse health-related quality of life over time, including more days spent with poor physical and mental health, compared to baseline. There appears to be a clear prognostic signal in the elderly in terms of physiologic reserve, burden of chronic organ dysfunction, and nature of the health trajectory before the critical illness with regards to prognostication for survival, function, and health-related quality of life; emphasis on physiologic rather than chronologic age may provide valuable insight into projected outcome.

Neuromuscular Dysfunction

Muscle weakness and impaired function constitute an important morbidity of severe critical illness. A continuum of weakness begins within hours of mechanical ventilation,[34] is demonstrable by bedside evaluation within 1 week of ICU admission using the Medical Research Council scoring system,[35] and may persist with incomplete recovery for years after ICU discharge[5,36–41] (see Fig. 68-2). In the ICU context, muscle weakness has been linked to prolonged mechanical ventilation,[42,43] delay in ICU and hospital discharge, increase in associated costs,[44,45] and increased likelihood of death.[46]

Many challenges confound the ability to characterize and intervene in neuromuscular disability after critical illness. Important heterogeneity exists in susceptibility and risk factors across different critically ill patient populations. There are no validated measures to reliably risk stratify patients according to physical disability and no consistent nomenclature for the spectrum of lesions that constitute muscle weakness and wasting. Currently, different terminologies coexist in the literature and include critical illness polyneuropathy, critical illness polyneuropathy and myopathy, critical illness neuromyopathy, ICU-acquired paresis, critical illness myopathy and/or neuropathy. This complexity is compounded by the observation that nerve and muscle injury may coexist, and it is difficult to delineate discrete risk factors and natural history. There are obstacles in terms of the variety and sensitivity of testing methods, criteria for diagnosis, surveillance and selection bias in evaluation and reporting. Sensory and motor evaluations are limited in heavily sedated patients, and, therefore, clinical bedside testing and determination of the prevalence of these lesions may be unreliable.

Despite these limitations, a recent classification system was proposed by Stevens et al (Table 68-1).[47] This system is simple, accessible, and clinically relevant, and emphasizes clinical assessment and bedside testing. It proposes a broad classification for ICU-acquired weakness and highlights it as a diagnosis of exclusion, onset during the critical illness, ventilator dependence, and weakness demonstrable by use of bedside hands-on muscle testing (Medical Research Council score). A diagnosis of critical illness polyneuropathy is made in those who meet criteria for ICU-acquired weakness and have electrophysiologic evidence of a sensorimotor axonal polyneuropathy. A diagnosis of pure critical illness myopathy is made in patients who meet criteria for ICU-acquired weakness and who have myopathic features on electromyelography during muscle contraction and/or myopathic biopsy.

This section discusses the pathophysiologic mechanisms for muscle and nerve injuries (Fig. 68-4). Given the limitations in this distinction, as outlined above, the mechanisms are broadly grouped as critical illness polyneuropathy and critical illness myopathy.

CRITICAL ILLNESS POLYNEUROPATHY

Background and Incidence. Bolton et al published a landmark study on critical illness polyneuropathy in 1984.[48] They described a primary axonopathy that presented as a mixed sensorimotor neuropathy in five critically ill patients who were ventilator dependent. Detection of the true incidence of critical illness myopathy is complicated by poor consensus on surveillance, timing, and nature of testing, and formal definition and diagnostic criteria (as outlined above). When patients are evaluated solely on the presence of clinical weakness, studies demonstrate an incidence of 25% to 36%.[35,49] A review of 1421 critically ill patients, evaluated using diagnostic tests (nerve conduction velocities, needle electromyography, direct muscle stimulation, histopathology of muscle or nerve tissue) or a combination of test findings and clinical findings, reported an incidence of critical illness neuromyopathy of 46% (95% CI: 43% to 49%).[50]

TABLE 68-1: SUMMARY OF DIAGNOSTIC CRITERIA FOR INTENSIVE CARE UNIT-ACQUIRED WEAKNESS, CRITICAL ILLNESS POLYNEUROPATHY, AND CRITICAL ILLNESS MYOPATHY

Diagnostic criteria for ICU-acquired weakness (ICUAW) 1, 2, 3 or 4, 5 below
1. Generalized weakness developing after the onset of critical illness
2. Weakness is diffuse (involving both proximal and distal muscles), symmetric, flaccid, and generally spares cranial nerves
3. MRC (Medical Research Council) sum score[a] <48, or mean MRC score <4 in all testable muscle groups noted on two or more occasions separated by >24 hours
4. Patient dependent on mechanical ventilation
5. Other causes of weakness not related to underlying critical illness have been excluded

Diagnostic criteria for critical illness polyneuropathy (CIP)
1. Patient meets criteria for ICUAW
2. Compound muscle action potential amplitudes are decreased to <80% of lower limit of normal in two or more nerves
3. Sensory nerve action potential amplitudes are decreased to <80% of lower limit of normal in 2 or more nerves
4. Normal or near-normal nerve conduction velocities without conduction block
5. Absence of a decremental response on repetitive nerve stimulation

Diagnostic criteria for critical illness myopathy (CIM)
1. Patient meet criteria for ICUAW
2. Sensory nerve action potential amplitudes are >80% of the lower limit of normal in two or more nerves
3. Needle electromyogram in two or more muscle groups demonstrates short-duration, low-amplitude motor unit potentials with early or normal full recruitment with or without fibrillation potentials
4. Direct muscle stimulation demonstrates reduced excitability (muscle-to-nerve ratio >0.5 in two or more muscle groups)
5. Muscle histology is consistent with a myopathy

Probable CIM: criteria 1, 2, 3, or 4; or 1 and 5 (listed above)
Definite CIM: criteria 1, 2, 3 or 4, 5 (listed above)

[a]MRC Sum score assesses three muscle groups in each of the upper and lower limbs. Each muscle group score ranges from 0 (paralysis) to 5 (normal muscle strength), and the overall score ranges from 0 to 60.

Etiology and Pathophysiology

Systemic Inflammatory Response Syndrome and Sepsis

Critical illness polyneuropathy has been associated with sepsis and systemic inflammatory response syndrome in multiple cohort studies.[50] In sepsis, critical illness polyneuropathy is linked to microcirculatory perturbations with resultant axonal injury and degeneration. A recent report describes proinflammatory cytokine (tumor necrosis factor-(and interleukin-1)-mediated increased expression of E-selectin on the endoneurial and epineurial vessels

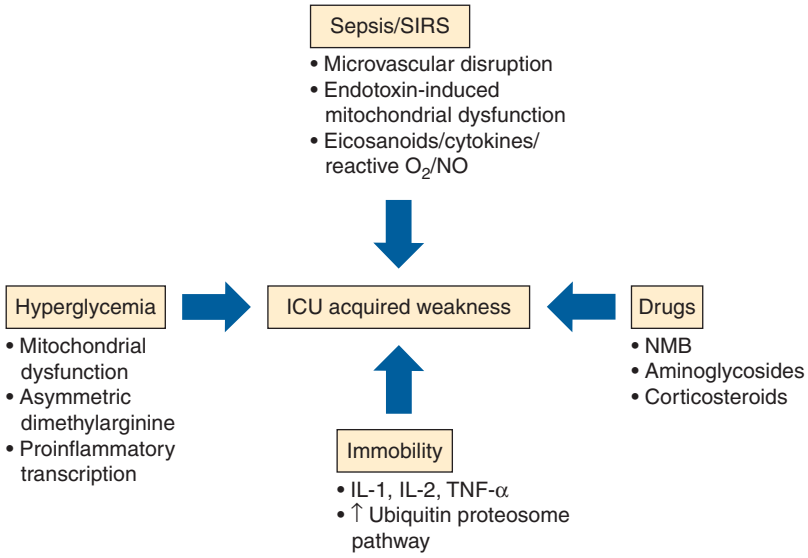

FIGURE 68-4 Risk factors for ICU acquired weakness. *IL-1*, interleukin-1; *IL-2*, interleukin-2; *NMB*, neuromuscular blockers; *NO*, nitric oxide; *TNF-α*, tumor necrosis factor alpha. (Adapted, with permission, from Stevens RD. *Crit Care Clin.* 2008;24:1–24.)

of peripheral nerves.[51] There may be functional disruption of nerve action potential early in the course of disease, which may be a harbinger of later structural derangement of the nerve.[52]

Hyperglycemia Hyperglycemia in critically ill surgical and medical populations is consistently associated with ICU-acquired weakness.[53,54] Van den Berghe et al demonstrated that tight glycemic control reduced critical illness polyneuropathy in defined by neurophysiologic testing, from 51.9% in control subjects to 28.7% among insulin-treated patients.[53,54] Hyperglycemia may be harmful based on mitochondrial dysfunction and the deleterious effects of oxidant injury and apoptosis.[55,56] Derangement of nitric oxide production is also a postulated mechanism,[57] as is the role of insulin in inhibiting proinflammatory transcription factors and promotion of neuroregeneration during critical illness.[58,59]

Pharmacologic Agents Early reports suggested an association between neuromuscular dysfunction and exposure to neuromuscular blockers and systemic corticosteroids.[60–62] This risk was profiled in patients with status asthmaticus who developed ICU-acquired weakness and received treatment with both agents.[63] These risks have not been borne out in systematic review because of confounding by exposure to aminoglycosides, vasopressors, and renal replacement therapy in sepsis and systemic inflammatory response syndrome patients.[50,64–65] In a 1-year outcomes study in patients with ARDS, exposure to any systemic corticosteroid was significantly associated with a decrease in 6-minute walking distance at 3 months in a multivariable model, and patients demonstrated important proximal weakness in the shoulder and hip girdle at that time point.[3] A recent trial using 48 hours of continuous paralytic in patients with severe lung injury saw significant organ function improvement, and the continuous paralytic was not associated with an increased risk of ICU-acquired weakness assessed by manual muscle testing at ICU discharge.[66] No long-term follow-up, however, was done, and there is concern that manual muscle testing may not have adequate sensitivity to detect ICU-acquired weakness.[66] Early corticosteroid use appears to be strongly associated with ICU-acquired weakness, although the risk associated with paralytic use remains somewhat uncertain.

CRITICAL ILLNESS MYOPATHY

Background and Incidence. Critical illness myopathy currently encompasses critical illness myopathy, acute quadriplegic myopathy, thick filament myopathy, and necrotizing myopathy, and the incidence varies between 48% and 96% in studies that included muscle biopsy.[65] Critical illness myopathy is a nonnecrotizing diffuse myopathy associated with fatty degeneration of muscle fibers, fiber atrophy, and fibrosis.[67] This lesion has also been linked to corticosteroid and paralytic exposure and may be clinically indistinguishable from critical illness polyneuropathy because patients are also weak, paretic, and difficult to wean.

Thick-filament myopathy shows a selective loss of myosin filaments in the context of significant corticosteroid or neuromuscular blocker exposure and immobility.[68] Acute necrotizing myopathy is distinguished by extensive myonecrosis with vacuolization and phagocytosis of muscle fibers, and is linked to corticosteroid and neuromuscular blocker exposure and multisystem organ dysfunction.[69]

Etiology and Pathophysiology. The pathophysiology of critical illness myopathy involves catabolism, inflammation, and derangement of membrane excitability. An increase in urinary nitrogen loss, low glutamine, protein, and DNA levels in muscle biopsies, and upregulation of the calpain and ubiquitin proteolytic pathways and apoptosis have all been documented.[70]

Inactivity in critically ill patients propagates inflammatory mediators, which stimulate protein loss in differentiated muscle cells, activate signaling events that promote oxidative injury and disruption of insulin receptor signaling with resultant substrate reduction and impairment of myofibril growth and repair.[71] Interleukin-1, interleukin-6, and tumor necrosis factor-α have proinflammatory properties and have all been implicated in muscle degradation in critical illness and augmentation of proteolysis and muscle loss. Muscle membrane inexcitability may also contribute to weakness and is related to inactivation of sodium channels. Allen et al recently reported altered muscle-fiber excitability and evidence for muscle membrane dysfunction as the principal underlying abnormality in critical illness myopathy.[72]

Pulmonary Function

Pulmonary function outcomes may be heterogeneous after an episode of ARDS. Many ARDS survivors have persistent pulmonary function impairments: typically, mild restrictive changes with an associated reduction in diffusion capacity.[3,19] Others have documented more diversity in outcome, with significant variability in the proportion of patients with obstructive (0% to 33%) and restrictive (0% to 50%) defects, as well as compromised diffusion capacity (33% to 82%).[73] There are reports of mild pulmonary function abnormalities associated with decreased health-related quality of life 1 year following hospital discharge[27] and no improvement in pulmonary function after the first year.[74] Most recent data from a 5-year outcomes cohort study in patients with severe ARDS shows normal to near normal pulmonary function achieved by 6 months to 1 year after ICU discharge and continued stability over the 5-year study period.[5]

There are imaging studies of ARDS survivors at 6 to 10 months,[75] 3 years,[76] and 5 years.[5,77] Investigators have noted that most patients with ARDS had minor localized changes in the nondependent lung zones (Fig. 68-5), and were able to document some association with severity of lung injury

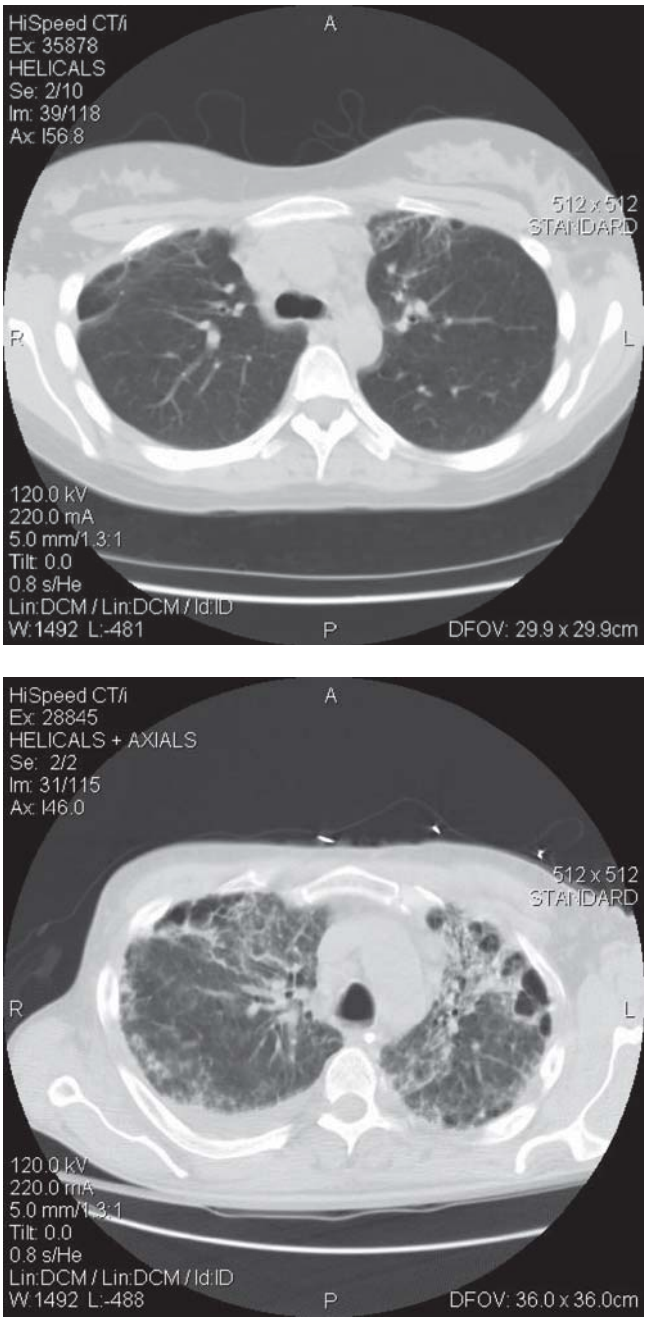

FIGURE 68-5 *Top Panel:* Computed tomography (CT) findings at 1 year after acute respiratory distress syndrome (ARDS) in a young, previously healthy person without preexisting lung disease. Finding of minor nondependent fibrosis and minor cystic changes were most common in this group. *Bottom panel:* CT findings at 1 year after ARDS in same group of ARDS survivors with an example of a rare finding of more marked nondependent fibrosis, bronchiectasis, and cystic changes.

and duration of mechanical ventilation.[75,76] There were also findings of bronchiectasis or new pulmonary fibrosis in one-third of patients in one study[5] (Fig. 68-5) and loss of ventral distribution in reticular pattern in patients treated with extracorporeal membrane oxygenation.[77]

The variability in reported pulmonary outcomes to date suggests possible confounding by smoking history, preexisting obstructive or restrictive pulmonary disease, physiologic restriction related to ICU-acquired weakness affecting respiratory muscles, presence of other pulmonary processes that fulfill the ARDS definition but that have a very different natural history (e.g., cryptogenic organizing pneumonia), and loss to follow-up that continues to challenge validity and interpretation of follow-up data. Most outcome studies found ARDS survivors are often unable to resume their prior physical function, and the degree of pulmonary dysfunction documented across studies does not solely explain their degree of functional limitation.

Additional Physical Morbidities

The spectrum of physical morbidities after critical illness is shown in Figure 68-1.

ENTRAPMENT NEUROPATHY

The Toronto ARDS Outcomes study observed a 6% prevalence of peroneal and ulnar nerve palsies.[3] Although this represents only a small proportion of patients, these nerve palsies complicated rehabilitation therapy and precluded return to original work in some cases. Recovery was protracted, although by 5 years all had resolved.

HETEROTOPIC OSSIFICATION

Heterotopic ossification is the deposition of paraarticular ectopic bone and has been previously associated with polytrauma, burns, pancreatitis, and ARDS.[78] Heterotopic ossification is linked with paralysis and prolonged immobilization. There was a 5% prevalence of heterotopic ossification in the Toronto ARDS cohort study with all patients having large joint immobilization, leading to important functional limitation.[3] Heterotopic ossification is remediable with appropriate surgical intervention, and screening for it may help to improve long-term functional outcomes (see Fig. 68-1).

COSMESIS

After a life-threatening event, concerns about cosmesis might be considered trivial. The physically transformative nature of critical illness, however, cannot be overstated. Many patients suffer from the often devastating emotional effects related to their altered appearance. From the 5-year ARDS outcomes study by Herridge et al,[5] patients had ongoing concerns about cosmesis, including scars from laparotomy; chest tube; central line, arterial line, and tracheostomy insertion; burns; striae from volume overload (see Fig. 68-1); and facial scars from prolonged noninvasive mask ventilation. Many patients underwent tracheostomy revision. Patients reported that cosmetic concerns contributed to social isolation and sexual dysfunction.

CRITICAL ILLNESS AND BRAIN INJURY

Psychiatric Morbidity

Psychiatric disorders are common among survivors of critical illness. The prevalence of depression and anxiety in different samples of ICU survivors ranges from 10% to 58%.[12,79–82] In a recent systematic summary, Davydow et al reported that 28% of post-ICU patients had clinically significant depression.[81] Neither sex, age, nor severity of illness at ICU admission were consistent risk factors for this, but early post-ICU depressive symptoms were a strong risk factor for subsequent depressive symptoms and associated with a reduction in quality of life.[82]

Depression in ARDS survivors ranges from 17% to 58%, with some suggestion that patients with ARDS have a greater degree of depression compared to populations of general critically ill patients.[8,20,79,81,82] Risk factors associated with depression in patients with ARDS have included duration of mechanical ventilation, ICU length of stay and sedation, alcohol dependence, female gender, and younger age.[8,82] Predictors of anxiety at 1 year included ratio of arterial oxygen tension to inspired oxygen fraction and duration of mechanical ventilation; prediction of anxiety at 2 years was anxiety at 1 year.[82] A recent study found that hypoglycemia may be an important risk factor for depression in ARDS survivors and this warrants further investigation.[83] Post-ICU affective disorders are likely multifactorial and further study will be needed to better understand patient predisposition, illness, and treatment-specific determinants of affective morbidity, and appropriate tools for diagnosis and monitoring.

Posttraumatic stress disorder (PTSD) is the development of characteristic symptoms that occur following a traumatic event(s) where triggers include a serious personal threat experienced with helplessness and intense fear.[84] The diagnostic criteria include a history of traumatic event(s) accompanied by symptoms from each of three symptom clusters: hyperarousal symptoms, intrusive recollections, and avoidance or numbing symptoms. A number of studies have examined relationships between life-threatening critical illnesses and its treatment and the development of PTSD. Schelling et al published a landmark paper on PTSD after critical illness.[26] These authors evaluated health-related quality of life and PTSD in a cohort of eighty ARDS survivors 4 years after ICU discharge. Almost one-third of the ARDS survivors reported impaired memory, bad dreams, anxiety, and sleeping difficulties after ICU discharge. The prevalence of PTSD was 28% and the number of adverse ICU-related memories recalled by patients was the major risk factor for PTSD. Kapfhammer et al found that 44% of critically ill patients developed PTSD at hospital discharge and 24% had PTSD symptoms 8 or more years later.[85] Davydow et al reported the median point prevalence of questionnaire-ascertained "clinically significant" PTSD symptoms was 22%, and the median point prevalence of clinician-diagnosed PTSD was 19% in populations of general critically ill patients.[86] Prior psychopathology, greater ICU benzodiazepine administration, post-ICU memories of frightening and/or psychotic experiences in the ICU, and absence of any ICU memory were consistent risk factors for post-ICU PTSD.[87]

Patients with ARDS may be more susceptible to PTSD than are critically ill patients in general, and these symptoms may persist for years. The prevalence of PTSD, as diagnosed by a psychiatrist, has been reported to be 44%, 25%, and 24% at hospital discharge, 5 years and then 8 years later, respectively.[8]

The etiology of psychiatric disorders following critical illness may be secondary to sequelae of brain injury sustained from critical illness and/or its treatments, a psychological reaction to the emotional and physiologic stress of critical illness, or both. Factors such as medications, physiologic changes, pain, altered sensory inputs, and an unfamiliar environment are all potential contributors to the development of psychiatric sequelae.[88–90] A recent review article found an association between recall of delusional memories after ICU discharge and PTSD-related symptoms, depression, and anxiety.[91] Factual memories do not seem to protect survivors from experiencing symptoms of PTSD. A study by Myhren et al, which evaluated 194 patients, found that 27% had symptoms of posttraumatic stress and predictors of PTSD were higher education level, optimism, factual recall, and memory of pain.[92]

Although we are just beginning to appreciate how long-standing and debilitating psychiatric disorders are following critical illness and the important contribution they make to decreased health-related quality-of-life and functional outcomes, recent studies are beginning to investigate potential interventions to prevent or reduce psychiatric sequelae. A recent review paper suggests that corticosteroid administration may be protective for post-ICU PTSD.[93] A novel study suggests that use of ICU diaries in critically ill patients may reduce the incidence of PTSD. Jones et al conducted a randomized, controlled trial, in which patients were provided with an ICU diary that contained information and photographs from their ICU stays.[94] Of the patients who received the diary, only 5% had clinically significant PTSD symptoms as compared to 13% of controls. Furthermore, the patients who experienced the greatest benefit from the ICU diary intervention were those who had substantial early PTSD symptoms.[94]

Neurocognitive Impairments

Critical illness is associated with new neurocognitive impairments[7,11,12] that may be permanent. In their landmark paper in 1999, Hopkins et al were the first to demonstrate that all survivors in their ARDS cohort had cognitive impairment, including deficits in memory, attention, or concentration, and a global loss of cognitive function at hospital discharge and continued dysfunction in 30% of patients at 1-year follow-up.[11] These findings persisted at 2-year

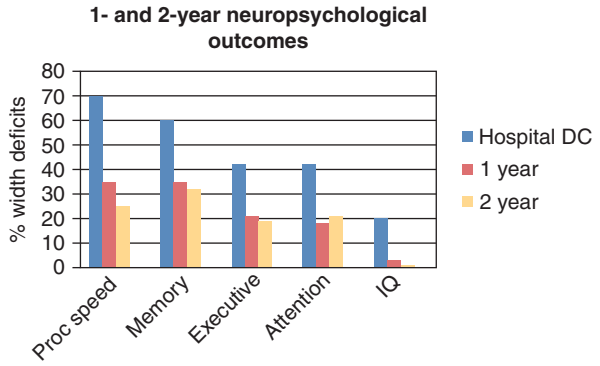

FIGURE 68-6 Domains of persistent neurocognitive dysfunction 1 to 2 years after an episode of acute respiratory distress syndrome. These include reductions in processing speed, memory, executive function, attention and concentration, and IQ. (Adapted, with permission, from Hopkins et al.[11] *J Int Neuropsych Assoc*. 2003;9:584.)

follow-up (Fig. 68-6).[12] These observations are robust and other investigators have documented the persistence of neurocognitive impairments in large numbers of patients at 2 months,[9] 9 months,[95] 1 year,[11] 2 years,[12] and 6 years.[96] Neurocognitive dysfunction appears to improve during the first 6 to 12 months after hospital discharge. The neurocognitive impairments are often long lasting and quite severe, and many patients continue to experience significant chronic neurocognitive impairments years after ICU discharge.[96] To date, almost 1000 patients in fifteen cohorts[79,96–100] have had some form of neurocognitive assessment after critical illness. Risk factors have included the nature of the insults experienced during critical illness and its treatment, presence of preexisting neurologic abnormalities, older age, and comorbid disorders that might render specific domains more vulnerable to critical illness-induced brain injury. For example, patients with ARDS with neurocognitive sequelae all fell below the sixth percentile of the normal distribution of neurocognitive functioning, and had significant deficits in wide-ranging cognitive domains, including memory, executive functioning, and mental-processing abilities.[2]

The question remains whether critical illness and/or its treatment is the cause of observed neurocognitive impairments or if the impairments disclose preexisting subclinical brain dysfunction. A recent longitudinal cohort study in older adults without premorbid neurocognitive impairments or dementia assessed neurocognitive function before and after an acute care or ICU hospitalization.[101] Those who underwent acute care or critical illness hospitalization had a greater decline in neurocognitive function and new incident dementia compared to individuals who were not hospitalized. The Health and Retirement Study findings were consistent with this observation. That study followed more than 27,000 older Americans who had neurocognitive assessment both before and after sepsis.[4] Patients with severe sepsis developed new, important, and persistent neurocognitive impairment. Thus, factors associated with acute or critical illness may be causally related to neurocognitive decline in older critically ill patients.[4,101]

PATHOPHYSIOLOGIC MECHANISMS OF NEUROCOGNITIVE IMPAIRMENTS

The etiology of neurocognitive dysfunction is complex, multifactorial, and interacts with concurrent comorbidities and individual susceptibility. It cannot be explained by severity of illness and, specifically, is not related to severity of illness scores, medical data, age, smoking, alcohol abuse, ICU length of stay, duration of mechanical ventilation, tidal volume, or days receiving sedative, narcotic, or paralytic medications.[12] Candidate pathophysiologic mechanisms may include hypoxemia,[11] sedatives or analgesics,[102] hypotension,[99] delirium,[103] hyperglycemia,[83] and sepsis and inflammation.[104]

Hypoxemia. Hopkins et al evaluated pulse oximetry in a prospective cohort of mechanically ventilated ARDS survivors and studied the relationship between the duration and severity of a mean oxygen saturation below 90 and neurocognitive outcome.[11] Mean saturations were below 90% for 122 ± 144 hours per patient, and the extent of hypoxemia correlated significantly with neurocognitive dysfunction (r^2 0.25 to 0.45; all $p < 0.01$).[11] Hypoxia may be associated with cortical atrophy[103–107] and ventricular enlargement consistent with neuronal cell loss, as well as an increase in ventricular volume.[106–108]

Hypotension. The relative contribution of hypotension to poor neurocognitive outcomes may be more equivocal. Previous studies have demonstrated a correlation between mean blood pressure less than 50 mm Hg and memory scores at hospital discharge.[109] Others have reported that the duration of hypotension only modestly correlated with impaired memory at hospital discharge and 1 year, but not at 2 years.[12]

Delirium. Delirium affects 60% to 80% of mechanically ventilated patients and often goes undiagnosed in the absence of systematic screening.[110–113] It is an independent risk factor for ICU and hospital length of stay,[113–115] increased cost,[116] long-term neurocognitive impairment,[117–118] and death.[119–121] In addition, there are studies that link the disturbing dreams or persecutory delusions experienced as part of delirium as important risk factors for the long-term development of PTSD (Fig. 68-7).[122]

There are emerging data highlighting the importance of delirium either as a marker for or part of the causal pathway for long-term neurocognitive dysfunction. A review of the association between delirium and long-term cognitive dysfunction[103] reported four studies with greater decline on neurocognitive measures at follow-up among patients experiencing delirium during hospitalization and four studies that found a higher incidence of dementia at long-term follow-up in elderly patients.[103] More recent studies in patients who had documented delirium have revealed long-term neurocognitive impairment in one-third of patients at 6-month follow-up.[7] This relationship has also been observed at 3 and 12 months in a different patient sample, and neuropsychological impairment was also significantly linked to days of delirium.[123]

FIGURE 68-7 Picture drawn by a critically ill patient illustrating the violent and persecutory delusions experienced during active delirium while in the ICU. This picture illustrates how patients perceive threats to their safety and violent acts being perpetrated upon them during their stay in the ICU. (Used, with permission, from Griffiths and Jones.[9])

Glucose Dysregulation. The relationship between blood glucose dysregulation and neurocognitive function has been evaluated at 1-year posthospital discharge,[124] and demonstrated an important relationship between moderate hyperglycemia during ICU and compromised neurocognitive outcomes in ARDS survivors. Recent data from surgical critically ill patients showed that hypoglycemia, hyperglycemia, and important fluctuations in blood glucose were also associated with compromise in cognitive outcome.[125] Hypoglycemia has been associated with a 3.6-fold increased risk of depression in patients with ARDS, further underscoring the relationship between glucose levels and neurological sequelae.[126]

Sedatives or Analgesics. The impact of sedatives, narcotics, and anesthetics on long-term neurocognitive function is conflicting, although there may be an important early signal in reports suggesting that neurotoxic effects are more pronounced in high-risk groups, such as the elderly (>75 years) or those who have sustained recent brain injury or neurocognitive impairment.[127,128] A recent substudy of the Awakening and Breathing Trial, however, showed that composite cognitive scores at 3-month and 12-month follow-up were similar between the intervention arm (spontaneous daily awakening and spontaneous breathing trials, with consequent less sedation exposure) compared to usual practice with spontaneous breathing trials.[129]

Inflammation, Systemic Inflammatory Response Syndrome, and Sepsis. Neurocognitive morbidity may also be generated by inflammatory mediators and cytokines propagated by sepsis and the systemic inflammatory response syndrome. The brain is vulnerable to systemic inflammatory reactions in sepsis[104] that penetrate the blood–brain barrier and may modulate brain activity. Endotoxin-induced inflammation and cytokine activation are associated with impaired learning and memory,[130] and neurocognitive dysfunction.[131] Animal models of sepsis demonstrate increased levels of interleukins 1 and 6 in the prefrontal cortex and hippocampus that are associated with learning and memory tasks.[132–133] Congruent with this finding, a recent long-term outcome study showed that sepsis survivors had neurocognitive impairments several years after hospital discharge.[134]

CAREGIVER AND FAMILY BURDEN IN CRITICAL ILLNESS

The impact of a severe episode of critical illness on the caregiver and family has only recently gained momentum as an important issue in critical care medicine. There is no question that the caregiver suffers enormously during and after the illness. Caregivers conduct bedside vigils for their loved ones during the ICU stay, and then are saddled with virtually complete responsibility for the medical and psychological care of their family member who often has new complex medical needs, perhaps unresolved delirium, and new functional dependence. In some ways, it is surprising that it has taken so long for the caregiver issues to have been prioritized and acknowledged as a key component in the patient's rehabilitation program and ultimate outcome.

Recent work indicates that close to 60% of ICU survivors who received long-term mechanical ventilation still required the assistance of a family caregiver 1 year after their critical illness.[28] Existing evidence suggests that providing such care may have a deleterious impact on caregivers, and may compromise health-related quality of life compared with age-matched and sex-matched persons.[18] There are also reports of important mental health issues in caregivers, including PTSD,[135] emotional distress,[18,136–138] caregiver burden,[139] depression,[140] and anxiety.[141]

In a recent review, Johnson[144] concluded that caregivers experience burden because of the patient's physical and psychological dysfunction and the challenges of managing complex care in the home. Lifestyle disruption and provision of high levels of care[19] also contribute to poor caregiver outcome.[19,145] Much of the current research work has been limited by the cross-sectional design and follow-up to 1 year after hospital discharge. It is likely that caregiver needs will change over time as patients move through different transitions in their recovery[146] and attempt to return to work and resume their prior lifestyle.[147]

CONTINUUM OF CARE DURING AND AFTER CRITICAL ILLNESS: INTENSIVE CARE UNIT AND POST-INTENSIVE CARE UNIT REHABILITATION

There are many barriers to improving outcome after critical illness in patients and family caregivers. First, we need to embrace the concept of a family-centered longitudinal

model of care and recovery where we acknowledge that both patients and family caregivers have important needs during and after the ICU stay and that these needs will evolve and change at different transition points during recovery.[146] Second, we need to be honest and acknowledge that current ICU practice patterns may result in additional injury to vulnerable end organs, and that muscle, nerve, and brain need to be prioritized as key organ systems that largely determine functional, neurocognitive, and health-related quality-of-life outcomes in our patients. Third, we need to design studies that help elucidate the relationships between practice and long-term outcome so we can better determine which morbidities are potentially modifiable. Fourth, we need to understand how to risk stratify and optimize subsequent acute and chronic rehabilitative needs, functional independence, and return to work and/or previous lifestyle. Fifth, we have minimal understanding of the basic science of ICU-acquired morbidity, and this needs urgent attention. Finally, we need to embrace, empower, and educate each member of our interprofessional teams to help them understand that what we practice every day may change the long-term outcome for our patients and their families.

Figure 68-8 outlines the concept that rehabilitation begins the moment the patient is admitted to the ICU and that the way in which we conduct our treatment may have important downstream ramifications. The effectiveness of resuscitation affects mortality and propagation of organ dysfunction and perhaps this also has implications for muscle, nerve, and brain injury.[147] The diaphragm is very vulnerable to rest and undergoes rapid proteolysis within hours of controlled mechanical ventilation.[34] Attempting to prioritize spontaneous ventilation modes to preserve the diaphragm makes sense but there are no studies that link spontaneous ventilation to improved longer-term outcome. The indication for and use of neuromuscular blockers and steroids remains controversial.

Perhaps one of the most fundamental limitations in constructing appropriate rehabilitation programs after critical illness is our current inability to risk stratify our patients. Risk stratification is a fundamental tenet upon which many other disciplines devise robust algorithmic treatment approaches to clinical problems. The heterogeneity of critically ill populations is an important barrier that needs to be addressed to be able to understand differences in functional outcome across different patient groups and the various factors that appear to drive a broad spectrum of outcome. For the sake of discussion and contrast, there is an enormous difference in functional outcome between relatively young survivors of ARDS[3,24] compared with older chronically critically ill patients,[1] despite the apparent similarities of severity of illness and a protracted ICU length of stay. The young, previously working, lung-injured group had few comorbid disorders, very low mortality after ICU discharge, and a significant, albeit less than predicted, improvement in

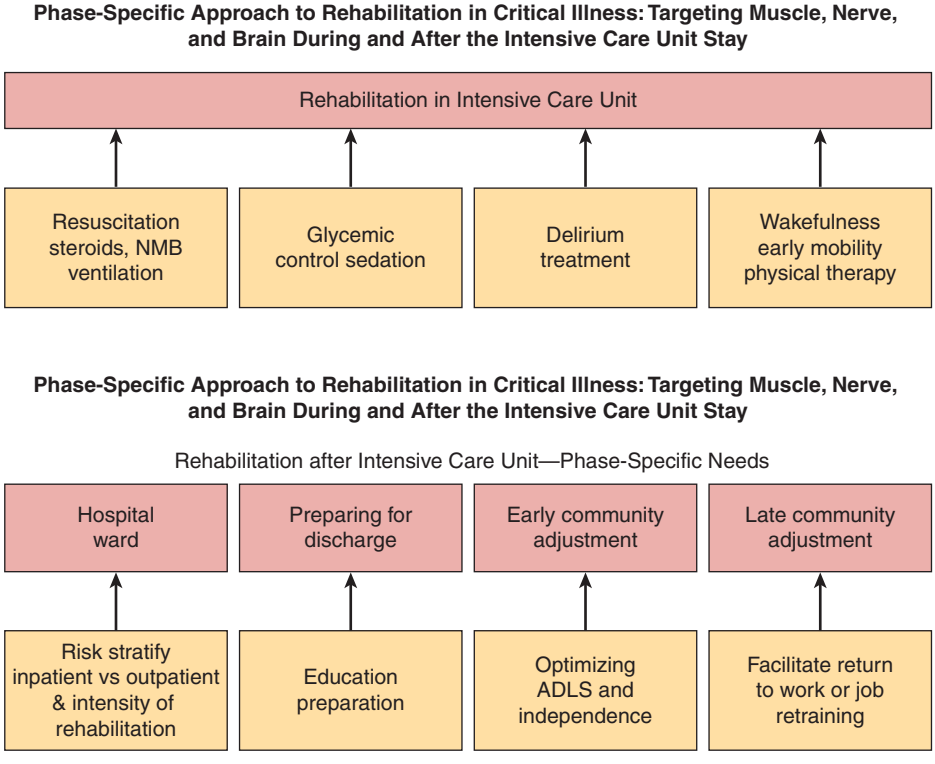

FIGURE 68-8 Rehabilitation continuum during and after the ICU stay. This highlights the concept that rehabilitation begins the moment the patient is admitted to the ICU and that our daily management may have an important impact on long-term outcome. It also highlights the various patient needs after they leave hospital and attempt reintegration into their prior lifestyle. (Adapted, with permission, from Herridge MS. Legacy of intensive care unit-acquired weakness. *Crit Care Med.* 2009;37[10 Suppl]:S457–S461.)

functional status at 1 year, and virtually all returned to independent living. This is in stark contrast to an older group of chronically critically ill patients with a significant burden of comorbid disease, with a 44% mortality at 1-year after ICU discharge and only 11% achieving a good (alive with no functional dependency) outcome.

Current interventional work has focused on early mobility, which a number of studies has shown to be safe and feasible and alters short-term outcome in those patients who were previously functional.[148–153] It is practical and logical to trial physiotherapy and occupational therapy interventions in those for whom there is a high likelihood for benefit.[152] This approach, however, although important and laudable, will not determine how interventions should be tailored to meet individual needs nor differentially applied because there are almost no guidelines on specific patient subgroups. For example, offering such interventions to subpopulations of patients whose muscles and nerves have sustained such profound injury that they have lost any potential for rehabilitation raises inappropriate expectation. There are currently many proposed models for complex rehabilitation after critical illness, but none has focused on how to tailor the program to individual need nor shown long-term efficacy.[154–157] A recent multicenter randomized trial of 286 critically ill patients assessed health-related quality of life and compared outcomes from a nurse-led intensive follow-up versus usual care at 12 months. There was no difference in health-related quality of life on the physical or mental health component scores, and the nurse-led follow-up program cost significantly more than usual care.[158] A self-help manual with instructions for physical therapy, however, improved 6-month outcomes in physical function assessed using the SF-36 health-related quality-of-life instrument; perhaps, patients and families could tailor this guide to individual need, although this consideration was not studied explicitly in this trial.[159]

I have outlined important neuropsychological disabilities in this chapter, and there has been some early work evaluating potential interventions to improve these outcomes. Jones et al evaluated whether a prospectively collected diary of a patient's ICU stay could reduce the development of new onset PTSD during convalescence after critical illness.[94] Patients with an ICU stay of more than 72 hours were recruited to the study and intervention patients received their ICU diary at 1 month after ICU discharge, and assessment for the development of PTSD was made at 3 months. They found that use of the diary was associated with a decrease in new-onset PTSD. These early data are very promising but further understanding of the longer-term effect of the diary intervention is warranted.

SUMMARY AND CONCLUSION

The current state of the art in the outcomes literature suggests that patients will sustain some degree of neuromuscular, functional, and neuropsychological morbidity as a result of their critical illness, and this does not appear to be wholly reversible over time, even in younger patients who were previously working and highly functional. Pulmonary outcomes will likely be very good in those who are younger and have no premorbid pulmonary disease. Health care costs after critical illness mirror those of chronic disease, but younger patients who receive support in transitioning back to work will overwhelmingly return to work. Patients with more comorbid illness and premorbid functional disability will have poor longer-term outcomes. Family caregivers may acquire new mood disorders that impair their health-related quality of life and may modify outcomes in patients. ICU-acquired weakness and brain injury represent major morbidities. Further basic science studies to elucidate the pathophysiology of brain, nerve, and muscle injury are urgently needed, as is work on risk stratification so that rehabilitation programs can be tailored to individual and family needs.
