Principles and Practice of MECHANICAL VENTILATION

THIRD EDITION

MARTIN J. TOBIN

Principles and Practice of Mechanical Ventilation

Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Principles and Practice of Mechanical Ventilation

Third Edition

Editor

Martin J. Tobin, MD

Professor of Medicine and Anesthesiology
Edward Hines, Jr., Veterans Administration Hospital and
Loyola University of Chicago Stritch School of Medicine
Editor emeritus, *American Journal of Respiratory and Critical Care Medicine*

CONTRIBUTORS

Marcelo B. P. Amato, MD, PhD
Associate Professor
Pulmonary
University of São Paulo
São Paulo, SP, Brazil
Supervisor—Respiratory ICU
Chapter 9: Pressure-Controlled and Inverse-Ratio Ventilation

Elie Azoulay, MD, PhD
Hôpital Saint-Louis
Medical ICU
Université Paris-Diderot
Sorbonne Paris-Cité,
Faculté de médecine
Paris, France
Chapter 66: The Ethics of Withholding and Withdrawing Mechanical Ventilation

Robert B. Banzett, PhD
Associate Professor
Department of Medicine
Harvard Medical School
Boston, Massachusetts

Division of Pulmonary, Critical Care, and Sleep Medicine
Beth Israel Deaconess Medical Center
Boston, Massachusetts
Chapter 55: Addressing Respiratory Discomfort in the Ventilated Patient
Chapter 56: Ventilator-Supported Speech

Ahmet Baydur, MD, FACP, FCCP
Professor of Clinical Medicine
Division of Pulmonary and Critical Care Medicine
Keck School of Medicine
University of Southern California
Los Angeles, California
Chapter 32: Mechanical Ventilation in Neuromuscular Disease

Jennifer C. Beck, PhD
Staff Scientist
Keenan Research Centre
Li Ka Shing Knowledge Institute of St. Michael's Hospital
Toronto, Ontario, Canada

Assistant Professor
Pediatrics
University of Toronto
Toronto, Ontario, Canada
Chapter 13: Neurally Adjusted Ventilatory Assist

Andrew D. Bersten, MBBS, MD
Professor
Critical Care Medicine
Flinders University School of Medicine
Adelaide, South Australia

Director
ICCU
Flinders Medical Centre
Adelaide, South Australia
Chapter 65: Fluid Management in the Ventilated Patient

Lluis Blanch, MD, PhD
Senior
Critical Care Center
Hospital de Sabadell
Sabadell, Spain

Critical Care Center,
Hospital de Sabadell,
Corporació Sanitària Parc Taulí
Institut Universitari Fundació Parc Taulí-Universitat Autònoma de Barcelona
Sabadell, Spain

CIBER Enfermedades Respiratorias—ISCIII, Spain
Chapter 22: Transtracheal Gas Insufflation, Transtracheal Oxygen Therapy, Emergency Transtracheal Ventilation

Michela Bombino, MD
Staff Physician
Department of Perioperative Medicine and Intensive Care
A.O. Ospedale S. Gerardo
Monza, Italy
Chapter 21: Extracorporeal Carbon Dioxide Removal

Richard D. Branson, MSc, RRT
Professor
Surgery
University of Cincinnati
Cincinnati, Ohio

Adjunct Faculty
School of Aerospace Medicine
Wright Patterson Air Force Base
Dayton, Ohio
Chapter 15: Feedback Enhancements on Conventional Ventilator Breaths
Chapter 27: Transport of the Ventilator-Supported Patient

Laurent J. Brochard, MD
Professor
Department of Anesthesiology, Pharmacology,
Intensive Care Medicine
University of Geneva, School of Medicine
Geneva, Switzerland

Head
Intensive Care Unit
Geneva University Hospital
Geneva, Switzerland
Chapter 8: Pressure-Support Ventilation

Robert Brown, MD
Pulmonary and Critical Care Unit
Department of Medicine
Massachusetts General Hospital
Boston, Massachusetts

Harvard Medical School
Boston, Massachusetts
Chapter 55: Addressing Respiratory Discomfort in the Ventilated Patient
Chapter 56: Ventilator-Supported Speech

Claudia Brusasco, MD
Researcher
Department of Surgical Sciences and Integrated Diagnostics
University of Genova
Genova, Italy
Chapter 24: Mechanical Ventilation during General Anesthesia

Shannon S. Carson, MD
Associate Professor
Pulmonary and Critical Care Medicine
University of North Carolina School of Medicine
Chapel Hill, North Carolina
Chapter 67: Economics of Ventilator Care

Jean E. Chastre, MD
Professor of Medicine
Réanimation Médicale
University Pierre-et-Marie Curie, Paris 6
Paris, France

Head of Department
Réanimation Médicale
Hôpital Pitié-Salpêtrière
Paris, France
Chapter 46: Pneumonia in the Ventilator-Dependent Patient

Robert L. Chatburn, MHHS, RRT-NPS, FAARC
Professor
Medicine
Lerner College of Medicine of Case Western Reserve University
Clevelan, Ohio

Clinical Research Manager
Respiratory Institute
Cleveland Clinic
Cleveland, Ohio
Chapter 2: Classification of Mechanical Ventilators and Modes of Ventilation
Chapter 3: Basic Principles of Ventilator Design

Gene L. Colice, MD
Professor
Medicine
The George Washington University School of Medicine
Washington, District of Columbia

Director, Pulmonary, Critical Care and Respiratory Services
Medicine
Washington Hospital Center
Washington, District of Columbia
Chapter 1: Historical Perspective on the Development of Mechanical Ventilation

Antonio Corrado, MD
Unità di Terapia Intensiva Respiratoria-Fisiopatologia Toracica
Azienda Ospedaliera-Universitaria Careggi
Firenze, Italy
Chapter 16: Negative-Pressure Ventilation

Heidi J. Dalton, MD, FCCM
Division and Section Chief, Critical Care Medicine
Director, ECMO
Phoenix Children's Hospital
Phoenix, Arizona
Chapter 20: Extracorporeal Life Support for Cardiopulmonary Failure

Nicolas de Prost, MD
Hôpitaux de Paris
Hôpital Henri Mondor
Service de Réanimation Médicale
Créteil, France
Chapter 42: Ventilator-Induced Lung Injury

Steven Deem, MD
Professor
Anesthesiology and Medicine
University of Washington
Seattle, Washington

Director, Neurocritical Care
Harborview Medical Center
Seattle, Washington
Chapter 38: Airway Management

Rajiv Dhand, MD, FCCP, FACP, FAARC
Professor
Medicine
University of Tennessee Graduate School of Medicine
Knoxville, Tennessee

Chairman
Medicine
University of Tennessee Graduate School of Medicine
Knoxville, Tennessee
Chapter 63: Bronchodilator Therapy

Anthony F. DiMarco, MD
Professor
Department of Physiology & Biophysics
Case Western Reserve University
Cleveland, Ohio

Professor
MetroHealth Research Institute
MetroHealth Medical Center
Cleveland, Ohio
Chapter 62: Diaphragmatic Pacing

Didier Dreyfuss, MD
Professor
Department of Critical Care
Université Sorbonne Paris Cité and Hôpital Louis Mourier, Colombes
Colombes, France
Chapter 42: Ventilator-Induced Lung Injury
Chapter 51: Humidification

Mark W. Elliott, MD, FRCP (UK)
Department of Respiratory Medicine
St James's University Hospital
Leeds, West Yorkshire, United Kingdom
Chapter 34: Noninvasive Ventilation on a General Ward

Ali A. El-Solh, MD, MPH
Professor of Medicine, Anesthesiology, and Social and Preventive Medicine
Department of Medicine
University at Buffalo
Buffalo, New York

Director of Critical Care
VA Western New York Healthcare System
Buffalo, New York
Chapter 41: Complications Associated with Mechanical Ventilation

Jean-Yves Fagon, MD, PhD
Professor
Critical Care
Hôpiotal Européen Georges Pompidou, AP-HP and Paris Descarte University
Paris, France
Chapter 46: Pneumonia in the Ventilator-Dependent Patient

Niall D. Ferguson, MD, MSc
Associate Professor
Interdepartmental Division of Critical Care Medicine
University of Toronto
Toronto, Ontario, Canada

Director, Critical Care
Department of Medicine, Division of Respirology
University Health Network & Mount Sinai Hospital
Toronto, Ontario, Canada
Chapter 19: High-Frequency Ventilation

Antoni Ferrer, MD
Servei de Pneumologia
Hospital de Sabadell
Corporació Parc Taulí
Institut Universitari Fundació Parc Taulí
Universitat Autònoma de Barcelona
Sabadell, Spain
Chapter 37: Effect of Mechanical Ventilation on Gas Exchange

Alison B. Froese, MD, FRCP(C)
Professor
Departments of Anesthsiology and Perioperative Medicine, Pediatrics, Physiology
Queen's University
Kingston, Ontario, Canada

Attending Physician
Department of Anesthesiology and Perioperative Medicine
Kingston General Hospital
Kingston, Ontario, Canada
Chapter 19: High-Frequency Ventilation

Marcelo Gama de Abreu, MD, PhD, DESA
Professor of Anesthesiology and Intensive Care
Department of Anesthesiology and Intensive Care
University Hospital Carl Gustav Carus,
Dresden University of Technology
Dresden, Germany
Chapter 24: Mechanical Ventilation during General Anesthesia

Pamela C. Garcia-Filion, PhD, MPH
Research Scientist
Critical Care
Phoenix Children's Hospital
Phoenix, Arizona
Chapter 20: Extracorporeal Life Support for Cardiopulmonary Failure

Luciano Gattinoni, MD
Full Professor
Dipartimento di Anestesiologia, Terapia Intensiva e Scienze Dermatologiche
Fondazione IRCCS CaUniversità degli Studi di Milano
Milan, Italy

Dipartimento di Anestesia, Rianimazione e Terapia del Dolore
Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico
Milan, Italy
Chapter 21: Extracorporeal Carbon Dioxide Removal
Chapter 49: Prone Positioning in Acute Respiratory Failure

Dimitris Georgopoulos, MD, PhD
Professor
Intensive Care Medicine
University of Crete, Scool of Medine
Heraklion, Crete
Chapter 35: Effects of Mechanical Ventilation on Control of Breathing

Ivan Goldstein, MD, PhD
Réanimation Chirugicale Polyvalente Pierre Viars
Hôpital Pitié-Salpêtrière
Assistance Publique Hôpitaux de Paris
Université Pierre et Marie Curie
Paris, France
Chapter 64: Inhaled Antibiotic Therapy

Hernando Gomez, MD
Assistant Professor
Department of Critical Care Medicine
University of Pittsburgh Medical Center
Pittsburgh, Philadelphia
Chapter 36: Effect of Mechanical Ventilation on Heart–Lung Interactions

Massimo Gorini, MD
Federico II University Hospital
School of Medicine
Naples, Italy
Chapter 16: Negative-Pressure Ventilation

Jesse B. Hall, MD
Section Chief
Professor of Medicine
Pulmonary and Critical Care
University of Chicago
Chicago, Illinois
Chapter 50: Pain Control, Sedation, and Neuromuscular Blockade

Jürg Hammer, MD
Associate Professor
Division of Intensive Care and Pulmonology
University Children's Hospital Basel (UKBB)
Basel, Switzerland

Medical Director
Division of Intensive Care and Pulmonology
University Children's Hospital Basel (UKBB)
Basel, Switzerland
Chapter 23: Mechanical Ventilation in the Neonatal and Pediatric Setting

Patrick J. Hanly, MD, FRCPC, MRCPI, D, ABSM
Professor
Medicine
University of Calgary, Faculty of Medicine

University of Manitoba
Winnipeg, Manitoba, Canada

Research Professor
Department of Medicine
University of Calgary
Calgary, Alberta, Canada
Chapter 12: Proportional-Assist Ventilation

This page intentionally left blank

PREFACE

More than twenty years have passed since *Principles and Practice of Mechanical Ventilation* was first conceived. With this third edition, the textbook has come of age. When the first proposal of the book was under consideration, reviewers thought that the corpus of knowledge pertaining to mechanical ventilation would not be sufficient to merit the publication of a large tome; they opined that the contents of such a book would require much padding. This time around, the challenge has been to fit everything into a constrained number of pages. Virtually every aspect of mechanical ventilation has evolved substantially over the past twenty years, and many new areas have emerged. Novel ventilator modes have been introduced, previously discarded modes have acquired a new lease of life, and long-surviving methodologies have undergone considerable refinement. Much of the progress has stemmed from research into the mechanisms whereby ventilators harm patients. In turn, we have learned how minor adjustments to ventilator settings can markedly enhance patient comfort and survival. A comparison of the third and first editions of *Principles and Practice of Mechanical Ventilation* provides proof of the tremendous progress in this field during the past twenty years.

Trainees hear much about the practice of medicine, as in phrases such as clinical practice guidelines. As physicians grow older, they realize that many popular practices turn out to be ephemeral—it is biomedical principles that remain evergreen. Mechanical ventilation remains rooted in physiological principles; it is these principles that guide practice. The wise physician is ever mindful of the need to balance principles with practice—to achieve the right equilibrium between theory and pragmatic action. Without a sound knowledge of the biomedical principles that govern ventilator management, a physician is reduced to setting a ventilator in a hit-or-miss manner or to follow a cookbook recipe. With a deep understanding of physiologic principles, a physician is better equipped to make expert iterative adjustments to the ventilator as a patient's condition changes over time. As with previous editions, readers will find detailed accounts of both biomedical principles and practical advice throughout this textbook.

Electronic technology has transformed medical publishing, providing rapid access to a rich store of information. Contrasted with the hours previously spent in the periodical rooms of a library, authors now retrieve pertinent articles at the click of a mouse. But reading material online is not an unalloyed good. Deeply engaged reading requires focused attention and commitment, whereas reading online is accompanied by a dramatic increase in the opportunities for distraction. Media do not simply act as passive channels of communication, they also shape the process of thought. Cognitive scientists have begun to uncover the differences between reading online and off. Deep reading without distraction leads to the formation of rich mental connections across regions of the brain that govern such cognitive functions as memory and interpretation. Neuroscientists expect the internet to have far-reaching effects on cognition and memory. In contrast to a book, which is a machine for focusing attention and demanding the deep thinking that generates memory, the internet is a machine that scatters attention and diffuses concentration. Given the importance of rapid decisions in critical care medicine, which demand instant memory recall, a trainee is best advised to acquire the foundations for his or her storehouse of knowledge from a textbook rather than from online resources.

Another advantage of a textbook is that it provides a comprehensive account of a discipline in a single source, where clinicians can turn to find answers to their questions about mechanical ventilation. Commonly used online resources, such as *UpToDate*, are directed toward generalists and do not provide the depth of knowledge expected of a subspecialist. The information presented in medical journals is fragmentary by design; no attempt is made to fit published information into the mosaic of existing knowledge and topics deemed unfashionable by editors are ignored. Trainees who rely on bundles of reprints tend to be ignorant of the boundaries of a subspecialty and unaware of major lacunae in their knowledge base. No series of journal articles can compete with a textbook in this regard.

For a textbook to provide authoritative coverage of a field, the selection of authors is crucial. For each chapter, I selected scientists and clinicians who are at the forefront of research in a given subfield. Many of these authors undertook the seminal research that established a new area of mechanical ventilation, which was subsequently enriched and expanded by the work of other investigators. Being at the forefront of an area, these authors are attuned to evolving developments in a subfield, which makes their accounts extremely current and guards against early obsolescence of the material

included in their chapter. Each chapter has been extensively revised; twenty-five new authors provide fresh accounts of previously covered areas; many new topics have been added; and several chapters found in previous editions were deleted. I personally edited every line of each manuscript to ensure reliability of the presented information and to achieve a uniform style throughout the book.

Given that *Principles and Practice of Mechanical Ventilation* has become one of the classics on the McGraw-Hill list, the publisher decided to introduce color printing throughout the new edition. The result is a book that is not only informative but also aesthetically attractive. The large number of high-quality illustrations provides a pedagogical resource for readers who are preparing slides for lectures.

This book would not have been possible without the help of several people, and to them I am extremely grateful. First and foremost are the more than 100 authors, whose knowledge, commitment and wisdom form the core of the book. As with the two previous editions, I am most grateful to Amal Jubran and Franco Laghi for advice at several stages of this project. I thank Lynnel Hodge for invaluable assistance on a day-to-day basis. Richard Adin copyedited the manuscripts with a lawyer's eye for precision, and Brain Belval and Karen Edmondson at McGraw-Hill and Aakriti Kathuria at Thomson Digital skillfully guided the book through its production. Finally, I thank my family for their forbearance.

HISTORICAL PERSPECTIVE ON THE DEVELOPMENT OF MECHANICAL VENTILATION

Gene L. Colice

The history of mechanical ventilation is intimately intertwined with the history of anatomy, chemistry, and physiology; exploration under water and in the air; and of course, modern medicine. Anatomists described the structural connections of the lungs to the heart and vasculature and developed the earliest insights into the functional relationships of these organs. They emphasized the role of the lungs in bringing air into the body and probably expelling waste products, but showed little understanding of how air was used by the body. Chemists defined the constituents of air and explained the metabolic processes by which the cells used oxygen and produced carbon dioxide. Physiologists complemented these studies by exploring the relationships between levels of oxygen and carbon dioxide in the blood and ventilation. Explorers tested the true limits of physiology. Travel in the air and under water exposed humans to extremes in ventilatory demands and prompted the development of mechanical adjuncts to ventilation. Following the various historical threads provided by the anatomists, chemists, physiologists, and explorers provides a useful perspective on the tapestry of a technique modern physicians accept casually: mechanical ventilation.

ANATOMISTS OF THE HEART AND LUNGS

Early Greeks

Early Greek physicians endorsed Empedocles' view that all matter was composed of four essential elements: earth, air, fire, and water. Each of these elements had primary qualities of heat, cold, moisture, and dryness.[1] Empedocles applied this global philosophic view to the human body by stating that "innate heat," or the soul, was distributed from the heart via the blood to various parts of the body.

The Hippocratic corpus stated that the purpose of respiration was to cool the heart. Air was thought to be pumped by the atria from the lungs to the right ventricle via the pulmonary artery and to the left ventricle through

the pulmonary vein.[2] Aristotle believed that blood was an indispensable part of animals but that blood was found only in veins. Arteries, in contrast, contained only air. This conclusion probably was based on his methods of sacrificing animals. The animals were starved, to better define their vessels, and then strangled. During strangulation, blood pools in the right side of the heart and venous circulation, leaving the left side of the heart and arteries empty.[2] Aristotle described a three-chamber heart connected with passages leading in the direction of the lung, but these connections were minute and indiscernible.[3] Presumably, the lungs cooled the blood and somehow supplied it with air.[4]

Erasistratus (born around 300 BC) believed that air taken in by the lungs was transferred via the pulmonary artery to the left ventricle. Within the left ventricle, air was transformed into *pneuma zotikon*, or the "vital spirit," and was distributed through air-filled arteries to various parts of the body. The *pneuma zotikon* carried to the brain was secondarily changed to the *pneuma psychikon* ("animal spirit"). This animal spirit was transmitted to the muscles by the hollow nerves. Erasistratus understood that the right ventricle facilitated venous return by suction during diastole and that venous valves allowed only one-way flow of blood.[1]

The Greek physician Claudius Galen, practicing in Rome around AD 161, demonstrated that arteries contain blood by inserting a tube into the femoral artery of a dog.[5,6] Blood flow through the tube could be controlled by adjusting tension on a ligature placed around the proximal portion of the artery. He described a four-chamber heart with auricles distinct from the right and left ventricles. Galen also believed that the "power of pulsation has its origin in the heart itself" and that the "power [to contract and dilate] belongs by nature to the heart and is infused into the arteries from it."[5,6] He described valves in the heart and, as did Erasistratus, recognized their essential importance in preventing the backward discharge of blood from the heart. He alluded several times to blood flowing, for example, from the body through the vena cava into the right ventricle and even made the remarkable statement that "in the entire body the arteries come together with the veins and exchange air and blood through extremely fine invisible orifices."[6] Furthermore, Galen believed that "fuliginous wastes" were somehow discharged from the blood through the lung.[6] Galen's appreciation that the lungs supplied some property of air to the body and discharged a waste product from the blood was the first true insight into the lung's role in ventilation. However, he failed in two critical ways to appreciate the true interaction of the heart and lungs. First, he believed, as did Aristotle and other earlier Greeks, that the left ventricle is the source of the innate heat that vitalizes the animal. Respiration in animals exists for the sake of the heart, which requires the substance of air to cool it. Expansion of the lung caused the lightest substance, that is, the outside air, to rush in and fill the bronchi. Galen provided no insight, though, into how air, or *pneuma*, might be drawn out from the bronchi and lungs into the heart. Second, he did not clearly describe the true circular nature of blood flow from the right ventricle through the lungs and into the left ventricle and then back to the right ventricle. His writings left the serious misconception that blood was somehow transported directly from the right to the left ventricle through the interventricular septum.[1,5,6]

Renaissance Physicians

Byzantine and Arab scholars maintained Galen's legacy during the Dark Ages and provided a foundation for the rebirth of science during the Renaissance.[1,6,7] Around 1550, Vesalius corrected many inaccuracies in Galen's work and even questioned Galen's concept of blood flow from the right ventricle to the left ventricle. He was skeptical about the flow of blood through the interventricular pores Galen described.[1,6,8] Servetus, a fellow student of Vesalius in Paris, suggested that the vital spirit is elaborated both by the force of heat from the left ventricle and by a change in color of the blood to reddish yellow. This change in color "is generated in the lungs from a mixture of inspired air with elaborated subtle blood which the right ventricle of the heart communicates to the left. This communication, however, is made not through the middle wall of the heart, as is commonly believed, but by a very ingenious arrangement: the subtle blood courses through the lungs from the pulmonary artery to pulmonary vein, where it changes color. During this passage the blood is mixed with inspired air and through expiration it is cleansed of its sooty vapors. This mixture, suitably prepared for the production of the vital spirit, is drawn onward to the left ventricle of the heart by diastole."[6,9] Although Servetus' views proved ultimately to be correct, they were considered heretical at the time, and he was subsequently burned at the stake, along with most copies of his book, in 1553.

Columbus, a dissectionist to Vesalius at Padua, in 1559 suggested that blood travels to the lungs via the pulmonary artery and then, along with air, is taken to the left ventricle through the pulmonary vein. He further advanced the concept of circulation by noting that the left ventricle distributes blood to the body through the aorta, blood returns to the right ventricle in the vena cava, and venous valves in the heart allow only one-way flow.[1,6,10]

These views clearly influenced William Harvey, who studied anatomy with Fabricius in Padua from 1600 to 1602. Harvey set out to investigate the "true movement, pulse, action, use and usefulness of the heart and arteries." He questioned why the left ventricle and right ventricle traditionally were felt to play such fundamentally different roles. If the right ventricle existed simply to nourish the lungs, why was its structure so similar to that of the left ventricle? Furthermore, when one directly observed the beating heart in animals, it was clear that the function of both right and left ventricles also was similar. In both cases, when the ventricle contracted, it expelled blood, and when it relaxed, it received blood. Cardiac systole coincided with

arterial pulsations. The motion of the auricles preceded that of the ventricles. Indeed, the motions are consecutive with a rhythm about them, the auricles contracting and forcing blood into the ventricles and the ventricles, in turn, contracting and forcing blood into the arteries. "Since blood is constantly sent from the right ventricle into the lungs through the pulmonary artery and likewise constantly is drawn the left ventricle from the lungs…it cannot do otherwise than flow through continuously. This flow must occur by way of tiny pores and vascular openings through the lungs. Thus, the right ventricle may be said to be made for the sake of transmitting blood through the lungs, not for nourishing them."[6,11]

Harvey described blood flow through the body as being circular. This was easily understood if one considered the quantity of blood pumped by the heart. If the heart pumped 1 to 2 drams of blood per beat and beat 1000 times per half-hour, it put out almost 2000 drams in this short time. This was more blood than was contained in the whole body. Clearly, the body could not produce amounts of blood fast enough to supply these needs. Where else could all the blood go but around and around "like a stage army in an opera." If this theory were correct, Harvey went on to say, then blood must be only a carrier of critical nutrients for the body. Presumably, the problem of the elimination of waste vapors from the lungs also was explained by the idea of blood as the carrier.[1,6,11]

With Harvey's remarkable insights, the relationship between the lungs and the heart and the role of blood were finally understood. Only two steps remained for the anatomists to resolve. First, the nature of the tiny pores and vascular openings through the lungs had to be explained. About 1650, Malpighi, working with early microscopes, found that air passes via the trachea and bronchi into and out of microscopic saccules with no clear connection to the bloodstream. He further described capillaries: "… and such is the wandering about of these vessels as they proceed on this side from the vein and on the other side from the artery, that the vessels no longer maintain a straight direction, but there appears a network made up of the articulations of the two vessels…blood flowed away along [these] tortuous vessels … always contained within tubules."[1,6] Second, Borelli, a mathematician in Pisa and a friend of Malpighi, suggested the concept of diffusion. Air dissolved in liquids could pass through membranes without pores. Air and blood finally had been linked in a plausible manner.[1]

CHEMISTS AND PHYSIOLOGISTS OF THE AIR AND BLOOD

Understanding Gases

The anatomists had identified an entirely new set of problems for chemists and physiologists to consider. The right ventricle pumped blood through the pulmonary artery to the lungs. In the lungs the blood took up some substance, evidenced by the change in color observed as blood passes through the pulmonary circulation. Presumably the blood released "fuliginous wastes" into the lung. The site of this exchange was thought to be at the alveolar–capillary interface, and it probably occurred by the process of diffusion. What were the substances exchanged between blood and air in the lung? What changed the color of blood and was essential for the production of the "innate heat"? What was the process by which "innate heat" was produced, and where did this combustion occur, in the left ventricle as supposed from the earliest Greek physician-philosophers or elsewhere? Where were the "fuliginous wastes" produced, and were they in any way related to the production of "innate heat"? If blood were a carrier, pumped by the left ventricle to the body, what was it carrying to the tissues and then again back to the heart?

Von Helmont, about 1620, added acid to limestone and potash and collected the "air" liberated by the chemical reaction. This "air" extinguished a flame and seemed to be similar to the gas produced by fermentation. This "air" also appeared to be the same gas as that found in the Grotto del Cane. This grotto was notorious for containing air that would kill dogs but spare their taller masters.[1] The gas, of course, was carbon dioxide. In the late seventeenth century, Boyle recognized that there is some substance in air that is necessary to keep a flame burning and an animal alive. Place a flame in a bell jar, and the flame eventually will go out. Place an animal in such a chamber, and the animal eventually will die. If another animal is placed in that same chamber soon thereafter, it will die suddenly. Mayow showed, around 1670, that enclosing a mouse in a bell jar resulted eventually in the mouse's death. If the bell jar were covered by a moistened bladder, the bladder bulged inward when the mouse died. Obviously, the animals needed something in air for survival. Mayow called this the "nitro-aereal spirit," and when it was depleted, the animals died.[1,12] This gas proved to be oxygen. Boyle's suspicions that air had other qualities primarily owing to its ingredients seemed well founded.[13,14]

In a remarkable and probably entirely intuitive insight, Mayow suggested that the ingredient essential for life, the "nitro-aereal spirit," was taken up by the blood and formed the basis of muscular contraction. Evidence supporting this concept came indirectly. In the early 1600s, the concept of air pressure was first understood. von Guericke invented a pneumatic machine that reduced air pressure.[1,15] Robert Boyle later devised the pneumatic pump that could extract air from a closed vessel to produce something approaching a vacuum (Fig. 1-1). Boyle and Hooke used this pneumatic engine to study animals under low-pressure conditions. Apparently Hooke favored dramatic experiments, and he often demonstrated in front of crowds that small animals died after air was evacuated from the chamber. Hooke actually built a human-sized chamber in 1671 and volunteered to enter it. Fortunately, the pump effectively removed only about a quarter of the air, and Hooke survived.[16] Boyle

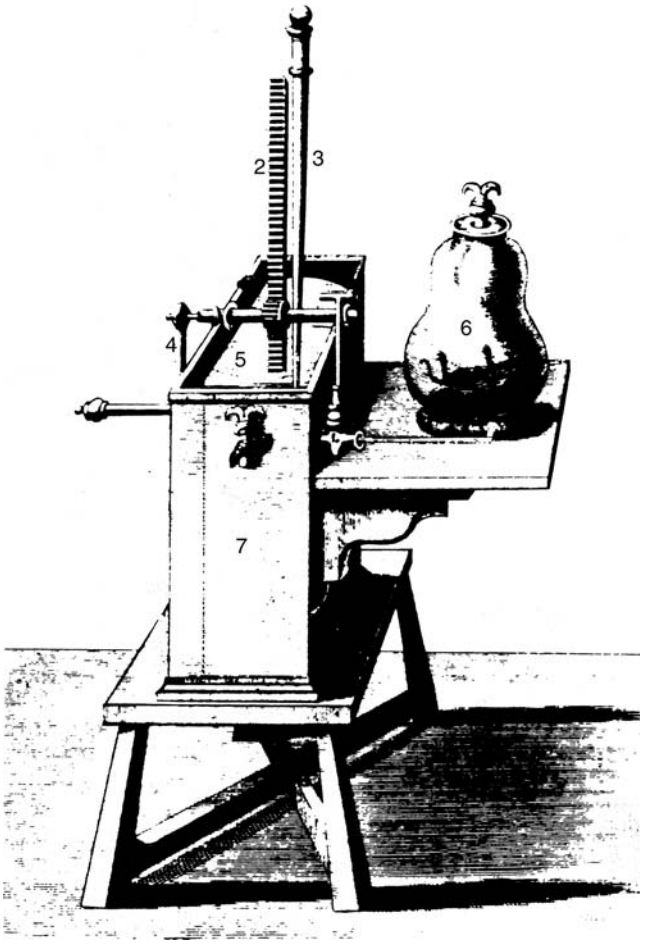

FIGURE 1-1 A pneumatical engine, or vacuum pump, devised by Hooke in collaboration with Boyle around 1660. The jar (6) contains an animal in this illustration. Pressure is lowered in the jar by raising the tightly fitting slide (5) with the crank (4). (Used, with permission, from Graubard.[6])

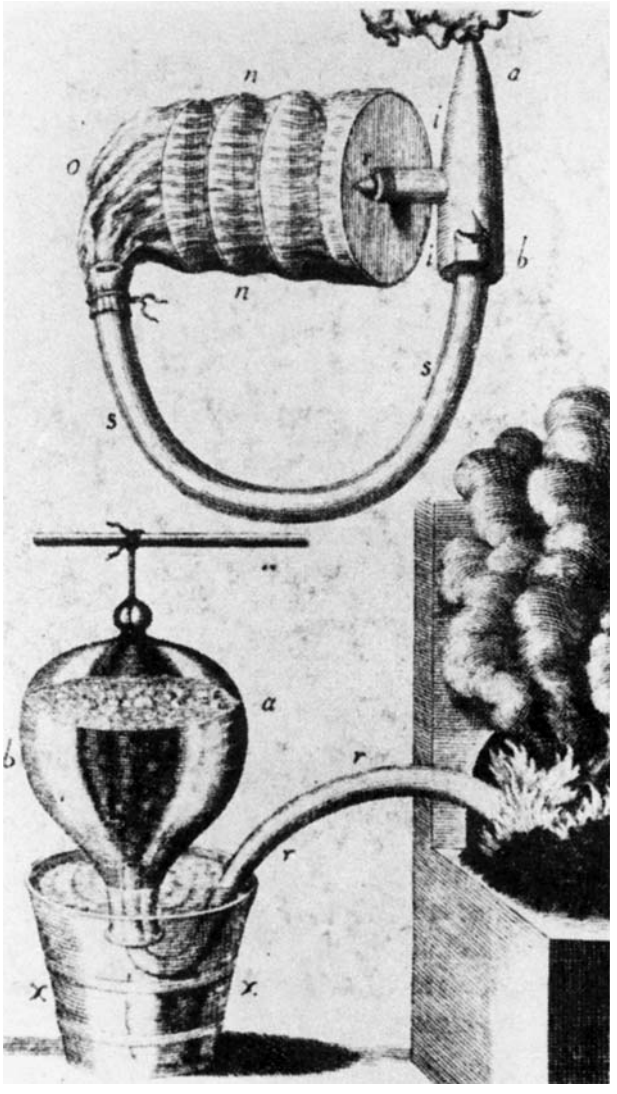

FIGURE 1-2 In 1727, Hales developed the pneumatic trough, shown on the bottom of this illustration. This device enabled him to collect gases produced by heating. On the top is a closed-circuit respiratory apparatus for inhaling the collected gases. (Used, with permission, from Perkins.[1])

believed that the difficulty encountered in breathing under these conditions was caused solely by the loss of elasticity in the air. He went on to observe, however, that animal blood bubbled when placed in a vacuum. This observation clearly showed that blood contained a gas of some type.[13,14] In 1727, Hales introduced the pneumatic trough (Fig. 1-2). With this device he was able to distinguish between free gas and gas no longer in its elastic state but combined with a liquid.[1] The basis for blood gas machines had been invented.

The first constituent of air to be truly recognized was carbon dioxide. Joseph Black, around 1754, found that limestone was transformed into caustic lime and lost weight on being heated. The weight loss occurred because a gas was liberated during the heating process. The same results occurred when the carbonates of alkali metals were treated with an acid such as hydrochloric acid. He called the liberated gas "fixed air" and found that it would react with lime water to form a white insoluble precipitate of chalk. This reaction became an invaluable marker for the presence of "fixed air." Black subsequently found that "fixed air" was produced by burning charcoal and fermenting beer. In a remarkable experiment he showed that "fixed air" was given off by respiration. In a Scottish church where a large congregation gathered for religious devotions, he allowed lime water to drip over rags in the air ducts. After the service, which lasted about 10 hours, he found a precipitate of crystalline lime ($CaCO_3$) in the rags, proof that "fixed air" was produced during the services. Black recognized that "fixed air" was the same gas described by von Helmont that would extinguish flame and life.[1,4,14]

In the early 1770s, Priestley and Scheele, working independently of each other, both produced and isolated "pure

air." Priestley used a 12-inch lens to heat mercuric oxide. The gas released in this process passed through the long neck of a flask and was isolated over mercury. This gas allowed a flame to burn brighter and a mouse to live longer than in ordinary air.[1,4,15] Scheele also heated chemicals such as mercuric oxide and collected the gases in ox or hog bladders. Like Priestley, Scheele found that the gas isolated made a flame burn brighter. This gas was the "nitro-aereal spirit" described by Mayow. Priestley and Scheele described their observations to Antoine Lavoisier. He repeated Priestley's experiments and found that if mercuric oxide was heated in the presence of charcoal, Black's "fixed air" would be produced. Further work led Lavoisier to the conclusion that ordinary air must have at least two separate components. One part was respirable, combined with metals during heating, and supported combustion. The other part was nonrespirable. In 1779, Lavoisier called the respirable component of air "oxygen." He also concluded from his experiments that "fixed air" was a combination of coal and the respirable portion of air. Lavoisier realized that oxygen was the explanation for combustion.[1,4,17]

Metabolism

In the 1780s, Lavoisier performed a brilliant series of studies with the French mathematician Laplace on the use of oxygen by animals. Lavoisier knew that oxygen was essential for combustion and necessary for life. Furthermore, he was well aware of the Greek concept of internal heat presumably produced by the left ventricle. The obvious question was whether animals used oxygen for some type of internal combustion. Would this internal combustion be similar to that readily perceived by the burning of coal? To answer this question, the two great scientists built an ice calorimeter (Fig. 1-3). This device could do two things. Because the melting ice consumed heat, the rate at which ice melted in the calorimeter could be used as a quantitative measure of heat production within the calorimeter. In addition, the consumption of oxygen could be measured. It then was a relatively simple task to put an animal inside the calorimeter and carefully measure heat production and oxygen consumption. As Lavoisier suspected, the amount of heat generated by the animal was similar to that produced by burning coal for the quantity of oxygen consumed.[1,4]

The Greeks suspected that the left ventricle produced innate heat, and Lavoisier himself may have thought that internal combustion occurred in the lungs.[4] Spallanzani, though, took a variety of tissues from freshly killed animals and found that they took up oxygen and released carbon dioxide.[1] Magnus, relying on improved methods of analyzing the gas content of blood, found higher oxygen levels in arterial blood than in venous blood but higher carbon dioxide levels in venous blood than in arterial blood. He believed that inhaled oxygen was absorbed into the blood, transported throughout the body, given off at the capillary level to the tissues, and there formed the basis for the formation of carbon dioxide.[18] In 1849, Regnault and Reiset perfected a closed-circuit metabolic chamber with devices for circulating air, absorbing carbon dioxide, and periodically adding oxygen (Fig. 1-4). Pettenkofer built a closed-circuit metabolic chamber large enough for a man and a bicycle ergometer (Fig. 1-5).[19] This device had a steam engine to pump air, gas meters to measure air volumes, and barium hydroxide to collect carbon dioxide. Although these devices were intended to examine the relationship between inhaled oxygen and exhaled carbon dioxide, they also could be viewed as among some of the earliest methods of controlled ventilation.

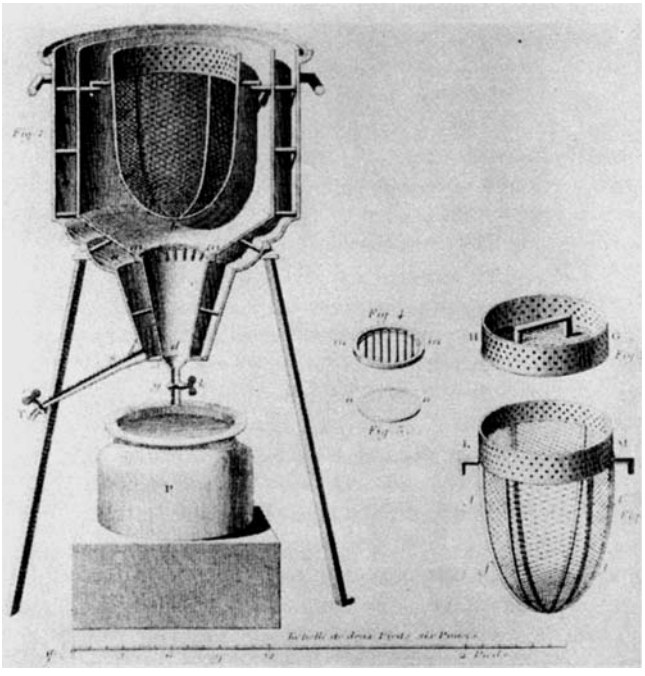

FIGURE 1-3 The ice calorimeter, designed by Lavoisier and Laplace, allowed these French scientists to measure the oxygen consumed by an animal and the heat produced by that same animal. With careful measurements, the internal combustion of animals was found to be similar, in terms of oxygen consumption and heat production, to open fires. (Used, with permission, from Perkins.[1])

Blood Gases and Ventilation

In separate experiments, the British scientist Lower and the Irish scientist Boyle provided the first evidence that uptake of gases in the lungs was related to gas content in the blood. In 1669, Lower placed a cork in the trachea of an animal and found that arterial blood took on a venous appearance. Removing the cork and ventilating the lungs with a bellows made the arterial blood bright red again. Lower felt that the blood must take in air during its course through the lungs and therefore owed its bright color entirely to an admixture of air. Moreover, after the air had

in large measure left the blood again in the viscera, the venous blood became dark red.[20] A year later Boyle showed with his vacuum pump that blood contained gas. Following Lavoisier's studies, scientists knew that oxygen was the component of air essential for life and that carbon dioxide was the "fuliginous waste."

About 1797, Davey measured the amount of oxygen and carbon dioxide extracted from blood by an air pump.[4] Magnus, in 1837, built a mercurial blood pump for quantitative analysis of blood oxygen and carbon dioxide content.[18] Blood was enclosed in a glass tube in continuity with a vacuum pump. Carbon dioxide extracted by means of the vacuum was quantified by the change in weight of carbon dioxide–absorbent caustic potash. Oxygen content was determined by detonating the gas in hydrogen.[15] A limiting factor in Magnus's work was the assumption that the quantity of oxygen and carbon dioxide in blood simply depended on absorption. Hence, the variables determining gas content in blood were presumed to be the absorption coefficients and partial pressures of the gases. In the 1860s, Meyer and Fernet showed that the gas content of blood was determined by more than just simple physical properties. Meyer found that the oxygen content of blood remained relatively stable despite large fluctuations in its partial pressure.[21] Fernet showed that blood absorbed more oxygen than did saline solution at a given partial pressure.[15]

Paul Bert proposed that oxygen consumption could not strictly depend on the physical properties of oxygen dissolving under pressure in the blood. As an example, he posed the problem of a bird in flight changing altitude abruptly. Oxygen consumption could be maintained with the sudden changes in pressure only if chemical reactions contributed to the oxygen-carrying capacity of blood.[15] In 1878, Bert described the curvilinear oxygen dissociation curves relating oxygen content of blood to its pressure. Hoppe-Seyler was instrumental in attributing the oxygen-carrying capacity of the blood to hemoglobin.[22] Besides his extensive experiments with animals in either high- or low-pressure chambers, Bert also examined the effect of ventilation on blood gas levels. Using a bellows to artificially ventilate animals through a tracheostomy, he found that increasing ventilation would increase oxygen content in blood and decrease the carbon dioxide content. Decreasing ventilation had the opposite effect.[15] Dohman, in Pflüger's laboratory, showed that both carbon dioxide excess and lack of oxygen would stimulate ventilation.[23] In 1885, Miescher-Rusch demonstrated that carbon dioxide excess was the more potent stimulus for ventilation.[1] Haldane and Priestley, building on this work, made great strides in analyzing the chemical control of ventilation. They developed a device for sampling end-tidal, or alveolar exhaled, gas (Fig. 1-6). Even small changes in alveolar carbon dioxide fraction greatly increased minute ventilation, but hypoxia did not increase minute ventilation until the alveolar oxygen fraction fell to 12% to 13%.[24]

Early measurements of arterial oxygen and carbon dioxide tensions led to widely divergent results. In Ludwig's laboratory the arterial partial pressure of oxygen was thought to be approximately 20 mm Hg. The partial pressure of carbon dioxide reportedly was much higher. These results could not entirely support the concept of passive gas movement between lung blood and tissues based on pressure gradients. Ludwig and others suspected that an active secretory process was involved in gas transport.[4] Coincidentally, the French biologist Biot observed that some deep-water fish had extremely large swim bladders. The gas composition in those swim bladders seemed to be different than that of atmospheric air. Biot concluded that gas was actively secreted into these bladders.[4,15,24,25] Pflüger and his coworkers developed the aerotonometer, a far more accurate device for measuring gas tensions than that used by Ludwig. When they obstructed a bronchus, they found no difference in the gas composition of air distal to the bronchial obstruction and that of pulmonary venous blood draining the area. They concluded that the lung did not rely on active processes for transporting oxygen and carbon dioxide; passive diffusion was a sufficient explanation.[26]

FIGURE 1-6 This relatively simple device enabled Haldane and Priestley to collect end-tidal expired air, which they felt approximated alveolar air. The subject exhaled through the mouthpiece at the right. At the end of expiration, the stopcock on the accessory collecting bag was opened, and a small aliquot of air was trapped in this device. (Used, with permission, from Best CH, Taylor NB, *Physiological Basis of Medical Practice.* Baltimore, MD: Williams & Wilkins; 1939:509.)

Although Pflüger's findings were fairly convincing at the time, Bohr resurrected this controversy.[27] He found greater variability in blood and air carbon dioxide and oxygen tensions than previously reported by Pflüger and suspected that under some circumstances secretion of gases might occur. In response, Krogh, a student of Bohr's, developed an improved blood gas–measuring technique relying on the microaerotonometer (Fig. 1-7). With his wife, Krogh convincingly showed that alveolar air oxygen tension was higher than blood oxygen tension and vice versa for carbon dioxide tensions, even when the composition of inspired air was varied.[28] Douglas and Haldane confirmed Krogh's findings but wondered whether they were applicable only to people at rest. Perhaps during the stress of either exercise or high-altitude exposure, passive diffusion might not be sufficient. Indeed, the ability to secrete oxygen might explain the tolerance to high altitude developed by repeated or chronic exposures. Possibly carbon dioxide excretion might occur with increased carbon dioxide

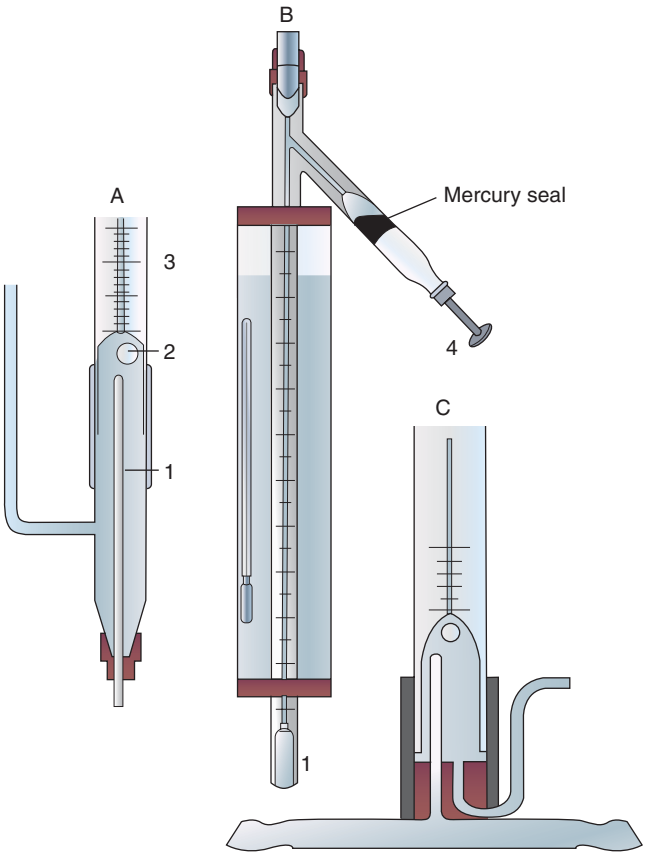

FIGURE 1-7 Krogh's microaerotonometer. **A.** An enlarged view of the lower part of *B*. Through the bottom of the narrow tube (1) in A, blood is introduced. The blood leaves the upper end of the narrow tube (1) in a fine jet and plays on the air bubble (2). Once equilibrium is reached between the air bubble and blood, the air bubble is drawn by the screw plunger (4) into the graduated capillary tube shown in **B.** The volume of the air bubble is measured before and after treatment with KOH to absorb CO_2 and potassium pyrogallate to absorb O_2. The changes in volume of the bubble reflect blood CO_2 and O_2 content. **C.** A model of A designed for direct connection to a blood vessel. levels.[26] In a classic series of experiments, Marie Krogh showed that diffusion increased with exercise secondary to the concomitant increase in cardiac output.[29] Barcroft put to rest the diffusion-versus-secretion controversy with his "glass chamber" experiment. For 6 days he remained in a closed chamber subjected to hypoxia similar to that found on Pike's Peak. Oxygen saturation of radial artery blood was always less than that of blood exposed to simultaneously obtained alveolar gas, even during exercise. These were expected findings for gas transport based simply on passive diffusion.[30]

With this body of work, the chemists and physiologists had provided the fundamental knowledge necessary for the development of mechanical ventilation. Oxygen was the component of atmospheric gas understood to be essential for life. Carbon dioxide was the "fuliginous waste" gas released from the lungs. The exchange of oxygen and carbon dioxide between air and blood was determined by the tensions of these gases and simple passive diffusion. Blood was a carrier of these two gases, as Harvey first suggested. Oxygen was carried in two ways, both dissolved in plasma and chemically combined with hemoglobin. Blood carried oxygen to the tissues, where oxygen was used in cellular metabolism, that is, the production of the body's "innate heat." Carbon dioxide was the waste product of this reaction. Oxygen and carbon dioxide tensions in the blood were related to ventilation in two critical ways. Increasing ventilation would secondarily increase oxygen tensions and decrease carbon dioxide levels. Decreasing ventilation would have the opposite effect. Because blood levels of oxygen and carbon dioxide could be measured, physiologists now could assess the adequacy of ventilation. Decreased oxygen tensions and increased carbon dioxide tensions played a critical role in the chemical control of ventilation.

It was not understood, though, how carbon dioxide was carried by the blood until experiments performed by Bohr[31] and Haldane.[32] The concept of blood acid–base activity was just beginning to be examined in the early 1900s. By the 1930s, a practical electrode became available for determining anaerobic blood pH,[33] but pH was not thought to be useful clinically until the 1950s. In 1952, during the polio epidemic in Copenhagen, Ibsen suggested that hypoventilation, hypercapnia, and respiratory acidosis caused the high mortality rate in polio patients with respiratory paralysis. Clinicians disagreed because high blood levels of "bicarbonate" indicated an alkalosis. By measuring pH, Ibsen was proved correct, and clinicians became acutely aware of the importance of determining both carbon dioxide levels and pH.[4] Numerous workers looked carefully at such factors as base excess, duration of hypercapnia, and renal buffering activity before Siggaard-Anderson published a pH/log P_{CO_2} acid–base chart in 1971.[34] This chart proved to be an invaluable basis for evaluating acute and chronic respiratory and metabolic acid–base disturbances. The development of practical blood gas machines suitable for use in clinical medicine did not occur until electrodes became available for measuring oxygen and carbon dioxide tensions in liquid solutions. Stow built the first electrode capable of measuring blood P_{CO_2}. As the basis for this device, he used a glass pH electrode with a coaxial central calomel electrode opening at its tip. A unique adaptation, however, was the use of a rubber finger cot to wrap the electrode. This wrap trapped a film of distilled water over the electrode. The finger cot then acted as a semipermeable membrane to separate the measuring electrode from the sample.[35] Clark used a similar idea in the development of an oxygen measuring device. Platinum electrodes were used as the measuring device, and polyethylene served as the semipermeable membrane.[36] By 1973, Radiometer was able to commercially produce the first automated blood gas analyzer, the ABL, capable of measuring P_{O_2}, P_{CO_2}, and pH in blood.[4]

EXPLORERS AND WORKING MEN OF SUBMARINES AND BALLOONS

Travel in the deep sea and flight have intrigued humankind for centuries. Achieving these goals has followed a typical pattern. First, individual explorers tested the limits of human endurance. As mechanical devices were developed to extend those limits, the deep sea and the air became accessible to commercial and military exploration. These forces further intensified the need for safe and efficient underwater and high-altitude travel. Unfortunately, the development of vehicles to carry humans aloft and under water proceeded faster than the appreciation of the physiologic risks. Calamitous events ensued, with serious injury and death often a consequence. Only a clear understanding of the ventilatory problems associated with flight and deep-sea travel has enabled human beings to reach outer space and the depths of the ocean floor.

Exploration Under Water

Diving bells undoubtedly were derived from ancient humans' inverting a clay pot over their heads and breathing the trapped air while under water. These devices were used in various forms by Alexander the Great at the siege of Tyre in 332 BC, the Romans in numerous naval battles, and pirates in the Black Sea.[37,38] In the 1500s, Sturmius constructed a heavy bell that, even though full of air, sank of its own weight. When the bell was positioned at the bottom of fairly shallow bodies of water, workers were able to enter and work within the protected area. Unfortunately, these bells had to be raised periodically to the surface to refresh the air. Although the nature of the foul air was not understood, an important principle of underwater work, the absolute need for adequate ventilation, was appreciated.[15]

Halley devised the first modern version of the diving bell in 1690 (Fig. 1-8). To drive out the air accumulated in the bell and "made foul" by the workers' respiration, small barrels of air were let down periodically from the surface and opened within the bell. Old air was released through the top of the bell by a valve. In 1691, Papin developed a technique for constantly injecting fresh air from the surface directly into the bell by means of a strong leather bellows. In 1788, Smeaton replaced the bellows with a pump for supplying fresh air to the submerged bell.[15,37,38]

Techniques used to make diving bells practical also were applied to divers. Xerxes used them to recover sunken treasure.[39] Sponge divers in the Mediterranean in the 1860s could stay submerged for 2 to 4 minutes and reach depths of 45 to 55 m.[40] *Amas,* female Japanese divers using only goggles and a weight to facilitate rapid descent, made dives to similar depths.[41] Despite the remarkable adaptations of breath-holding measures developed by these naked divers,[42] the commercial and military use of naked divers was limited. In 77 AD, Pliny described divers breathing through tubes while submerged and engaged in warfare. More sophisticated diving suits with breathing tubes were described by Leonardo da Vinci in 1500 and Renatus in 1511. Although these breathing tubes prolonged underwater activities, they did not enable divers to reach even moderate depths.[15] Borelli described a complete diving dress with tubes in the helmet for recirculating and purifying air in 1680 (Fig. 1-9).[37]

Klingert described the first modern diving suit in 1797.[37] It consisted of a large helmet connected by twin breathing pipes to an air reservoir that was large enough to have an associated platform. The diver stood on the platform and inhaled from the air reservoir through an intake pipe on the top of the reservoir and exhaled through a tube connected to the bottom of the reservoir. Siebe made the first commercially viable diving dress. The diver wore a metal helmet riveted to a flexible waterproof jacket. This jacket extended to the diver's waist but was not sealed. Air under pressure was pumped from the surface into the diver's helmet and escaped through the lower end of the jacket. In 1837, Siebe modified this diving dress by extending the jacket to cover the whole body. The suit was watertight at the wrists and ankles. Air under pressure entered the suit through a one-way valve at the back of the helmet and was released from the suit by an adjustable valve at the side of the helmet (Fig. 1-10).[37] In 1866, Denayouze incorporated a metal air reservoir on the back of the diver's suit. Air was pumped directly into the reservoir, and escape of air from the suit was adjusted by the diver.[15]

Siebe, Gorman, and Company produced the first practical self-contained diving dress in 1878. This suit had a copper chamber containing potash for absorbing carbon dioxide and a cylinder of oxygen under pressure.[37] Fleuss cleverly revised this diving suit in 1879 to include an oronasal mask with an inlet and an exhaust valve. The inlet valve allowed inspiration from a metal chamber containing oxygen under pressure. Expiration through the exhaust valve was directed into metal chambers under a breastplate that contained carbon dioxide absorbents. Construction of this appliance was so precise that Fleuss used it not only to stay under water for hours but also to enter chambers containing noxious gases. The Fleuss appliance was adapted rapidly and successfully to mine rescue work, where explosions and toxic gases previously had prevented such efforts.[43]

As Siebe, Gorman, and Company successfully marketed diving suits, commercial divers began to dive deeper and longer. Unfortunately, complications developed for two separate reasons. Decompression illness was recognized first. In 1830, Lord Cochrane took out a patent in England for "an apparatus for compressing atmospheric air within the interior capacity of subterraneous excavations [to]… counteract the tendency of superincumbent water to flow by gravitation into such excavations…and which apparatus at the same time is adapted to allowing workmen to carry out their ordinary operations of excavating, sinking, and mining."[38] In 1841, Triger described the first practically applied caisson for penetrating the quicksands of the Loire River (Fig. 1-11).[44] This caisson, or hollow iron tube, was sunk to a depth of 20 m. The air within the caisson was

FIGURE 1-8 Halley's version of the diving bell. Small barrels of fresh air were lowered periodically to the bell, and the worker inside the bell released the air. "Foul air" often was released by way of a valve at the top of the bell. Workers could exit the bell for short periods. (Used, with permission, from Hill.[38])

compressed by a pump at the surface. The high air pressure within the caisson was sufficient to keep water out of the tube and allow workers to excavate the bottom. Once the excavation reached the prescribed depth, the caisson was filled with cement, providing a firm foundation. During the excavation process, workers entered and exited the caisson through an airlock. During this work, Triger described the first cases of "caisson disease," or decompression illness, in workers after they had left the pressurized caisson. As this new technology was applied increasingly in shaft and tunnel work (e.g., the Douchy mines in France in 1846; bridges across the Midway and Tamar rivers in England in

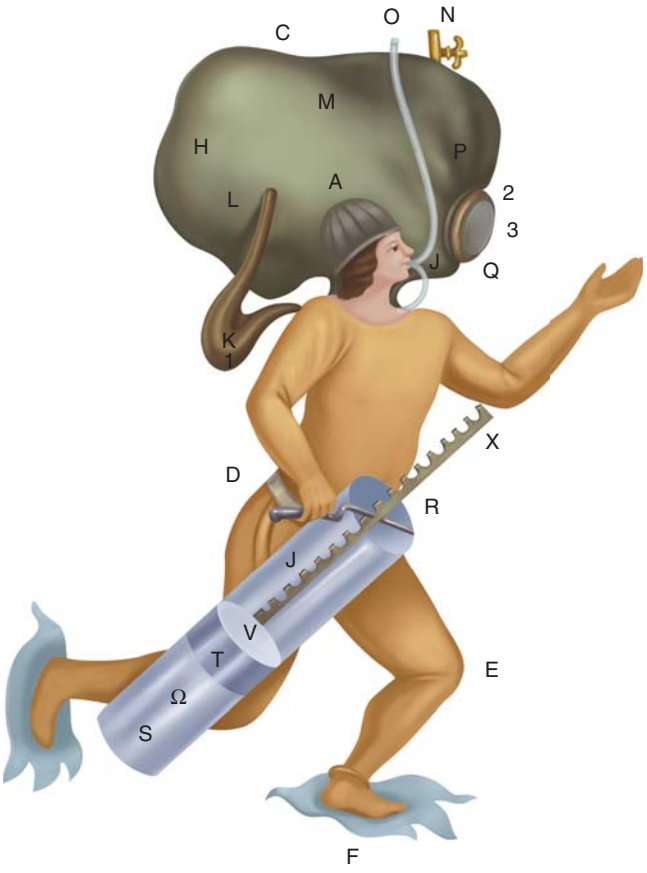

FIGURE 1-9 A fanciful diving suit designed by Borelli in 1680. (Used, with permission, from Hill.[38])

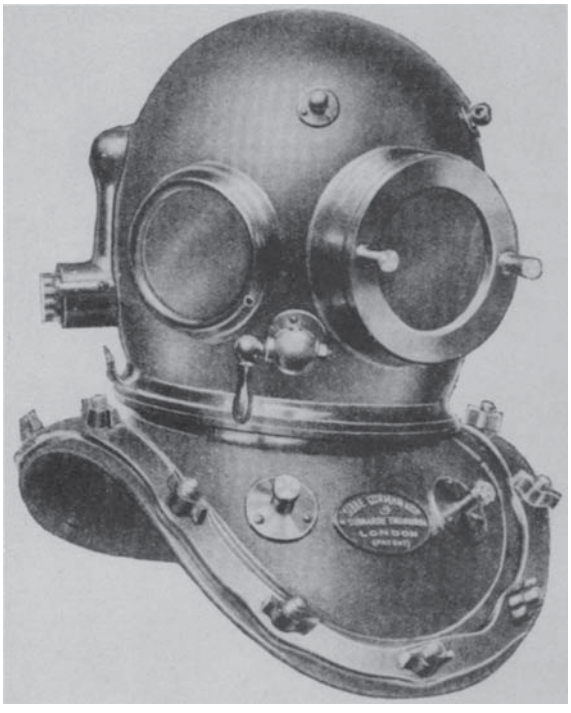

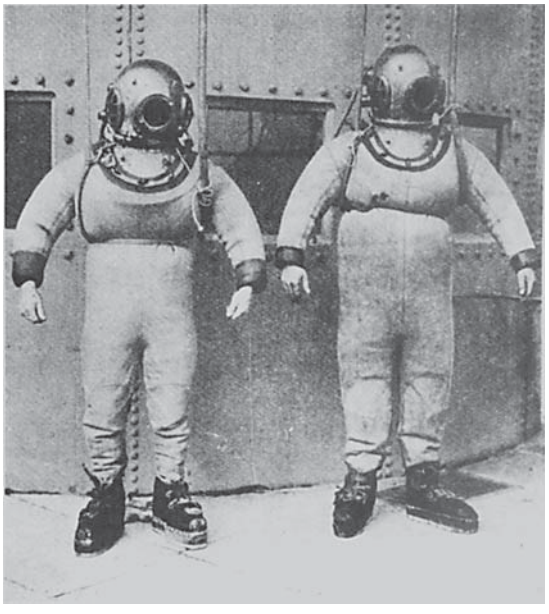

FIGURE 1-10 **A.** The metal helmet devised by Siebe is still used today. **B.** The complete diving suit produced by Siebe, Gorman, and Company in the nineteenth century included the metal helmet, a diving dress sealed at the wrists and ankles, and weighted shoes. (Used, with permission, from Hill.[38])

1851 and 1855, respectively; and the Brooklyn Bridge, constructed between 1870 and 1873), caisson disease was recognized more frequently. Bert was especially instrumental in pointing out the dangers of high pressure.[15] Denayouze supervised many commercial divers and probably was among the first to recognize that decompression caused illness in these divers.[15] In the early 1900s, Haldane developed safe and acceptable techniques for staged decompression based on physiologic principles.[38]

Haldane also played a critical role in examining how well Siebe's closed diving suit supplied the ventilation needs of divers. This work may have been prompted by Bert's studies with animals placed in high-pressure chambers. Bert found that death invariably occurred when inspired carbon dioxide levels reached a certain threshold. Carbon dioxide absorbents placed in the high-pressure chamber prevented deaths.[15] Haldane's studies in this area were encouraged by a British Admiralty committee studying the risks of deep diving in 1906. Haldane understood that minute ventilation varied directly with alveolar carbon dioxide levels. It appeared reasonable that the same minute ventilation needed to maintain an appropriate $P_{A_{CO_2}}$ at sea level would be needed to maintain a similar $P_{A_{CO_2}}$ under water. What was not appreciated initially was that as the diver descended and pressure increased, pump ventilation at the surface necessarily also would have to increase to maintain minute ventilation. Haldane realized that at 2 atmospheres of pressure, or 33 ft under water, pump ventilation would have to double to ensure appropriate ventilation. This does

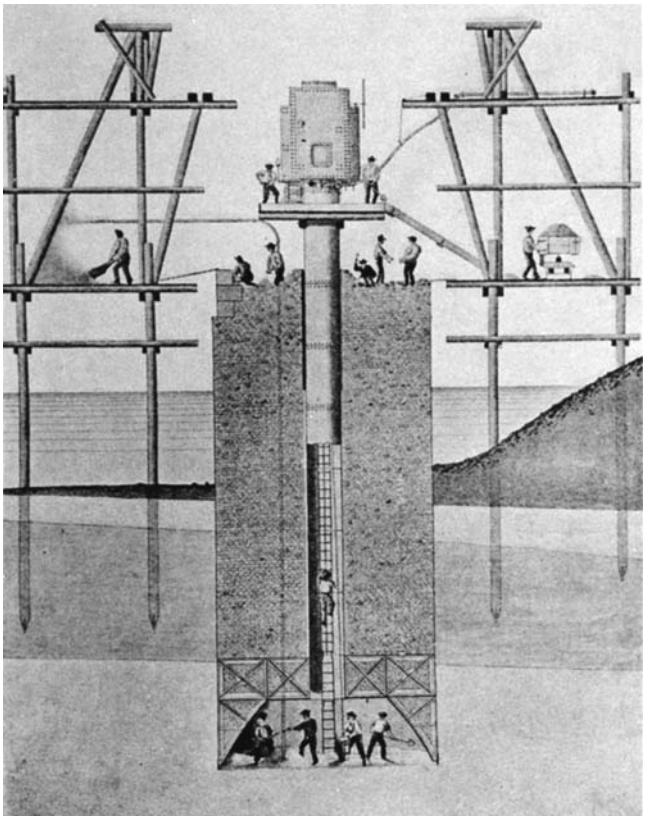

FIGURE 1-11 The caisson is a complex device enabling workers to function in dry conditions under shallow bodies of water or in other potentially flooded circumstances. A tube composed of concentric rings opens at the bottom to a widened chamber, where workers can be seen. At the top of the tube is a blowing chamber for maintaining air pressure and dry conditions within the tube. Workers enter at the top through an air lock and gain access to the working area via a ladder through the middle of the tube. (Used, with permission, from Hill.[38])

not take into account muscular effort, which would further increase ventilatory demands. Unfortunately, early divers did not appreciate the need to adjust ventilation to the diving suit. Furthermore, air pumps often leaked or were maintained inadequately. Haldane demonstrated the relationship between divers' symptoms and hypercapnia by collecting exhaled gas from divers at various depths. The fraction of carbon dioxide in the divers' helmets ranged from 0.0018 to 0.10 atm.[26,38] The investigations of Bert and Haldane finally clarified the nature of "foul air" in diving bells and suits and the role of adequate ventilation in protecting underwater workers from hypercapnia. Besides his work with divers, Haldane also demonstrated that the "black damp" found in mines actually was a dangerously toxic blend of 10% CO_2 and 1.45% O_2.[45] He developed a self-contained rescue apparatus for use in mine accidents that apparently was more successful than the Fleuss appliance.[46]

Diving boats were fancifully described by Marsenius, in 1638, and others. Only the boat designed by Debrell in 1648 appeared plausible because "besides the mechanical contrivances of his boat, he had a chemical liquor, the fumes of which, when the vessel containing it was unstopped, would speedily restore to the air, fouled by the respiration, such a portion of vital spirits as would make it again fit for that office." Although the liquor was never identified, it undoubtedly was an alkali for absorbing carbon dioxide.[38] Payerne built a submarine for underwater excavation in 1844. Since 1850, the modern submarine has been developed primarily for military actions at sea.

Submarines are an intriguing physiologic experiment in simultaneously ventilating many subjects. Ventilation in submarines is complex because it involves not only oxygen and carbon dioxide levels but also heat, humidity, and body odors. Early work in submarines documented substantial increases in temperature, humidity, and carbon dioxide levels.[47] Mechanical devices for absorption of carbon dioxide and air renewal were developed quickly,[48] and by 1928, Du Bois thought that submarines could remain submerged safely for up to 96 hours.[49] With the available carbon dioxide absorbents, such as caustic soda, caustic potash, and soda lime, carbon dioxide levels could be kept within relatively safe levels of less than 3%. Supplemental oxygen carried by the submarine could maintain a preferred fractional inspired oxygen concentration above 17%.[39,50–52]

Exploration in the Air

In 1782, the Montgolfier brothers astounded the world by constructing a linen balloon about 18 m in diameter, filling it with hot air, and letting it rise about 2000 m into the air. On November 21, 1783, two Frenchmen, de Rozier and the Marquis d'Arlandes, were the first humans to fly in a Montgolfier balloon.[53] Within a few years, Jeffreys and Blanchard had crossed the English Channel in a balloon, and Charles had reached the astonishing height of 13,000 ft in a hydrogen-filled balloon. As with diving, however, the machines that carried them aloft brought human passengers past the limits of their physiologic endurance. Glaisher and Coxwell reached possibly 29,000 ft in 1862, but suffered temporary paralysis and loss of consciousness.[4,26,54]

Acoste's description in 1573 of vomiting, disequilibrium, fatigue, and distressing grief as he traversed the Escaleras (Stairs) de Pariacaca, between Cuzco and Lima, Peru ("one of the highest places in the universe"), was widely known in Europe.[55] In 1804, von Humboldt attributed these high altitude symptoms to a lack of oxygen. Surprisingly, however, he found that the fraction of inspired oxygen in high-altitude air was similar to that found in sea-level air. He actually suggested that respiratory air might be used to prevent mountain sickness.[56] Longet expanded on this idea in 1857 by suggesting that the blood of high-altitude dwellers should have a lower oxygen content than that of sea-level natives. In a remarkable series of observations during the 1860s, Coindet described respiratory patterns of French people living at high altitude in Mexico City. Compared with sea-level values, respirations were deeper and more

frequent, and the quantity of air expired in 1 minute was somewhat increased. He felt that "this is logical since the air of altitudes contains in a given volume less oxygen at a lower barometric pressure…[and therefore] a greater quantity of this air must be absorbed to compensate for the difference."[15] Although these conclusions might seem reasonable now, physiologists of the time also considered decreased air elasticity, wind currents, exhalations from harmful plants, expansion of intestinal gas, and lack of support in blood vessels as other possible explanations for the breathing problems experienced at high altitude. Bert, the father of aviation medicine, was instrumental in clarifying the interrelationship among barometric pressure, oxygen tension, and symptoms. In experiments on animals exposed to low-pressure conditions in chambers (Fig. 1-12), carbonic acid levels increased within the chamber, but carbon dioxide absorbents did not prevent death. Supplemental oxygen, however, protected animals from dying under simulated high-altitude conditions (Fig. 1-13). More importantly, he recognized that death occurred as a result of the interaction of both the fraction of inspired oxygen and barometric pressure. When a multiple of these two variables—that is, the partial pressure of oxygen—reached a critical threshold, death ensued.[15,39]

Croce-Spinelli, Sivel, and Tissandier were adventurous French balloonists eager to reach the record height of 8000 m. At Bert's urging, they experimented with the use of oxygen tanks in preliminary balloon flights and even in Bert's decompression chamber. In 1875, they began their historic attempt to set an altitude record supplied with oxygen cylinders (Fig. 1-14). Unfortunately, at 24,600 ft they released too much ballast, and their balloon ascended so rapidly that they were stricken unconscious before they could use the oxygen. When the balloon eventually returned to earth, only Tissandier remained alive.[4,54] This tragedy shook France. The idea that two men had died in the air was especially disquieting.[53] Unfortunately, the reasons for the deaths of Croce-Spinelli and Sivel were not clearly attributed to hypoxia. Von Schrotter, an Austrian physiologist, believed Bert's position regarding oxygen deficit as the lethal threat and encouraged Berson to attempt further high-altitude balloon flights. He originally devised a system for supplying oxygen from a steel cylinder with tubing leading to the balloonists. Later, von Schrotter conceived the idea of a face mask to supply oxygen more easily and also began to use liquid oxygen. With these devices, Berson reached 36,000 ft in 1901.[4,54]

The Wright brothers' historic flight at Kitty Hawk in 1903 substantially changed the nature of flight. The military value of airplanes soon was appreciated and applied during World War I. The Germans were especially interested in increasing the altitude limits for their pilots. They applied the concepts advocated by von Schrotter and provided liquid oxygen supplies for high-altitude bombing

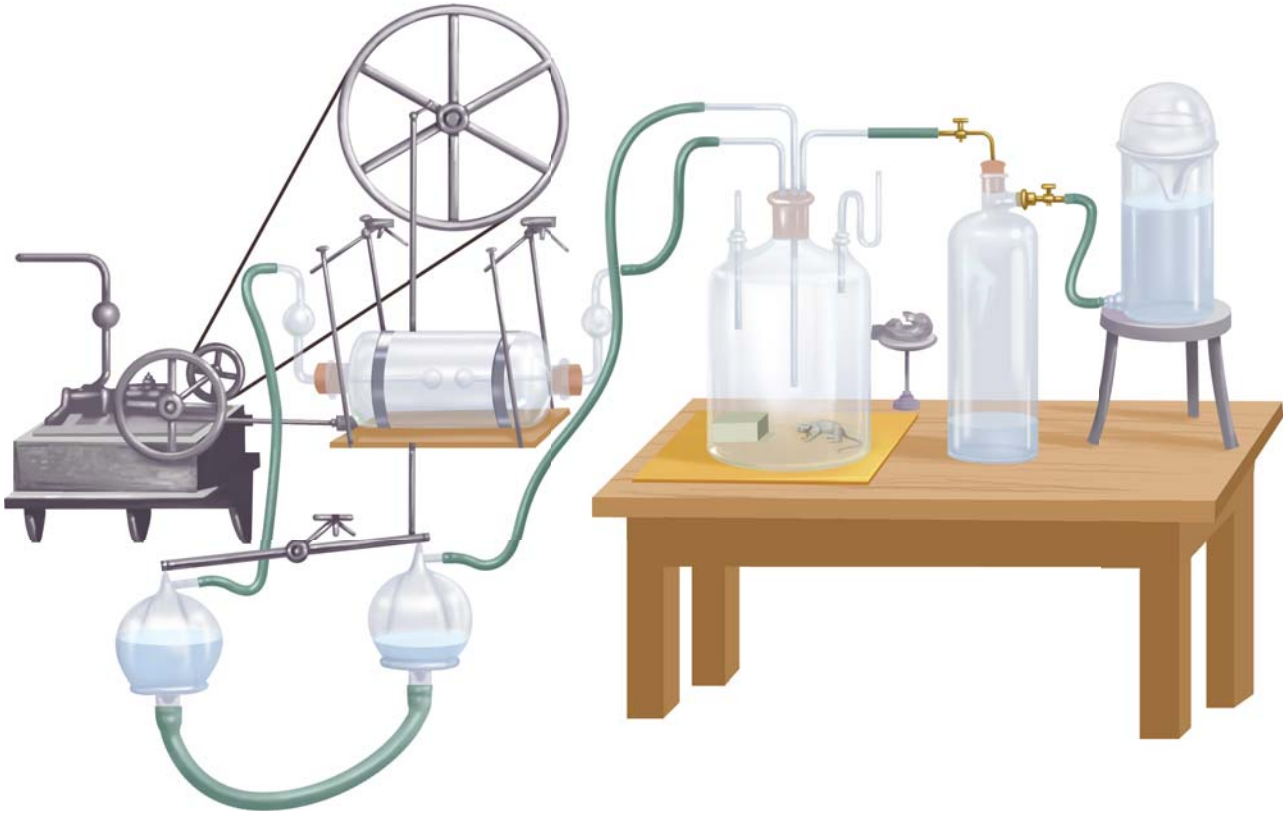

FIGURE 1-12 A typical device used by Bert to study animals under low-pressure conditions. (Used, with permission, from Bert.[15])

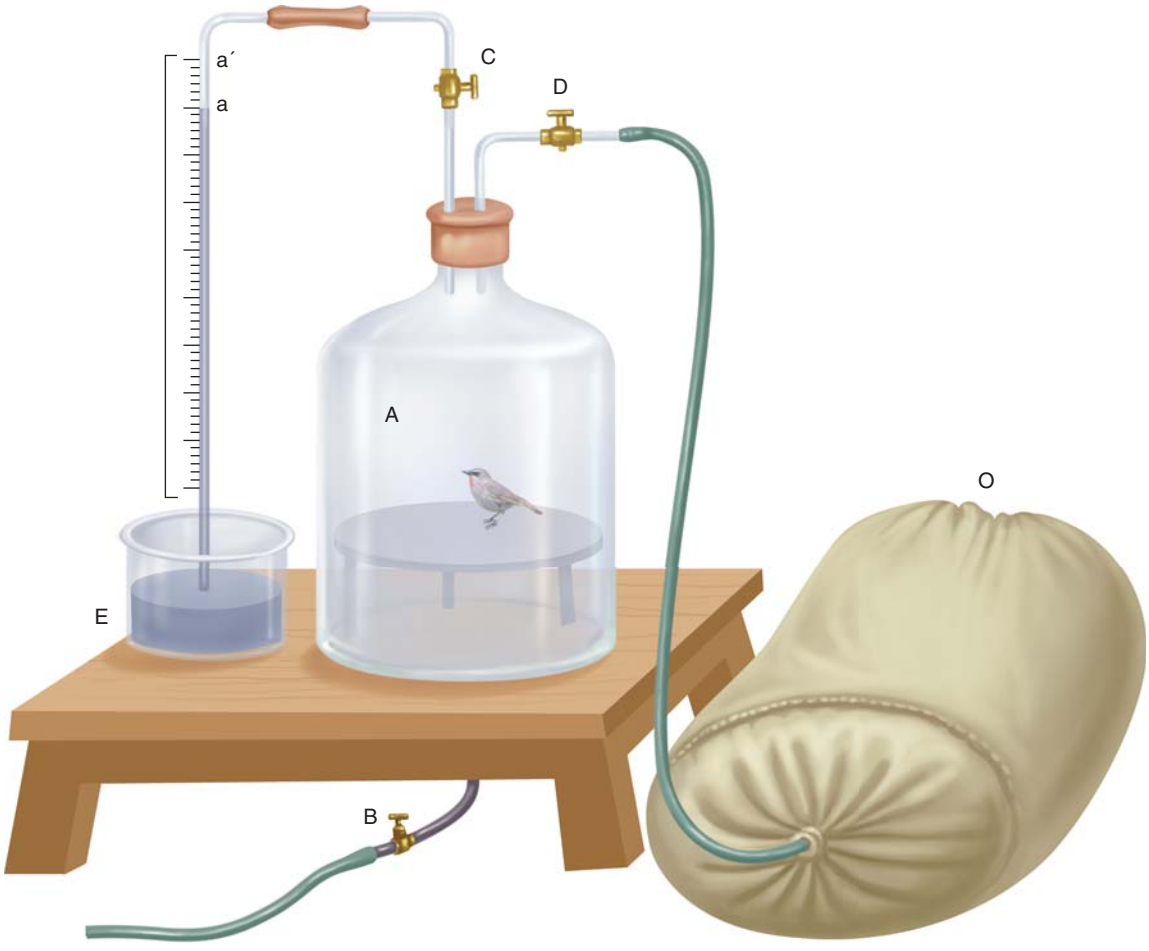

FIGURE 1-13 A bird placed in a low-pressure bell jar can supplement the enclosed atmospheric air with oxygen inspired from the bag labeled O. Supplemental oxygen prolonged survival in these experiments. (Used, with permission, from Bert.[15])

flights. Interest in airplane flights for commercial and military uses was especially high following Lindbergh's solo flight across the Atlantic in 1927. Much work was done on valves and oxygen gas regulators in the hope of further improving altitude tolerance. A series of high-altitude airplane flights using simple face masks and supplemental oxygen culminated in Donati's reaching an altitude of 47,358 ft in 1934. This was clearly the limit for human endurance using this technology.[4,54]

Somewhat before Donati's record, a breakthrough in flight was achieved by Piccard, who enclosed an aeronaut in a spherical metal chamber sealed with an ambient barometric pressure equivalent to that of sea level. The aeronaut easily exceeded Donati's record and reached 55,000 ft. This work recapitulated the important physiologic concept, gained from Bert's earlier experimental work in high-altitude chambers, that oxygen availability is a function of both fractional inspired oxygen and barometric pressure. Piccard's work stimulated two separate investigators to adapt pressurized diving suits for high-altitude flying. In 1933, Post devised a rubberized, hermetically sealed silk suit. In the same year, Ridge worked with Siebe, Gorman, and Company to modify a self-contained diving dress for flight. This suit provided oxygen under pressure and an air circulator with a soda lime canister for carbon dioxide removal. These suits proved quite successful, and soon pilots were exceeding heights of 50,000 ft. Parallel work with sealed gondolas attached to huge balloons led to ascents higher than 70,000 ft. In 1938, Lockheed produced the XC-35, which was the first successful airplane with a pressurized cabin (Fig. 1-15).[4,54] These advances were applied quickly to military aviation in World War II. The German Air Ministry was particularly interested in developing oxygen regulators and valves and positive-pressure face masks for facilitating high-altitude flying.[57]

Work throughout World War II defined limits for technological support of high-altitude flight. Pilots could reach up to 12,000 ft safely without oxygen supplements. Above this limit, oxygen-enriched air was essential. With flights going above 25,000 ft, oxygen supplementation alone usually was insufficient, and some type of pressurized system—cabin, suit, or mask—was needed. Pressurization as an adjunct, however, reached its limit of usefulness at approximately 80,000 ft. At this altitude, air compressors

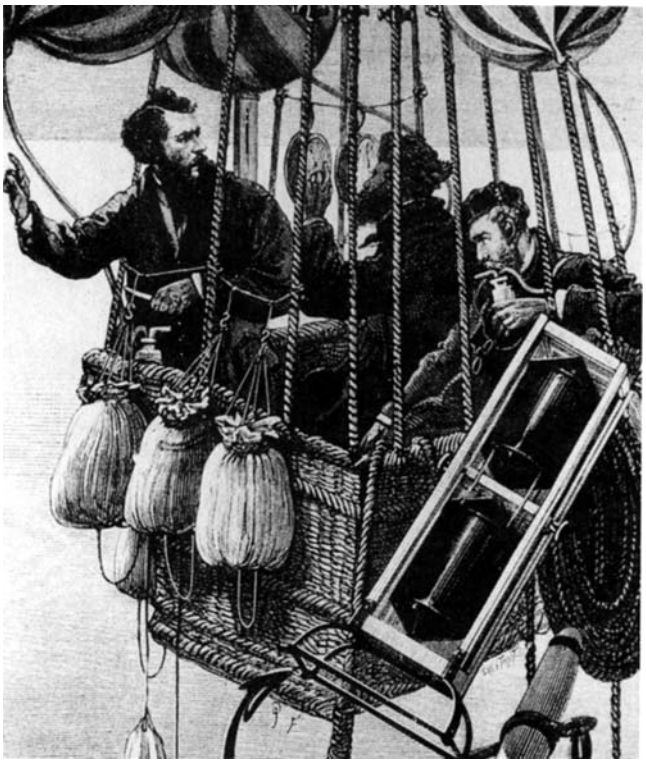

FIGURE 1-14 The adventurous French balloonists Croce-Spinelli, Sivel, and Tissandier begin their attempt at a record ascent. The balloonist at the right can be seen inhaling from an oxygen tank. Unfortunately, the supplemental oxygen did not prevent tragic results from a too rapid ascent. (Used, with permission, from Armstrong HG. *Principles and Practice of Aviation Medicine.* Baltimore, MD: Williams & Wilkins; 1939:4.)

became too leaky and inefficient to maintain adequate pressurization. A completely sealed cabin was essential to protect passengers adequately from the rarefied atmosphere outside. An altitude of 80,000 ft thus became a functional definition of space because at this height complete control of the atmosphere in the plane (i.e., the supply of oxygen, a means of removing carbon dioxide, and adequate control of temperature and humidity) was required.[58,59] Advances in submarine ventilatory physiology were adapted to the space program. In 1947, the American Air Force began the XI program, which culminated in the production in 1952 of the X15 aircraft. This plane reached a top speed of 4159 miles per hour at an altitude of 314,750 ft. More importantly, the technology developed for this plane was a prelude to manned satellite programs. The United States Mercury and the Russian Vostok programs both relied on rockets to boost small, one-person capsules into space orbit. The Mercury capsule had a pure oxygen atmosphere at a reduced cabin pressure. In addition, the pilot wore a pressurized suit with an independent, closed oxygen supply. In April 1961, Gagarin was the first person to be launched into space. Shepard followed soon after, in May 1961, and reached an altitude of 116 miles. More sophisticated space flight—in the Gemini, Apollo, and space station programs—was based on similar ventilation systems and principles.[60]

FIGURE 1-15 Lockheed produced the XC-35 in 1938. This was the first plane to have a pressurized cabin. (Used, with permission, Armstrong HG. *Principles and Practice of Aviation Medicine.* Baltimore, MD: Williams & Wilkins; 1939:337.)

MECHANICAL VENTILATION OF RESUSCITATION AND ANESTHESIA

Vivisection

Galen described ventilating an animal as follows: "If you take a dead animal and blow air through its larynx [through a reed], you will fill its bronchi and watch its lungs attain the greatest distention."[61] Unfortunately, Galen failed to appreciate how ventilating the lungs could help him in his vivisection work. Galen operated on many living animals, but his studies on the function of the heart were limited by the risk of pneumothorax. Opening the thoracic cavity almost certainly resulted in death of the animal.[1,6] More than a thousand years later, Vesalius realized that ventilation could protect animals from pneumothorax.[62,63] The lungs would collapse and the beating heart would almost stop when Vesalius opened the chest cavity, but the heart could be restarted by inflating the lungs through a reed tied into the trachea. Paracelsus, a contemporary of Vesalius, is reported to have used a similar technique around 1530 in attempting to resuscitate a human. Did Paracelsus adapt Vesalius's research efforts, or vice versa?[63] It is also unclear whether Vesalius himself tried artificial ventilation during the dissection of a Spanish nobleman. Legend has it that when the nobleman's heart began to beat once more, Vesalius's medical associates were so outraged that they reported him to the religious authorities. Vesalius only avoided being burned at the stake by embarking on a pilgrimage to the Holy Land, but he died during the voyage.[64]

Presumably, Harvey became familiar with Vesalius's use of ventilation during vivisection because he mentioned artificial ventilation in his work later in England.[63] Other English scientists soon after began to mention artificial

ventilation in their own studies.[65] In 1664, Hooke dramatically described dissecting a dog, placing a pipe into the windpipe of the animal, and using a pair of bellows to ventilate the dog (and keep the heart beating) for longer than an hour.[63] Lower, an associate of Hooke, showed that artificial respiration kept the color of blood red during dissection.[63]

Resuscitating the Apparantly Drowned

Artificial respiration with a bellows and tracheal tube remained popular for vivisection work but was applied to humans only after a curious turn of events. Attempts to resuscitate apparently dead people were first recorded in the mid-eighteenth century. The origins of this movement are not entirely clear. Indeed, there were strong reasons for people to fear the dead. The risk of contagious disease was well known—memories of the plague were still fresh—and religious beliefs dissuaded many from believing in the wisdom of resuscitation. Despite these disincentives, sporadic attempts were made at organized resuscitation. In 1740, the Académie des Sciences in Paris issued an *avis* strongly advising mouth-to-mouth respiration for resuscitating the apparently drowned.[63] In 1744, Tossach used this technique successfully in saving a life.[66] Fothergill soon after provided an excellent description of the mouth-to-mouth resuscitation technique, including the use of bellows if the "blast of a man's mouth" was not sufficient.[63,64,67,68] In 1760, Buchan went on to advise creating "an opening in the windpipe" when air cannot be forced into the chest through the mouth or nose.[69] Societal pressures led to widespread dissemination of knowledge about resuscitation techniques. In response to citizens' concerns about the large number of lives lost in canals, a group of influential laymen in Amsterdam formed the Society for the Rescue of Drowned Persons (*Maatschappy tot Redding von Dreykhingen*) in 1767.[63,64,67] The express purpose of this society was to publicize the need for and the techniques of resuscitation. Similar societies soon were formed in other maritime cities, such as Venice and Milan in 1768, Paris in 1771, London in 1774, and Philadelphia in 1780.

The Dutch method emphasized five steps: keeping the patient warm, artificial respiration through the mouth, fumigation with tobacco smoke through the rectum (Fig. 1-16), stimulants placed orally or rectally, and bleeding. Cogan, an English physician with a Dutch wife, translated a pamphlet describing the Dutch method into English. Hawes, an apothecary, read the pamphlet and led a concerted effort to introduce this technique into England. In encouraging this work, Hawes' activities led directly to the formation of the Royal Humane Society in 1774.[67] Through this society, many physicians were encouraged to develop techniques for resuscitating the apparently drowned. In 1776, Hunter advocated the use of a double bellows for artificial ventilation. The first stroke blew fresh air into the lung, and the second stroke sucked out stale air. He had perfected this technique during physiologic studies with dogs. Hunter advised the use of Priestley's pure air (oxygen) for resuscitation, but it is unclear whether this advice was ever followed.[64,67,70] In 1776, Cullen suggested relying on tracheal intubation and bellows ventilation for reviving the apparently dead.[71] In 1791, Curry developed an intralaryngeal cannula for this purpose, as did Fine in 1800. These cannulas could be placed through the nose, mouth, or trachea.

FIGURE 1-16 An attempt at resuscitating an apparently drowned person using the modified Dutch method. One resuscitator is assisting respiration by massaging the chest. The fumigator is instilling tobacco smoke through the rectum. (Used, with permission, from Morch.[64])

Many other physicians were encouraged to develop ingenious devices as resuscitation aids by the Royal Humane Society (Fig. 1-17). This society held competitions and offered prizes and medals for the best work in this area.[63,64,67,72] As an alternative to tracheal intubation, Chaussier constructed a simple bag and face mask for artificial ventilation in 1780 (Fig. 1-18). He thought that this device would protect the rescuer from the deleterious effects of exhaled air. Chaussier devised accessory tubing for the face mask to allow the use of supplemental oxygen.[73] Kite, Curry, and Chaussier also developed devices to assist the operator in cannulating the trachea through the mouth.[73,74]

As these techniques for resuscitation were gaining widespread acceptance, concerns were being raised about the effectiveness of bellows ventilation. Leroy, in a dramatic series of studies in 1827 and 1828, subjected an animal to overzealous bellows inflation and caused fatal pneumothorax.[75,76] Although later it was realized that the pressures reached in this demonstration were unlikely to be achieved in clinical practice,[63] the French Academy quickly condemned the technique. Despite adaptations of bellows to limit ventilatory volumes,[77] the Royal Humane Society also abandoned the use of tracheal intubation and bellows ventilation for resuscitation.[63] Consequently, positive-pressure ventilation was banned from medical practice early in its infancy, not to be routinely relied on for patient care until well into the twentieth century.

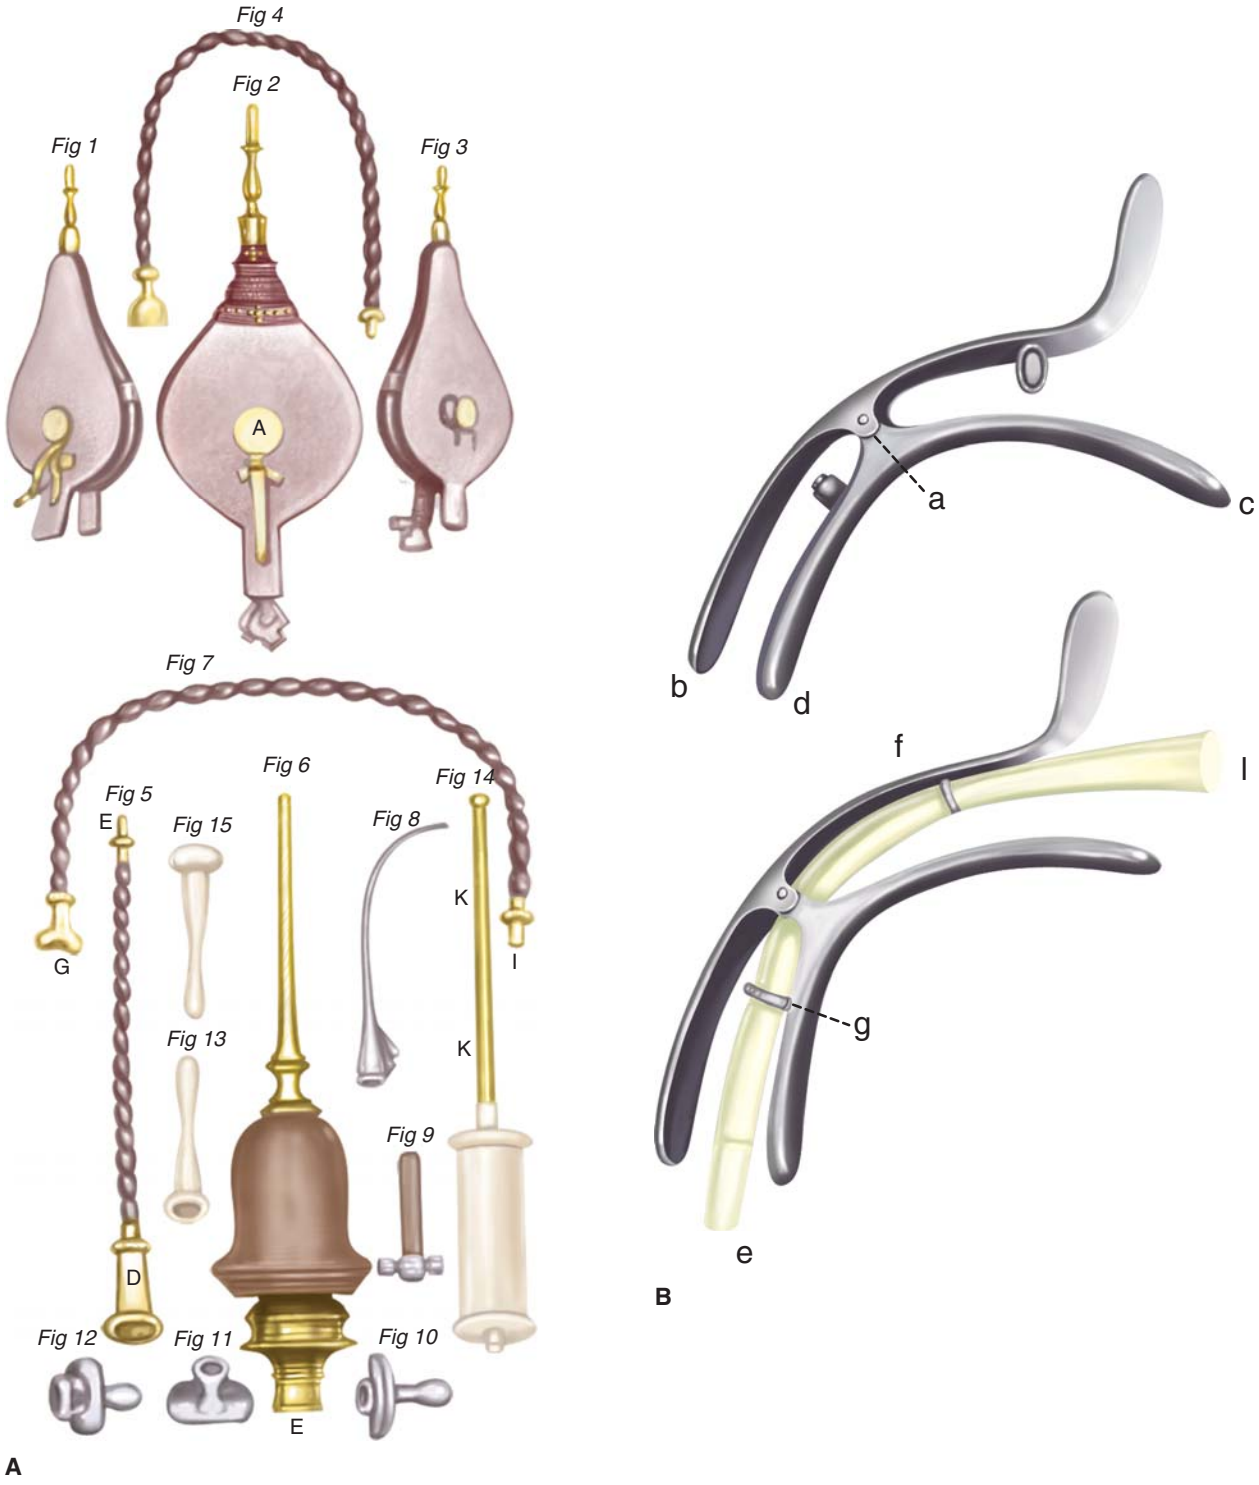

FIGURE 1-17 **A.** Examples of some of the devices included in the Royal Humane Society's compendium of resuscitation techniques in 1806. Figures 1, 2, and 3 are bellows of different sizes. Negative-Pressure Ventilators

As an alternative to positive-pressure ventilation, physicians began to develop machines for negative-pressure ventilation. The first tank respirator was produced by Dalziel, of Scotland, in 1832. It was an airtight box in which the patient sat enclosed up to the neck. Negative pressure was created by bellows placed within the box but operated from the outside by a piston rod and one-way valve.[78,79]

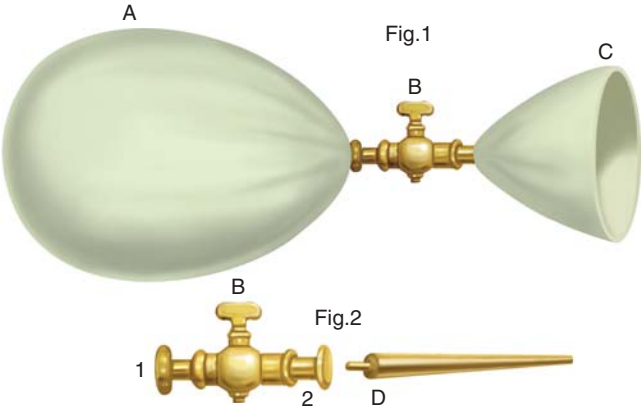

FIGURE 1-18 Chaussier developed this face mask and bag for artificial ventilation in 1780. (Used, with permission, from Mushin WW, Rendell-Baker L. *The Principles of Thoracic Anesthesia.* Oxford, England: Blackwell Scientific Publications; 1953:39.)

Jones, of Kentucky, patented the first tank respirator in America in 1864. The design appears similar to that of Dalziel's apparatus (Fig. 1-19).[78,80] Although Jones used this device to treat asthma and bronchitis, he also claimed cures for paralysis, neuralgia, rheumatism, seminal weakness, and dyspepsia.[80] Von Hauke designed a series of cuirass and tank respirators in the 1870s that were intended specifically to treat patients with respiratory diseases, but he showed little insight into the physiologic basis for how this type of respirator might be of benefit in lung disease. Woillez presented his version of a tank respirator to the French Academy of Medicine in 1876 (Fig. 1-20). It was basically a hollow cylinder of metal with a rigid lower end and an upper end enclosing a neck made of a rubber diaphragm seal. Air was evacuated from the cylinder by a bellows. Woillez understood the physiologic basis of ventilation and incorporated a bar placed on the patient's sternum to measure tidal excursions and adequacy of ventilation. Unfortunately, this device seemed to have been used only for resuscitating the apparently drowned and with little success.[78,81]

Many other ingenious devices were invented for negative-pressure ventilation over the next 50 years. Breuillard, of Paris, patented a tank respirator operated by a steam boiler.[78,80] Bell devised a vacuum jacket for newborns with neonatal respiratory distress. A resuscitation box developed by Braun reportedly was quite useful for children with respiratory distress (Fig. 1-21).[78,80,82] Eisenmenger designed a prototype respirator that extended from the upper part of the sternum to the pubis (Fig. 1-22A). A more

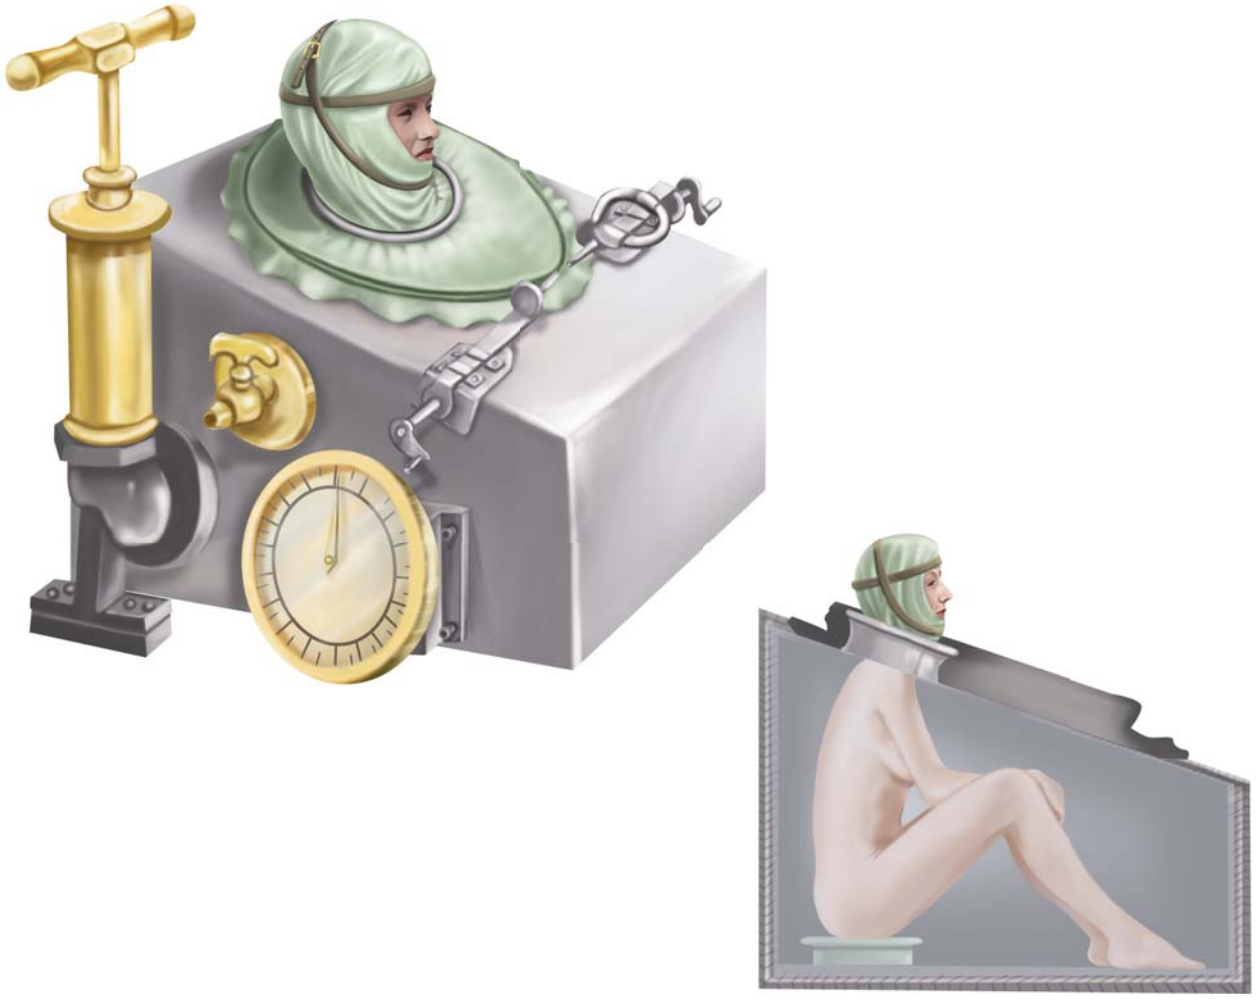

FIGURE 1-19 The body-enclosing tank respirator constructed by Jones in 1864. The large syringe was used to create negative pressure. (Used, with permission, from Emerson JH. *Evolution of Iron Lungs.* Cambridge, MA: JH Emerson; 1978:fig. 1.)

sophisticated device covered the chest and only a portion of the abdomen (Fig. 1-22B). These devices allowed positive-pressure compression of the chest to assist exhalation and negative-pressure suction to facilitate inhalation.[78,80,83] A later device, called the *Eisenmenger biomotor,* was patented in 1927, and had only an abdominal cuirass shell.[84] An important advantage of these devices was the access they allowed to the patient for nursing care. This consideration prompted Lord, of Worcester, to build a respirator room (Fig. 1-23). Huge pistons in the ceiling created the pressure changes but required heavy equipment.[78,80] Severy, in 1916, and Schwake, in 1926, built negative-pressure ventilators that required the patient to stand (Fig. 1-24). Although they incorporated ingenious mechanical elements, their practicality for severely ill patients was limited.[80]

The first negative-pressure ventilator to be used successfully in clinical practice on a widespread basis was the Drinker-Shaw "iron lung" developed in 1928 (Fig. 1-25).[80,84–86] With this device, the body was enclosed entirely within a cylindrical sheet-metal tank sealed at the lower end. The patient's head protruded out the upper end through a close-fitting rubber collar. Pressure within the chamber could be either increased or decreased by air blowers. This design is remarkably similar to the spirophore first built by Woillez in 1876. Unfortunately, it suffered from several of the same disadvantages, being cumbersome and inconvenient for patient care. Despite these limitations, this iron lung saved many lives during polio epidemics. When the Consolidated Gas Company of New York paid for large numbers of these machines to be built, their use spread quickly worldwide.[80] A severe poliomyelitis epidemic in 1931 prompted Emerson to build a simplified and improved tank respirator (Fig. 1-26). Because of its low cost, ease of operation, and technologic improvements, the Emerson tank respirator became the mainstay in treating patients with respiratory paralysis from polio[80] until reintroduction of positive-pressure ventilation in the 1950s.

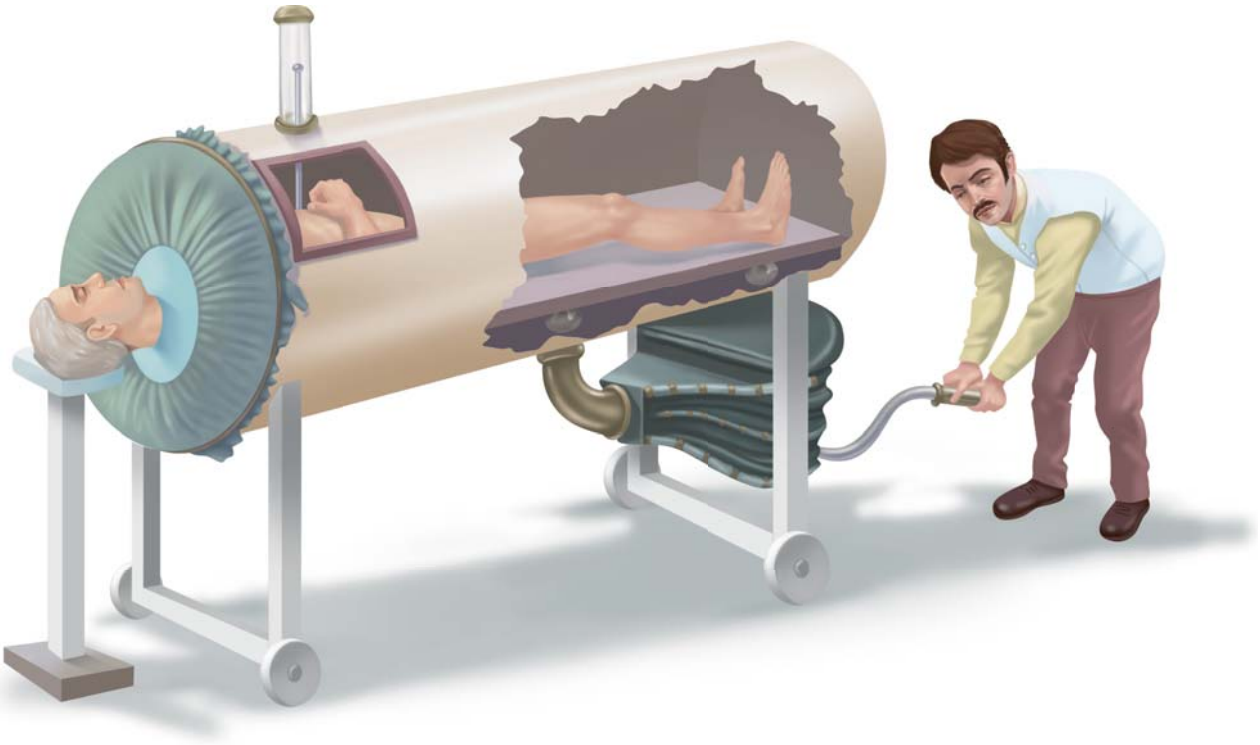

FIGURE 1-20 The spirophore produced by Woillez in 1876 had a rod placed on the patient's sternum to indicate the adequacy of tidal excursions. (Used, with permission, from Emerson JH: *Evolution of Iron Lungs.* Cambridge, MA: JH Emerson; 1978:fig. 2.)

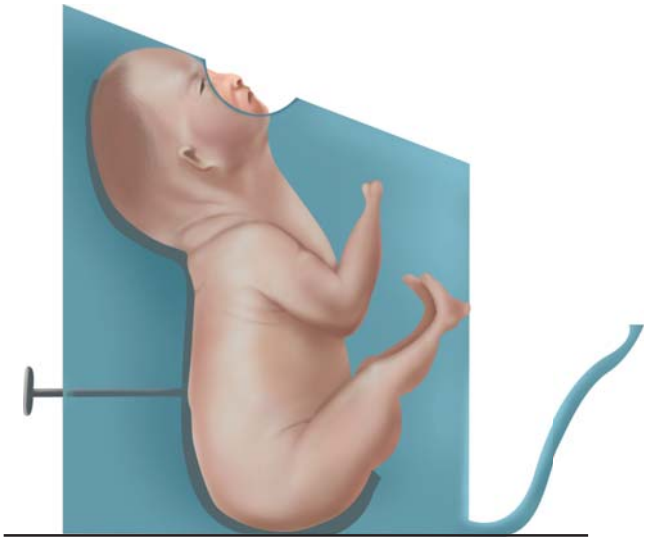

FIGURE 1-21 In Egon Braun's resuscitation box, children were seated in a plaster mold with their noses and mouths protruding through a rubber diaphragm. The operator blew through the tube on the right first, compressing the chest. Then suction was applied to the tube expanding the chest. (Used, with permission, from Emerson JH. *Evolution of Iron Lungs.* Cambridge, MA: JH Emerson; 1978:fig. 4.)

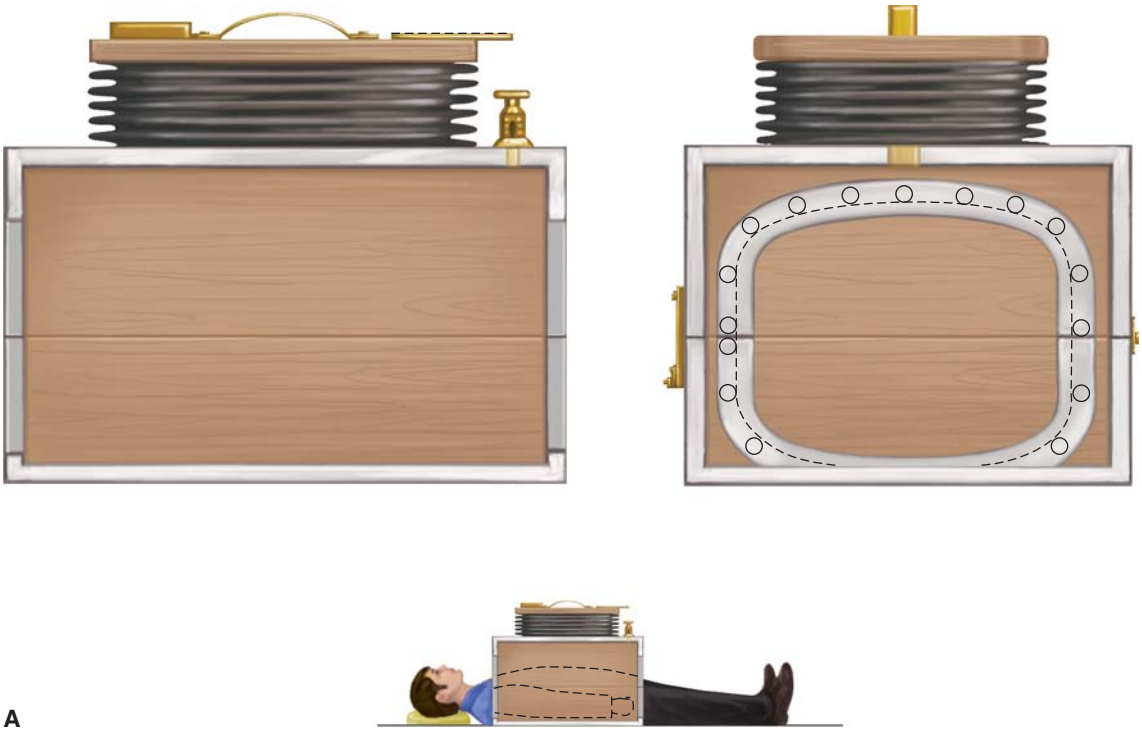
Positive-Pressure Ventilation

IN THE PHYSIOLOGY LABORATORY

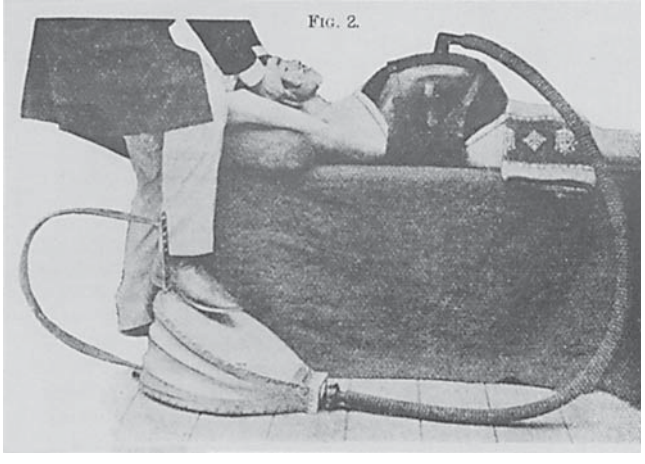
Although positive-pressure ventilation was disavowed by clinicians, throughout the middle to late 1800s, physiologists relied increasingly on positive-pressure ventilation in animal experiments. Hering and Breuer used this technique to examine how alterations in lung volume influenced the vagi in 1868.[87] Bert, in his studies on blood oxygen and carbon dioxide content, wrote of giving animals sufficient curare to induce total paralysis and of providing artificial ventilation through a tracheostomy tube in 1878. A bellows with a graduated handle for controlling tidal volume proved to be quite effective in these experiments (Fig. 1-27).[15] Pflüger[26] and Head[88] described complex experiments in which cuffed tubes were used to ventilate isolated portions of the lung. Bowditch wrote of a simple but reliable volume-cycled ventilator used for animal studies as a standard piece of laboratory equipment at Harvard in 1879 (Fig. 1-28).[89]

IN THE OPERATING ROOM

The reintroduction of positive-pressure ventilation into clinical medicine occurred in two stages. Initially, positive-pressure ventilation was used in the operating room



A



B

FIGURE 1-22 **A.** Eisenmenger's earlier version of his cuirass shell. A foot bellows allows positive and negative pressure to assist expiration and inspiration, respectively. This device is quite similar to chest shells still in use today. (Eisenmenger R. Apparatus for maintaining artificial respiration. *Lancet.* 1904;1:515.)

around the turn of the twentieth century. There was a clear and pressing need for positive-pressure ventilation to facilitate thoracic surgery. From the time of Galen, it was appreciated that opening the thorax invariably caused fatal pneumothorax. Vesalius had shown that positive-pressure ventilation could keep an animal's lungs inflated and the animal alive during these operations, but this lesson seems to have been forgotten. Consequently, lung surgery in the nineteenth century was limited to rare cases of draining lung abscesses and bronchiectatic or tuberculous cavities. Although pneumonectomy had been performed successfully in animals by 1881,[90,91] between 1880 and 1920 the mortality rate for thoracic surgery remained high, and these procedures were performed infrequently.[90,92] By 1896, Quénu and Longuet realized that to have success in thoracic operations, one had "to maintain a difference in pressure between the intra-alveolar air and the surrounding air." The surgeon could choose either to "lower the extra thoracic pressure, the intrapulmonary tension remaining the same, making it necessary…to operate in a relative vacuum, or to increase the intrabronchial pressure."[93] Only after positive-pressure ventilation had become a well-established technique during surgery was it applied to nonoperative patients, beginning in the 1950s.

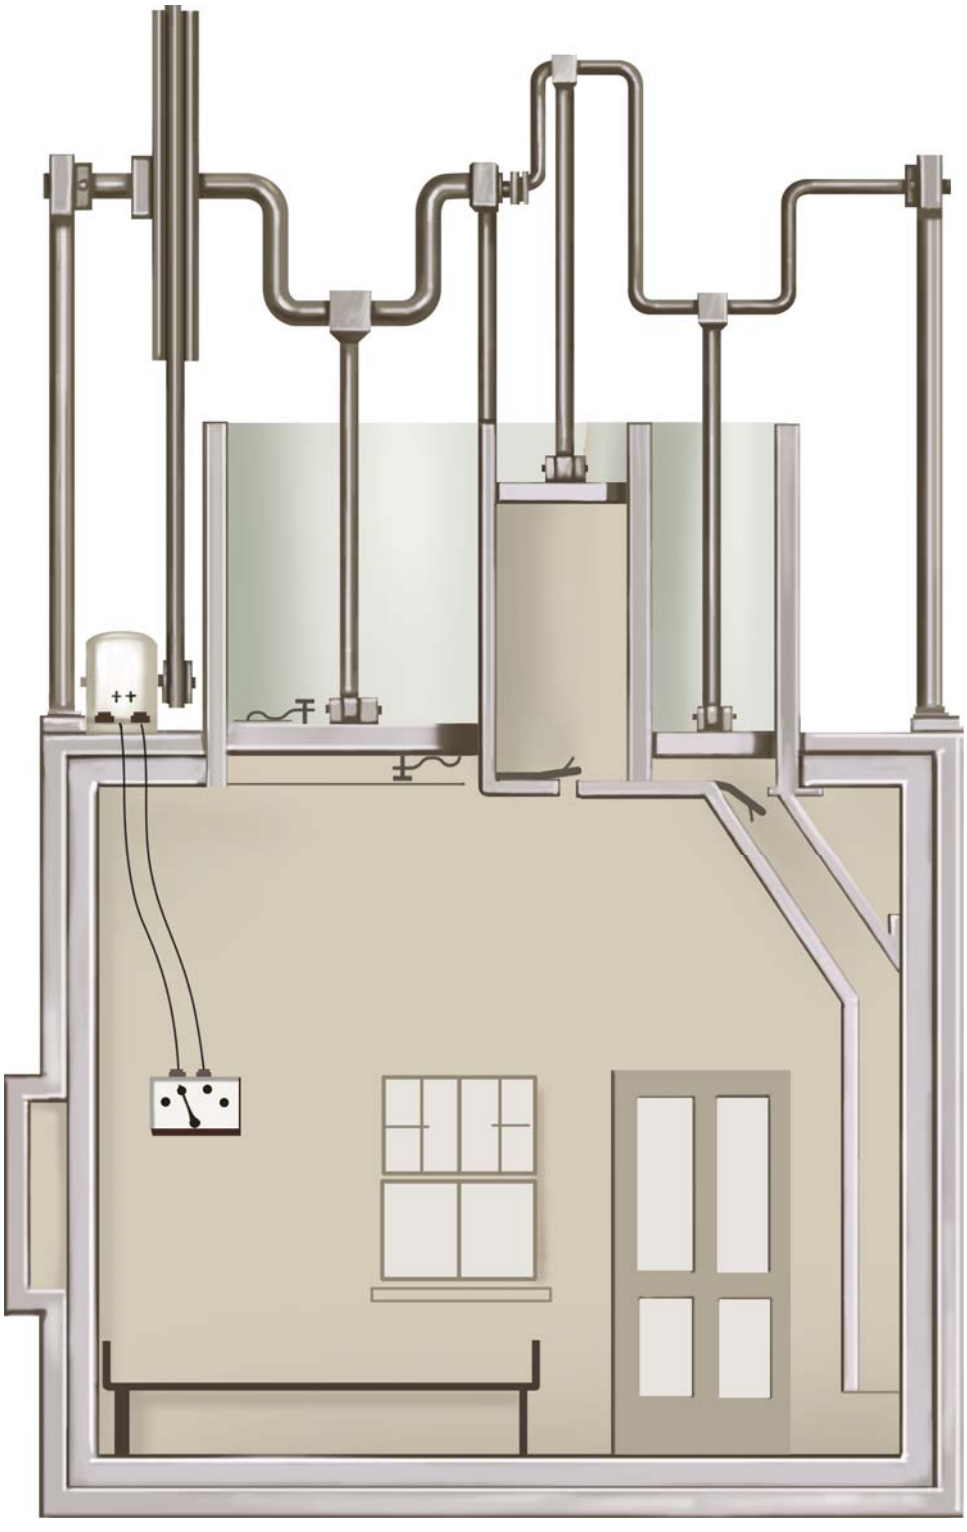


FIGURE 1-23 A negative-pressure respirator room, patented by Lord in 1908, provided optimal access to the patient for the nursing staff. (Used, with permission, from Emerson JH. *Evolution of Iron Lungs.* Cambridge, MA: JH Emerson; 1978:fig. 8.)

Tracheal Intubation

The obvious way to increase intrabronchial pressure would be to follow Vesalius's example by placing a tube in the trachea and inflating the lungs with a bellows. Positive-pressure ventilation had been well standardized in the physiology laboratory. Although techniques to cannulate the trachea had been developed in the late eighteenth century, translaryngeal intubation still was viewed skeptically by many physicians until the early 1900s.[94] Physicians only became reassured about the usefulness of translaryngeal intubation through work on controlling the airway. The most compelling reason for airway control always had been upper-airway obstruction. Tracheostomy historically was a well-known method of gaining access to the airway in such situations. Indirect references to this technique can be found in such ancient texts as the *Rig Veda*, written between 2000 and 1000 BC, and *Eber's Papyrus*, from about 1550 BC. Alexander the Great reputedly performed a tracheostomy with his sword in 400 BC on a soldier who was choking on a bone.[95] According to Frost[96] and McClelland,[97] Asclepiades of Bithynia was the first surgeon to perform tracheostomy routinely, around 100 BC. The Roman Antyllos also was noted for his skill in this procedure in 340 AD.[96] Although few surgeons were reported to have performed this procedure during the Dark Ages, Brasavola reintroduced the technique to the medical community in 1546. In 1833, Trousseau clearly demonstrated the lifesaving value of tracheostomy for managing upper-airway obstruction with his report on 200 of these operations for diphtheria.[96,97]

A small number of pioneering physicians experimented with techniques and devices to cannulate the trachea through either the nose or the mouth (translaryngeal intubation) in the late eighteenth century as a practical alternative to tracheostomy for managing upper-airway obstruction. Depaul, who succeeded Chaussier at the maternity hospital in Paris, successfully modified Chaussier's tubes for managing neonatal respiratory distress.[73] Bouchut used a silver truncated cone, "a little smaller than a thimble," to dilate the larynx in two children with diphtheria in1858.[98] Although transiently successful, Trousseau discouraged this approach and confirmed tracheotomy as the preferred approach. MacEwen of Glasgow used translaryngeal intubation to manage a small number of patients with upper

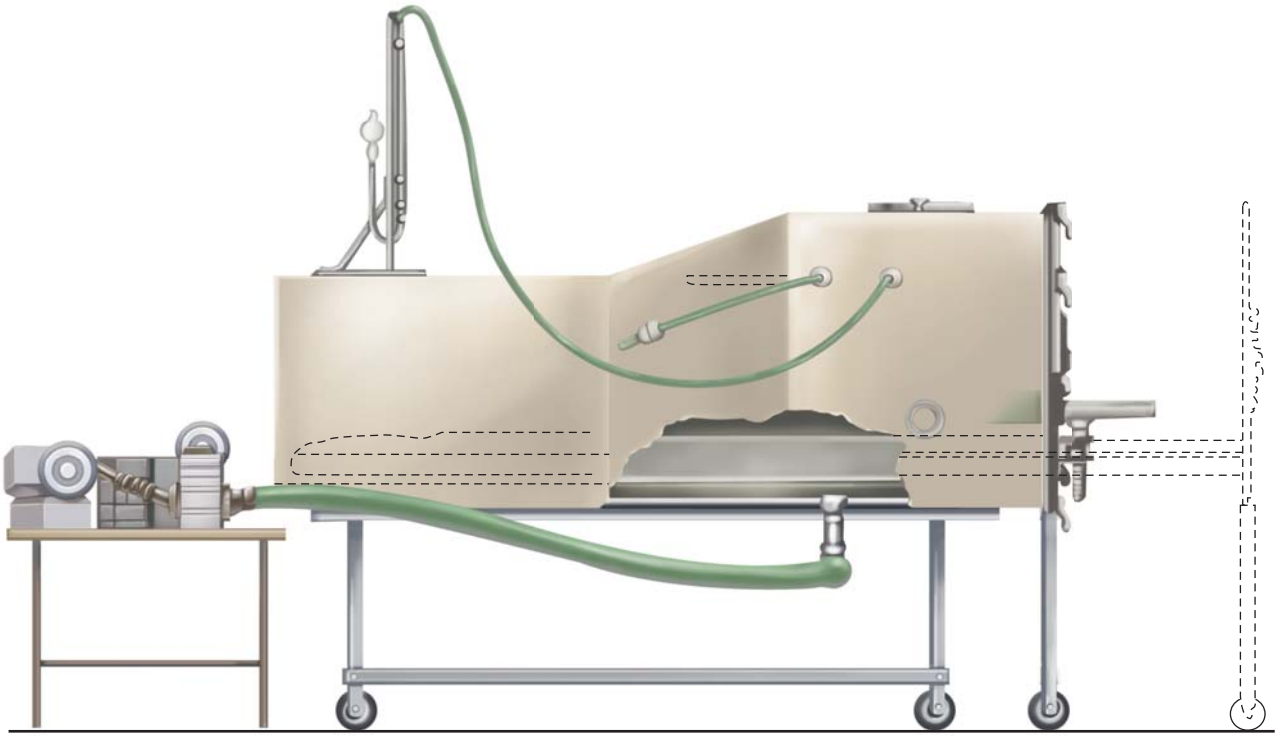

FIGURE 1-25 The Drinker-Shaw iron lung, developed in 1928, had a sliding bed and a close-fitting rubber collar for sealing the patient's neck. The patient's head protruded from the device at the right and rested on a flat support. (Used, with permission, from Emerson JH. *Evolution of Iron Lungs.* Cambridge, MA: JH Emerson; 1978:fig. 13.)

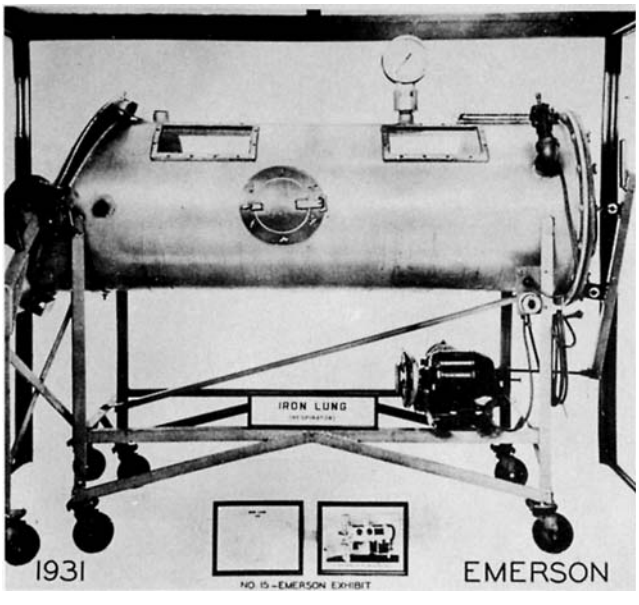

FIGURE 1-26 The Emerson tank respirator, built in 1931, used a bellows device to change pressure (hand pumps also were available in case of electricity failure), was less cumbersome and expensive than the Drinker-Shaw iron lung, and was easily opened and closed for nursing care. airway obstruction and probably diphtheria in 1880.[99] O'Dwyer of New York proved to be the most persistent advocate of intralaryngeal tubes for managing upper airway obstruction. He was appointed to the medical staff of a foundling home in 1872. At that time the leading cause of infant mortality was diphtheria of the larynx. Even with tracheotomy, the survival rates for this condition were abysmal. O'Dwyer worked from 1880 to 1885 on developing a device for intubating the larynx, but his initial experience with a bivalved device proved unsuccessful. Despite

initial skepticism by the medical community about this technique, O'Dwyer persevered and later developed a more successful, simple, open-tube approach.[100–102] O'Dwyer, through his efforts over years and experience in hundreds of patients, should be recognized as the first physician to effectively advocate the use of translaryngeal intubation for managing upper-airway obstruction.[98]

Tracheal Anesthesia

As clinicians began to appreciate the value of translaryngeal intubation for managing upper-airway obstruction, anesthetists slowly began to grasp how useful this technique might be for administering anesthesia in the operating room. Ether anesthesia had first been used during an operation by Morton in 1846.[103] Snow, in 1858, gave rabbits chloroform vapor through a tracheostomy tube.[104] Trendelenburg apparently adapted this method for use in patients during operations on the mouth and larynx. A practical problem limiting these operations at the time was aspiration of blood into the lungs during the procedure. Trendelenburg solved this problem by devising a cuffed tracheostomy tube for sealing the airway in 1869 (Fig. 1-29).[73] With this cuffed tracheostomy tube in place, inhalational anesthesia could only be given practically through the tube itself. MacEwen's original work on translaryngeal intubation for upper-airway obstruction included one case in which successful anesthesia given through the tube allowed surgical removal of a pharyngeal tumor.[98] Maydl of Prague and Eisenmenger of Vienna both described cases of upper-airway surgery in 1893 using endotracheal anesthesia.[105]

Tuffier and Hallion, in 1896, ventilated animal lungs through a translaryngeal tube to prevent collapse during surgery.[106] Doyen improved their techniques.[107] Fell was well aware of the use of forced respiration, using a bellows to administer positive-pressure ventilation through a tracheotomy tube, from animal experiments, but had never heard hint of this technique possibly being useful in humans. He realized, though, that forced respiration might be a practical method for managing patients with respiratory paralysis from opiate overdose.[108] Fell considered that "if the respirations could be kept up by suitable means for a sufficient time to permit the elimination of the poison, life might be saved. He reported use of this technique in both opiate and anesthetic drug overdose.[109] O'Dwyer modified Fell's device so that it could be attached to a translaryngeal tube, and soon the Fell-O'Dwyer apparatus for mechanical ventilation was marketed. Matas realized that if anesthesia

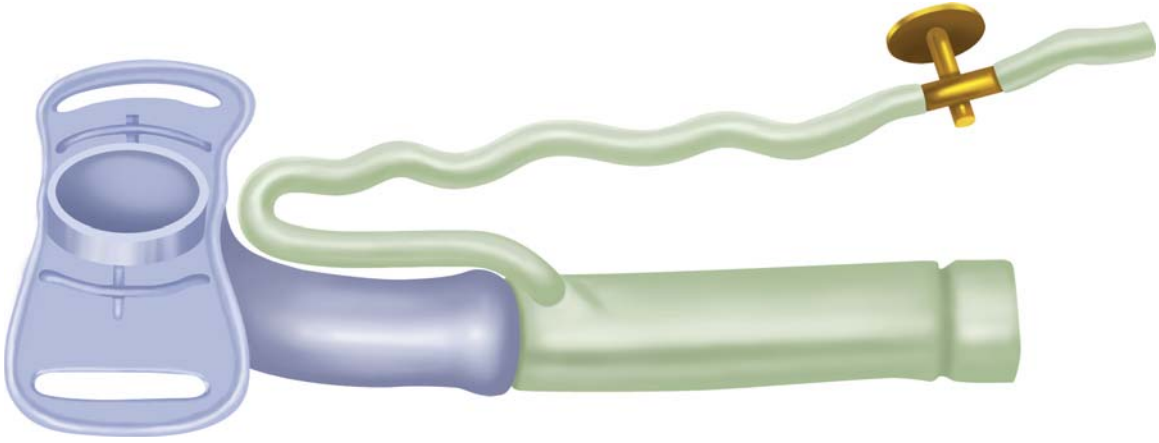

FIGURE 1-29 Trendelenburg first used this type of tracheostomy tube with inflatable cuff to prevent aspiration during operations on the mouth and larynx in 1869. could be administered readily through the apparatus, the Fell-O'Dwyer ventilator would be well suited for managing intrathoracic surgery. Matas modified this ventilator successfully and indicated that the new machine indeed was effective (Fig. 1-30).[107,110]

The interest in translaryngeal intubation for administering anesthesia and facilitating positive-pressure ventilation was stuttering at first. Kuhn apparently used this technique regularly and with great success. He experimented extensively with both the size and position of the tracheal tube, even using separate tubes for inhalation and exhalation.[111] In 1909, Meltzer and Auer modified this technique. Instead of using a tracheal tube that nearly approximated the diameter of the trachea and allowing the patients to inhale and exhale through that same tube, these physiologists used a narrow-bore tube. Air was blown into the lung through the tube and allowed to escape from the lung between the external wall of the tube and the trachea. This technique was referred to as *endotracheal insufflation.*[112] Ellsberg was the first to use endotracheal insufflation on a patient,[113] but others criticized the technique. Meyer disparagingly called Meltzer's insufflation method the "blowpipe apparatus." Meyer cited numerous concerns (e.g., risks of aspiration through the tube; incomplete control of airway pressure, especially when closing the chest; unreliable administration of anesthesia; and difficulties placing the tracheal tube correctly) and concluded that endotracheal insufflation was not suitable for thoracic surgery.[94]

Differential Pressure

Around 1904, Sauerbruch devised a working model of a cabinet that generated negative pressure around the lung. Sauerbruch built a small airtight operating room with the patient's body and the surgeon inside. The patient's head extended out of the room. By applying suction to this room, differential pressure was created across the pleural surface, atmospheric pressure within the bronchial tree, and negative pressure outside the lung (Fig. 1-31).[64] Meyer built a much larger version of a negative-pressure apparatus. The entire operating room was subjected to suction, and a small chamber was built within the operating room to enclose the patient's head and the anesthetist. This chamber either could be kept at atmospheric pressure or could subjected to positive pressure (Fig. 1-32).[114]

Surgeons also had the option of using devices that employed positive pressure without intubation to inflate

the lungs. Brauer is credited as devising the first positive-pressure cabinet in 1904. This apparatus was large enough for the patient's head to fit inside. Positive pressure in the cabinet would be transmitted to the lungs during the patient's respiratory efforts.[64,115–117] Modifications of the positive-pressure cabinet were put forth by Murphy,[115] Green,[116] and Green and Janeway (Fig. 1-33).[117] As an alternative to cabinets, other surgeons used face masks and helmets to supply positive-pressure ventilation (Fig. 1-34).[118–120]

Several factors favored the endotracheal insufflation method for both anesthesia and lung inflation during thoracic operations. The differential-pressure chambers were either large and cumbersome or small and confining, and all were expensive. A device for endotracheal insufflation, which was portable and easy to use, was built in 1910 by Elsberg for less than $100,[121] although more complex devices also were built (Fig. 1-35). The positive-pressure cabinets limited access to the patient's head during the procedure. Positive-pressure masks were not reliable in maintaining lung inflation. Techniques and devices for facilitating translaryngeal intubation were being developed quickly. Dorrance[122] described a simple endotracheal tube made of flexible rubber with an inflatable cuff at its distal end. Janeway developed the first modern laryngoscope, an invaluable aid for

translaryngeal intubation.[64] Jackson was instrumental in providing clear guidelines for performing translaryngeal intubation.[123] With these developments, endotracheal insufflation became firmly established, and new devices for anesthesia and ventilation by insufflation were developed quickly.[124,125] Many other devices for positive-pressure ventilation, including the "pulmotor" portable resuscitator, were devised in the early 1900s.[64]

Translaryngeal Intubation

By World War I, endotracheal intubation had become an invaluable method for enabling extensive plastic facial reconstructions. However, anesthetists began to express dissatisfaction with the insufflation technique for anesthesia and ventilation. Insufflation did not protect from aspiration, especially during upper-airway operations. In these procedures, pharyngeal packing to prevent aspiration required placement of two tubes, one for insufflation and the other for exhalation. Placement of two tubes was technically difficult. Anesthetists would much prefer to use a cuffed tracheal tube, which, of course, was not feasible with insufflation. Anesthetists were finding that nitrous oxide was a better anesthetic agent than chloroform or ether, but it was very expensive to administer by insufflation. Periodic deflations of the lung usually were required, with insufflation to ensure adequate carbon dioxide removal. As a consequence of these problems with insufflation, Magill and Rowbotham returned to Matas's old "inhalation" method. They used a tracheal tube large enough to allow both inhalation and exhalation. A balloon cuff could be attached to the outer distal end of the tube to prevent aspiration.[105,126,127] Rowbotham also was instrumental in popularizing nasotracheal intubation.[128] A number of cleverly designed machines were produced before World War II that could be used to administer anesthesia and artificial ventilation via positive-pressure rhythmic "insufflation"(ventilation) through these large-diameter tubes.[64,129,130] By 1934, Guedel and Treweek described apneic anesthesia, or purposely giving enough anesthesia to cause complete respiratory paralysis. Artificial respiration by rhythmic bag ventilation adequately supported the patient during apnea. This technique provided the "quiet" field necessary for abdominal and thoracic surgery.[131]

Further favoring the use of translaryngeal intubation was recognition of retained pulmonary secretions as a cause of postoperative morbidity and mortality. As pointed out by Jackson in 1911, "when tracheal and bronchial secretions are in excess of the amount required properly to moisten the inspired air, they become a menace to life unless removed."[132] Postoperative atelectasis, attributed to retention of thick bronchial secretions and inhibition of coughing, was first described in 1928.[133] Bronchoscopy and intratracheal suctioning were the earliest techniques advised for removing secretions,[132,134,135] but it became apparent that easy access to the tracheobronchial tree for repeated suctioning might be necessary in difficult cases. Tracheostomy was recommended as early as 1932 specifically for this problem in polio patients,[136,137] and later for patients with a variety of surgical problems.[138–141] Physicians soon realized that suctioning through a large tube placed translaryngeally might be just as effective as through a tracheotomy tube. In the 1940s, case reports began to appear describing the successful and prolonged use of translaryngeal intubation for tracheobronchial toilet.[142–144] Modification of tracheal tubes to include "Murphy eyes" at the tips probably has reduced the likelihood that these tubes would become occluded by mucus.[145]

For the Nonoperative Patient

The second stage of the reintroduction of positive-pressure ventilation into clinical practice involved nonoperative patients and occurred dramatically in the 1950s. There had been isolated reports of physicians using positive-pressure ventilation for purely mechanical problems before this time. Bert describes a positive-pressure chamber built by Jourdanet in the 1870s (Fig. 1-36) and used for a variety of mechanical problems.[15] Williams wrote of treating pulmonary disease with a pneumatic differentiation chamber in 1885. The patients were placed within a cabinet, and the air in this cabinet was exhausted by suction. Simultaneously, "antiseptic air charged with remedial agents" was administered to the patient's mouth. The reduced pressure around the thorax and atmospheric pressure applied to the lungs were thought to dilate the lungs beneficially. Remarkable improvements were described for a wide variety of lung disorders with this device.[146] Fell used a bellows ventilator to manage respiratory depression secondary to opiate overdose in the late 1880s.[108] A remarkable series of studies described the use of positive-pressure respiration for the treatment of pulmonary edema.[147–149] The emphasis of these studies was not to assist respiration—forced

FIGURE 1-36 Jourdanet used this positive-pressure chamber to treat patients with a wide variety of disorders in the 1870s. (Used, with permission, from Bert.[15])

FIGURE 1-37 Young patients with respiratory paralysis from polio being treated in an "iron lung." (Photograph by Hansel Mieth, courtesy Time Life Pictures, Getty Images, 1938.)

respiration by intubation was felt to be unjustifiable[147]—but to use positive pressure to counterbalance the backward pressure on the pulmonary capillaries.[149] The widespread use of positive-pressure ventilation did not begin, however, until its value was demonstrated dramatically during a polio epidemic in Copenhagen in 1952.

PARALYTIC POLIO

A series of polio epidemics had swept across Europe and the United States in the 1930s and 1940s. Respiratory paralysis secondary to poliomyelitis was an infrequent but feared complication. Even with the best management techniques using iron lungs and cuirass ventilators (Fig. 1-37), the mortality rate for polio-induced respiratory paralysis probably was approximately 85%.[64] In the late summer of 1952, an epidemic struck Copenhagen. Of the first thirty-one patients admitted to Blegdamshospital, Copenhagen's hospital for communicable diseases, during this epidemic with respiratory paralysis, twenty-seven died within 3 days. Out of desperation, Henry Lassen, the chief physician and epidemiologist, called the freelance anesthetist Bjorn Ibsen for consultative advice. After reviewing the medical records and autopsy results, Ibsen made two startling conclusions. First, he felt that in the fatal cases there was insufficient atelectasis within the lungs to make adequate ventilation impossible. Second, he suggested that the increased blood levels of total CO_2 did not reflect metabolic alkalosis, as was generally believed, but rather acute respiratory acidosis. Ibsen's observations about respiratory acidosis were derived directly from work he had performed measuring exhaled carbon dioxide levels in the operating theater. Ibsen, as the anesthetist, had noted that exhaled carbon dioxide levels fluctuated during the course of surgery and could be compensated by more vigorous bag ventilation. Most importantly, when exhaled carbon dioxide levels increased, the patients in the operating theater had developed clammy skin and high blood pressure, similar signs to those found in the paralytic polio patients just before death. Based on these observations, Ibsen suggested inadequate ventilation as the cause of death and advised tracheostomy to allow the operative techniques of positive-pressure ventilation.

Lassen was not convinced; the iron lung and cuirass respirators had reliably provided adequate ventilation in the past. Lassen argued that it was unlikely that positive-pressure ventilation would save paralytic polio patients if the underlying disease process actually included extensive brainstem involvement.[150]

As a counterargument, Ibsen cited recent experience in the United States with a positive-pressure valve capable of providing mechanical positive-pressure ventilation to polio patients. These valves were developed as a result of intense interest by the U.S. Air Force during World War II in using positive pressure to increase altitude tolerance in pilots.[151,152] The unique attribute of these valves, such as the pneumatic balance respirator (PBR), was their ability to convert a continuous positive pressure into intermittent positive pressure. Intermittent positive-pressure breathing was applied in the late 1940s to a variety of medical problems and found to be effective in providing artificial ventilation to an apneic person;[153–155] in managing acute pulmonary edema, acute asthma, and postoperative patients with poor respiratory excursion;[154] possibly in improving oxygenation in various lung diseases;[156] and in administering medications by nebulization[157]. The Bennett valve was adapted as a positive-pressure respirator attachment for the standard tank respirator during the 1948 Los Angeles poliomyelitis epidemic (Fig, 1-38). The PBR supplied intermittent positive-pressure breaths in synchrony with the tank respirator's inspiratory negative-pressure phase.[158] Use of the PBR along with the tank respirator significantly reduced the case-fatality rate of respiratory paralysis associated with polio.[159]

Lassen eventually agreed to a trial of Ibsen's theory. The thirty-second patient with respiratory paralysis admitted to Blegdamshospital was the poignant case of a 12-year-old girl. When her condition deteriorated, Ibsen asked a surgeon to perform a tracheostomy, and a cuffed tracheal tube was introduced. During the procedure, the girl became comatose. Ibsen initially was unable to ventilate her effectively. He assumed that retained secretions were the problem, and he suctioned her. Her condition deteriorated further, and many physicians observing the trial began to leave, assuming that the outcome would be fatal. In this desperate situation, Ibsen decided to paralyze the girl. She collapsed immediately, and Ibsen finally was able to ventilate her adequately.

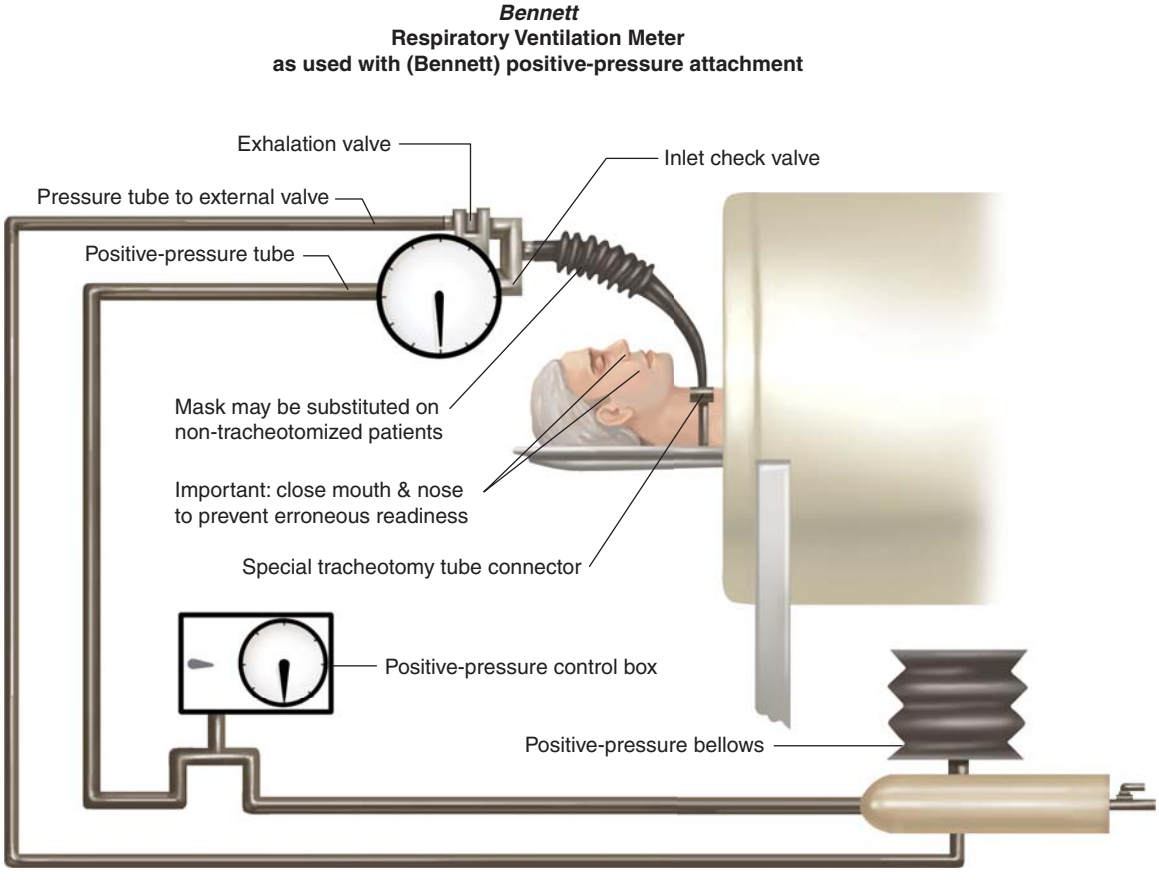

FIGURE 1-38 A schematic of the Bennett positive-pressure valve used via a tracheostomy tube in a patient in an iron lung. (Used, with permission, from Bower AG, Bennett VR, Dillon JB, Axelrod B. Investigation on the care and treatment of poliomyelitis patients. *Ann West Med Surg.* 1950;4:567.)

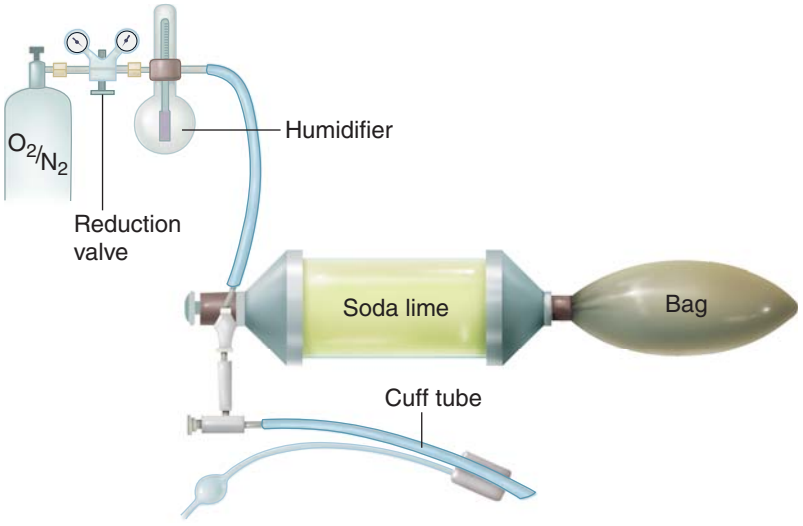

FIGURE 1-39 This hand ventilator was used in the Copenhagen polio epidemic of 1952 by hundreds of "ventilators" (i.e., medical students, technicians, volunteers, and others) to save many lives. (Lassen HCA. A preliminary report on the 1952 epidemic of poliomyelitis in Copenhagen with special reference to the treatment of acute respiratory insufficiency. *Lancet.* 1953;1:37–41.)

Her condition improved immediately.[150] Eventually, arterial blood-gas levels confirmed Ibsen's suspicions about respiratory acidosis as the cause of death in the previous patients, and positive-pressure ventilation proved successful in substantially reducing the mortality rates from paralytic polio. The only drawback was the equipment available (Fig. 1-39). Only bag ventilation was possible. During the remainder of the epidemic, it is estimated that 1500 medical and dental students worked around the clock providing bag ventilation by hand to help support these patients.[160,161]

The Copenhagen experience provided the impetus for a revolution in the medical care of patients with respiratory failure. First, it confirmed the value of positive-pressure ventilation and demonstrated the need for practical mechanical ventilators. Second, by encouraging the grouping of acutely ill patients in certain sections of the hospital and the organization of intensive care for these patients, it led the way for the later development of intensive-care units.[160,161] Third, Ibsen realized that provisions had to be made for resuscitating acutely ill patients in small outlying towns and transporting them to specialized centers.[162] Accordingly, mobile teams were formed with expertise in performing translaryngeal intubation and tracheotomy. After intubation and stabilization, patients could be transferred secondarily. This was obviously the precursor of our present emergency medical system.

OTHER DISEASES WITH INADEQUATE VENTILATION

Although the results using positive-pressure ventilation for the respiratory paralytic form of polio were remarkable, application of this technique to other medical problems was slow. Extensive work in pulmonary emphysema and chronic bronchitis had confirmed that in severe cases ventilatory failure was accompanied by high carbon dioxide levels and low oxygen levels. Supplemental oxygen alone seemed to worsen the situation.[163] Sporadic reports described the use of mechanical ventilation for treating this problem. Usually used were body respirators,[163–167] but occasionally either intermittent positive-pressure breathing via a pneumatic balance respirator[164] or hand ventilation[166,167] was used transiently. By 1961, Munck had collected a total of forty-two case reports describing some form of mechanical ventilation for exacerbations of chronic obstructive pulmonary disease (COPD) with successful outcomes in thirty-one.[168] Munck's group was the first to rely strictly on positive-pressure ventilation through a tracheotomy tube to treat patients with COPD in acute respiratory crises. Their methods emphasized reliance on monitoring arterial blood oxygen, carbon dioxide, and pH levels. The average duration of treatment in their series was 24 days. They emphasized that mechanical ventilation provides a fair chance of "tiding patients with diffuse chronic lung disease over an episode of life-threatening respiratory failure—and of obtaining a reasonable recovery," provided there is some historical evidence of pulmonary reserve.[168]

Many other groups throughout the 1960s and early 1970s found that positive-pressure ventilation through either a translaryngeal tube or tracheostomy was an effective method of managing acute exacerbations of COPD.[169–178] Conservative treatment, including the use of controlled levels of supplemental oxygen, antibiotics, bronchodilators, and respiratory stimulants, was useful for treating some patients with acute ventilatory failure complicating chronic lung disease,[179,180] but it was soon recognized that in severe cases with either coma or deteriorating arterial blood-gas values,

endotracheal intubation and mechanical ventilation provided the most appropriate alternative.[181]

In 1951, Nilsson recognized the value of translaryngeal intubation for controlling the airway in patients with barbiturate poisoning.[182] He later emphasized that artificial respiration via a mechanical ventilator is essential when barbiturate poisoning causes apnea or respiratory insufficiency.[183] Avoiding the potentially stigmatizing tracheotomy scar also was an important consideration in patients prone to depression. Bjork pioneered the use of positive-pressure respirator treatment in postoperative thoracic surgery patients. Initially, he was conservative in his approach and postponed tracheotomy until the patient was in severe respiratory failure. By the late 1950s, however, he was performing elective tracheotomy after pulmonary resections and cardiovascular surgery and providing "prophylactic" positive-pressure ventilation to prevent atelectasis and to minimize "heavy respiratory work." He believed that any patient with a small cardiopulmonary reserve, who could become exhausted rapidly following major surgery, would benefit from this approach.[184–187] As these principles were established in thoracic surgery, they were also applied to patients with, for example, crush injury of the chest, pulmonary edema, renal failure, tetanus, pneumonia, or peritonitis. The best results were obtained when respirator treatment was initiated early in the acute illness and not when chances for recovery were nil.[188]

Modern Respirators

Providing mechanical ventilation on a widespread basis could only be achieved with reliable respirators. Morch built the first clinically proven volume ventilator during World War II in Denmark for use in the operating room. Because of the war, pistons and cylinders for this ventilator were made from discarded sewer pipes.[64] As a direct result of the 1952 polio epidemic in Denmark, Bang constructed a mechanical respirator. Manual ventilation of patients with respiratory paralysis was possible in Copenhagen because of the availability of medical students. In Skive, where Bang practiced, medical students were not available, and Bang's respirator was a practical necessity. Fortunately, it worked.[189,190] The Engstrom respirator, built for the same reasons, proved to be hugely successful for managing poliomyelitis patients.[191] This volume-cycled respirator also was used by Bjork in his outstanding work in postoperative respiratory care. By 1954, a number of modern automatic respirators had been developed in Europe.[192] Morch was instrumental in bringing the concept of positive-pressure ventilation across the Atlantic to America.[64,193] The incorporation of this technique into standard medical practice apparently was slower in the United States than in Scandinavia.[64] Tank respirators still were used routinely in the United States until the 1960s,[194,195] although the benefits of endotracheal intubation and positive-pressure ventilation were slowly being appreciated.[194,196] Since the 1950s, an enormous number of practical ventilators have been introduced for everyday use. This was paralleled by a significant increase in the number of patients receiving mechanical ventilation in American hospitals throughout the 1960s. Pontoppidan found a fivefold increase in artificial respiration cases at the Massachusetts General Hospital between 1960 and 1968.[197]

Intensive Care

Organizing the "intensive care" that patients with ventilatory failure required was a substantial logistical problem. The Danes had congregated respiratory patients in special units. By the middle to late 1960s, widespread experience had accumulated with intensive care units specifically designed for managing patients requiring sophisticated respiratory care and mechanical ventilation.[198–202] By the 1970s, several centers reported impressive reductions in mortality rate through reliance on the intensive care unit approach.[203–205]

Adequacy of Ventilation

Until arterial blood-gas machines became available commercially, physicians had to rely on laborious and exacting methods of measuring blood oxygen and carbon dioxide levels. Astrup and others emphasized that measuring Pa_{O_2}, Pa_{CO_2}, and pH should be the ultimate goal for determining how well the respirator actually was ventilating the patient.[206,207] By 1957, it was realized that intermittent positive-pressure breathing was not always effective in reducing hypercapnia in emphysema. In fact, the more severe the obstructive lung disease, the less effective pressure-cycled respirators seemed to be in producing hyperventilation.[208] Conversely, pressure-cycled respirators easily could overventilate a patient and convert a dangerous acidosis into an equally dangerous alkalosis.[209] The issue of pulmonary encephalopathy secondary to hypercapnia was of serious concern to physicians,[210] as was the realization that mechanical ventilation could be followed by paradoxical central nervous system acidosis.[211,212]

Supplemental oxygen had been used to treat numerous medical ailments since Priestley and Scheele had identified "pure air" in the 1770s. By the beginning of the twentieth century, the physiologic benefits of oxygen therapy were better understood, and physicians became more interested in using oxygen specifically to treat respiratory disorders. The intravenous injection of oxygen was advocated by Tunnicliffe and Stebbing in 1916,[213] but attracted little interest. Haldane devised an apparatus for supplying controlled amounts of oxygen[214] that was used on soldiers exposed to suffocating gases during World War I. Because patients with pneumonia had low blood-oxygen levels, Meakins used the Haldane apparatus to treat hypoxic patients with pneumonia.[215] Stadie constructed and used

an oxygen chamber for treating pneumonia in 1922.[216,217] Barach administered oxygen through tents, nasal catheters, and mouth funnels in 1926.[218] Physicians believed that oxygen was useful in reducing the mortality rate in pneumonia but did not understand why it was effective.[219,220] The belief that oxygen treatment was beneficial unfortunately led to its indiscriminant use. It was not appreciated that supplemental oxygen given to a patient with COPD who had an acute ventilatory crisis with hypercapnia could result in paradoxic hypoventilation and worsened respiratory acidosis. Campbell played a leading role in recognizing this problem and devising a device, the venturi mask, for administering oxygen in a controlled fashion with a reduced risk of carbon dioxide retention.[221–223]

Just as oxygen use generally was believed to be beneficial for treating respiratory disorders, the use of oxygen was incorporated routinely into many early mechanical ventilators. This approach was justified in some cases because oxygen requirements to achieve adequate arterial oxygenation often were surprisingly high.[224] Mean inspired oxygen levels in the early respirators, however, could not be regulated accurately. Substantial and occasionally dangerous variations in inspired oxygen levels were found when ventilators were compared directly.[225–227] Nash and coworkers pointed out the potential gravity of this problem when they linked, for the first time in humans, diffuse alveolar damage (or the *respirator lung syndrome*) with the prolonged use of ventilators delivering a high inspired oxygen concentration.[228]

As an interesting aside, Frumin and coworkers found that insertion of an expiratory resistance increased arterial oxygen levels in anesthetized, paralyzed, artificially ventilated humans.[229] Manipulation of airway pressure by immersion of the exhalation limb from a tracheotomy tube 1 to 4 cm under water had been shown previously to improve ventilation in patients with multiple rib fractures.[230] These simple measures for increasing airway pressure, termed variously the *positive expiratory pressure plateau,*[231] *continuous positive airway pressure,*[232,233] and later, *positive end-expiratory pressure,* were to prove enormously successful in improving oxygenation in patients with both adult and infant respiratory distress syndromes.

Quality Control of Ventilators

As the need for ventilators, gas cylinders, connectors, oxygen-delivery masks, and myriad other types of respiratory equipment increased, the number of manufacturers producing this equipment proliferated. Quality control among manufacturers varied and manufacturers produced equipment of various size specifications, making integration of breathing circuits difficult. Anesthesiologists were particularly concerned with these problems because of the difficulties they had encountered in establishing universal color codes for anesthetic gas cylinders during World War II. Carbon dioxide cylinders in Britain were painted green, but U.S. oxygen cylinders also were painted green. Inevitably, when U.S. and British anesthesiologists worked together, cylinders were filled with the wrong gas and deaths occurred.[234–236]

The American Society for Anesthetists (ASA) organized a Committee on Standardization of Anesthetic and Resuscitating Equipment, charged with forging a consensus on manufacturing standards for this type of equipment. The ASA, in 1955, approved financial support for the American National Standards Committee Z79 on Anesthesia and Respiratory Equipment to operate under the umbrella of American National Standards Institute (ANSI). Members of this committee included representatives of various medical specialties and principal manufacturers of anesthesia and respiratory equipment. Committee Z79 effectively developed standards for a wide range of respiratory equipment. Under the Medical Device Amendments of 1976, the Food and Drug Administration (FDA) was charged with regulatory responsibility for the safety and efficacy of medical devices. The FDA had a significant impact on refining the standards established by Committee Z79. In 1983, the relationship between ANSI and Committee Z79 was terminated for financial and liability reasons. At that time, the ASA agreed to transfer this committee's sponsorship to the American Society for Testing Materials (ASTM). The committee's name was then changed to F29.[236]

Numerous problems are encountered with positive-pressure ventilation. Concern about accidental disconnections from the ventilator led to alarm systems being developed. Adequate humidification of the ventilator air supply had to be ensured.[192] The risk of nosocomial pneumonia was not understood initially. Vigilant attention to sterilization of respiratory equipment, proper suctioning technique, and minimization of stagnant water in tubing and humidification sources was advised to reduce the risk of "ventilator lung."[198] There was considerable debate for decades over whether translaryngeal intubation was preferred over tracheotomy for patients requiring prolonged mechanical ventilation. Although this subject is still controversial, a consensus conference in 1986 recommended translaryngeal intubation as the preferred initial choice for obtaining airway control in most patients needing artificial respiration. Secondary tracheotomy could be deferred for up to 20 days or longer depending on the individual situation.[237]

Weaning

An intriguing problem developed as the use of positive-pressure ventilation became more widespread. Once patients were placed on a mechanical ventilator, how were they to be "weaned" eventually from such respiratory support? This question actually had two components: How could the physician determine when a patient was ready to be weaned? What methods could be used to facilitate the weaning process? Numerous criteria have been advocated as reasonable indicators that patients are weaning

candidates.[238–240] Similarly, numerous techniques have been proposed as useful modalities for maximizing the chances for a successful weaning process. Modifications of ventilator technology in the 1970s led to the proposal of such methods as intermittent mandatory ventilation[241,242] and mandatory minute volume[243] as alternatives to the standard T-piece method of weaning.[244–246] Although many physicians express strong preferences for one weaning modality over another,[247] it has never been shown clearly that modalities such as intermittent mandatory ventilation hasten the weaning process.[248,249] Whether more recently introduced technological advances in ventilator techniques, such as pressure-support and pressure-control ventilation, will improve the weaning process is unclear.

CONCLUSION

A rich and complex weave of discoveries in many different scientific and technical areas has brought us to the early 1990s, a time during which physicians have been trained to rely routinely on mechanical ventilation for managing all manner of acute, serious illnesses. Only 40 years ago, cadres of medical and dental students manually ventilated polio patients with respiratory paralysis, and at the turn of the twentieth century, a foot-operated bellows for mechanical ventilation was a remarkable innovation. In the late eighteenth century, the concept of using a bellows and translaryngeal tube for resuscitating the apparently drowned was just being introduced, and in the sixteenth century, Vesalius was forced to make a pilgrimage to the Holy Land to atone for the sin of restarting a Spanish nobleman's heart by inflating his lungs. The debt we owe to the many pioneers who have contributed to the advances in the field of mechanical ventilation is humbling, just as the hope for future unforeseeable developments in this field is enthralling.

PHYSICAL BASIS OF MECHANICAL VENTILATION

This page intentionally left blank

2

CLASSIFICATION OF MECHANICAL VENTILATORS AND MODES OF VENTILATION

Robert L. Chatburn

A good ventilator classification scheme describes how ventilators work in general terms, but with enough detail so that one particular model can be distinguished from others. It facilitates description by focusing on key attributes in a logical and consistent manner. A clear description allows us to quickly assess new facts in relation to our previous knowledge. Learning the operation of a new ventilator or describing it to others then becomes much easier. Understanding how the ventilator operates, we can then anticipate appropriate ventilator management strategies for particular clinical situations. The classification system described in this chapter is based on previously published work.[1–7]

A ventilator is simply a machine, a system of related elements designed to alter, transmit, and direct energy in a predetermined manner to perform useful work. We put energy into the ventilator in the form of electricity (energy = volts × amps × time) or compressed gas (energy = pressure × volume). That energy is transmitted or transformed (by the ventilator's drive mechanism) in a predetermined manner (by the control circuit) to augment or replace the patient's muscles in performing the work of breathing. Thus to understand mechanical ventilators in general, we must first understand their basic functions: (a) power input, (b) power transmission or conversion, (c) control scheme, and (d) output. This simple format can be expanded to add as much detail as desired (Table 2-1).

A discussion of input power sources and power conversion and transmission is beyond the scope of this chapter; these topics have been treated elsewhere.[7,8] The chapter does, however, explore in detail control schemes and ventilator modes because these directly affect patient management.

CONTROL SYSTEM

Models of Patient–Ventilator Interaction

To understand how a machine can be controlled to replace or supplement the natural function of breathing, we need to first understand something about the mechanics of breathing itself. The study of mechanics deals with forces, displacements, and the rate of change of displacement. In physiology, force is measured as pressure (pressure = force/area), displacement as volume (volume = area × displacement), and the relevant rate of change as flow [average flow = Δvolume/Δtime; instantaneous flow ($\dot{V}$) = dv/dt, the derivative of volume with respect to time]. Specifically, we are interested in the *pressure* necessary to cause a *flow* of gas to enter the airway and increase the *volume* of the lungs.

The study of respiratory mechanics is essentially the search for simple but useful models of respiratory system mechanical behavior. Figure 2-1 illustrates the process by which the respiratory system is represented first by a graphical model, and then by a mathematical model based on the graphical model. Pressure, volume, and flow are measurable

TABLE 2-1: OUTLINE OF VENTILATOR CLASSIFICATION SYSTEM

I. Input
  A. Pneumatic
  B. Electri
    1. AC
    2. DC (battery)

II. Power conversion and transmission
  A. External compressor
  B. Internal compressor
  C. Output control valves

III. Control scheme
  A. Control circuit
    1. Mechanical
    2. Pneumatic
    3. Fluidic
    4. Electric
    5. Electronic
  B. Control variables
    1. Pressure
    2. Volume
    3. Time
  C. Phase variables
    1. Trigger
    2. Target
    3. Cycle
    4. Baseline
  D. Modes of ventilation
    1. Control variable
    2. Breath sequence
    3. Targeting schemes

IV. Output
  A. Pressure waveforms
    1. Rectangular
    2. Exponential
    3. Sinusoidal
    4. Oscillating
  B. Volume waveforms
    1. Ascending ramp
    2. Sinusoidal
  C. Flow waveforms
    1. Rectangular
    2. Ascending ramp
    3. Descending ramp
    4. Sinusoidal

V. Alarms
  A. Input power alarms
    1. Loss of electric power
    2. Loss of pneumatic power
  B. Control circuit alarms
    1. General systems failure
    2. Incompatible ventilator settings
    3. Warnings (e.g., inverse inspiratory-to-expiratory timing ratio)
  C. Output alarms (high/low conditions)
    1. Pressure
    2. Volume
    3. Flow
    4. Time
      a. Frequency
      b. Inspiratory time
      c. Expiratory time
    5. Inspired gas
      a. Temperature
      b. FI_{O_2}

variables in the mathematical model that change with time over the course of one inspiration and expiration. The relation among them is described by the *equation of motion for the respiratory system.*[9] The derivation of this equation stems from a force-balance equation that is an expression of Newton's third law of motion (for every action, there is an equal and opposite reaction):

$$P_{TR} = P_E + P_R \quad (1)$$

where P_{TR} is the transrespiratory pressure (i.e., pressure at the airway opening minus pressure at the body surface), P_E is the pressure caused by elastic recoil (elastic load), and P_R is the pressure caused by flow resistance (resistive load).

Transrespiratory pressure can have two components, one generated by the ventilator (P_{vent}) and one generated by the respiratory muscles (P_{mus}). Elastic recoil pressure is the product of elastance (E = Δpressure/Δvolume) and volume. Resistive pressure is the product of resistance (R = Δpressure/Δflow) and flow. Thus, Eq. (1) can be expanded to yield the following equation for inspiration:

$$P_{vent} + P_{mus} = EV + R\dot{V} \quad (2)$$

The combined ventilator and muscle pressure causes volume and flow to be delivered to the patient. (Of course, muscle pressure may subtract rather than add to ventilator pressure in the case of patient–ventilator dyssynchrony, in which case both volume and flow delivery are reduced.) Pressure, volume, and flow are functions of time and are called *variables.* They are all measured relative to their values at end-expiration. Elastance and resistance are assumed to remain constant and are called *parameters.*

For passive expiration, both ventilator and muscle pressure are absent, so Eq. (2) becomes

$$-R\dot{V} = EV \quad (3)$$

The negative sign on the left side of the equation indicates flow in the expiratory direction. This equation also shows that passive expiratory flow is generated by the energy stored in the elastic compartment (i.e., lungs and chest wall) during inspiration.

Equation (2) shows that if the patient's respiratory muscles are not functioning, muscle pressure is zero, and the ventilator must generate all the pressure for inspiration. On the other hand, a ventilator is not needed for normal spontaneous breathing (i.e., vent pressure = 0). Between those two extremes, an infinite number of combinations of muscle pressure (i.e., patient effort) and ventilator pressure are possible under the general heading of "partial ventilator support." The equation of motion also gives the basis for defining an *assisted* breath as one for which ventilator pressure rises above baseline during inspiration or falls below baseline during expiration.

Control Variables

In the equation of motion, the mathematical form of any of the three variables (i.e., pressure, volume, or flow as functions of time) can be predetermined, making it the independent variable and making the other two the dependent variables. We now have a theoretical basis for classifying ventilators as pressure, volume, or flow controllers. Thus, during pressure-controlled ventilation, pressure is the independent variable and may take the form of, say, a step function (i.e., a rectangular pressure waveform). The shapes of the volume and flow waveforms for a passive respiratory system (P_{mus} = 0) then depends on the shape of the pressure waveform as well as the parameters of resistance and compliance. On the other hand, during volume-controlled ventilation, we can specify the shape of the volume waveform making flow-dependent and pressure-dependent variables. The same reasoning applies to a flow controller. Notable exceptions are interpulmonary percussive ventilation, and high-frequency

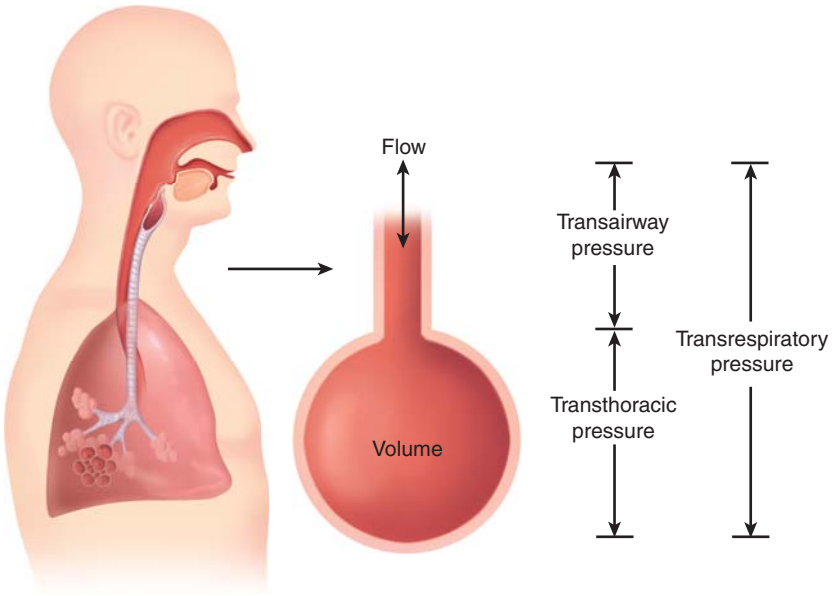

FIGURE 2-1 The respiratory system is often modeled as a single flow resistance (representing the endotracheal tube and the airways) connected to an elastic chamber (representing the lungs and chest wall). Flow through the airways is generated by transairway pressure (pressure at the airway opening minus pressure in the lungs). Expansion of the elastic chamber is generated by transthoracic pressure (pressure in the lungs minus pressure on the body surface). Transrespiratory pressure (pressure at the airway opening minus pressure on the body surface) is the sum of these two pressures and is the total pressure required to generate inspiration. The "airway-pressure" gauge on a positive-pressure ventilator displays transrespiratory pressure.

oscillatory ventilation, both of which control only the duration of flow pulses; the resulting airway pressure pulses along with actual inspiratory flows and volumes depend on the instantaneous values of respiratory system impedance. Because neither pressure, volume, nor flow in the equation of motion are predetermined, we would classify this type of device as a "time controller."

It follows from the preceding discussion that any conceivable ventilator can control only one variable at a time: pressure, volume, or flow. Because volume and flow are inverse functions of one another, we can simplify our discussion and consider only pressure and volume as *control variables*. I discuss later in "Modes of Ventilation" exactly how ventilator control systems work. We will see that it is possible for a ventilator to switch quickly from one control variable to another, not only from breath to breath, but even during a single inspiration.

Phase Variables

Because breathing is a periodic event, the ventilator must be able to control a number of variables during the respiratory cycle (i.e., the time from the beginning of one breath to the beginning of the next). Mushin et al[10] proposed that this time span be divided into four phases: the change from expiration to inspiration, inspiration, the change from inspiration to expiration, and expiration. This convention is useful for examining how a ventilator starts, sustains, and stops an inspiration and what it does between inspirations. A particular variable is measured and used to start, sustain, and end each phase. In this context, pressure, volume, flow, and time are referred to as *phase variables*.[11] Figure 2-2 shows the criteria for determining phase variables.

Trigger Variable

All ventilators measure one or more variables associated with the equation of motion (i.e., pressure, volume, flow, or time). Inspiration is started when one of these variables reaches a preset value. Thus, the variable of interest is considered an initiating, or *trigger*, variable. Time is a trigger variable when the ventilator starts a breath according to a set frequency independent of the patient's spontaneous efforts. Pressure is the trigger variable when the ventilator senses a drop in baseline pressure caused by the patient's inspiratory effort and begins a breath independent of the set frequency. Flow or volume are the trigger variables when the ventilator senses the patient's inspiratory effort in the form of either flow of volume into the lungs.

Flow triggering reduces the work the patient must perform to start inspiration.[12] This is so because work is proportional to the volume the patient inspires times the change in baseline pressure necessary to trigger. Pressure triggering requires some pressure change and hence an irreducible amount of work to trigger. With flow or volume triggering, however, baseline pressure need not change, and theoretically, the patient need do no work on the ventilator to trigger.

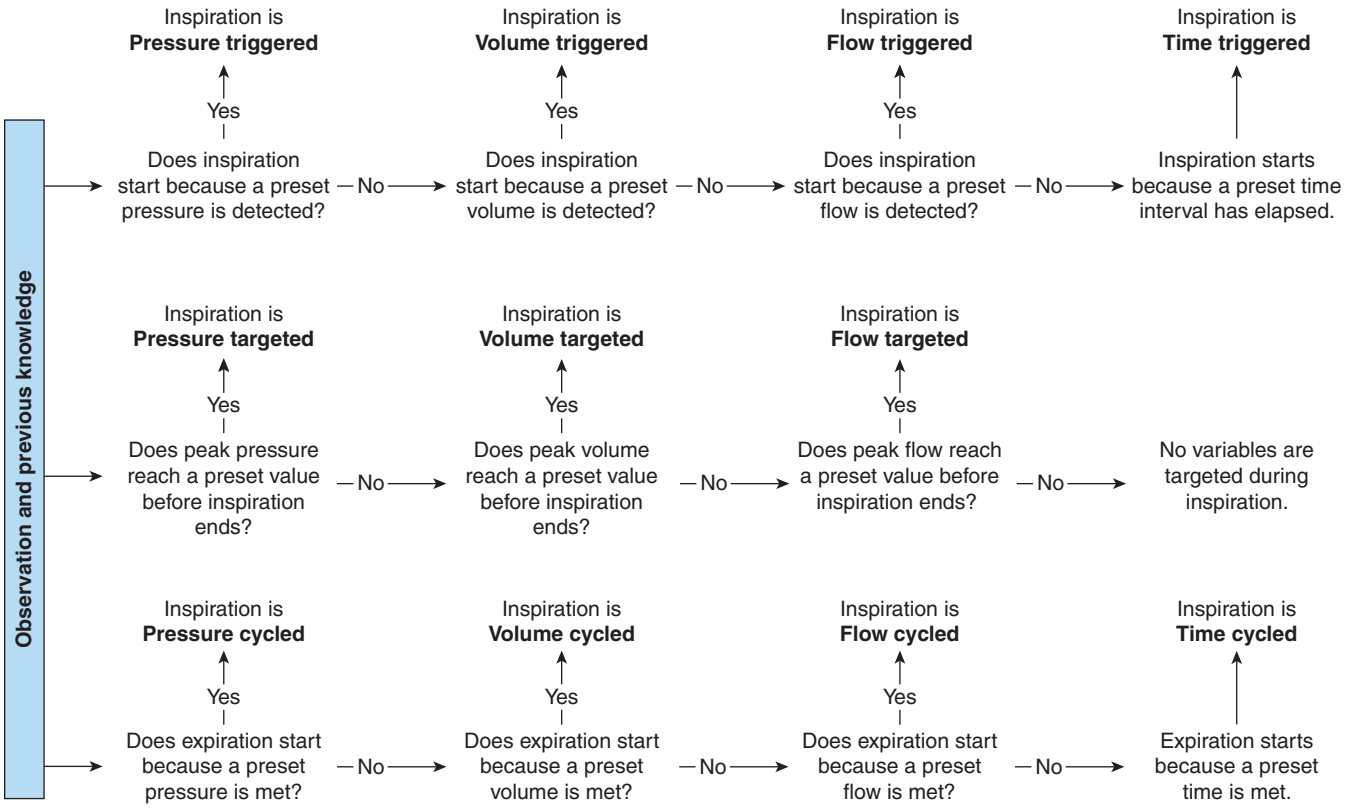

FIGURE 2-2 Criteria for determining the phase variables during a ventilator-assisted breath.

The patient effort required to trigger inspiration is determined by the ventilator's *sensitivity* setting. Some ventilators indicate sensitivity qualitatively ("min" or "max"). Alternatively, a ventilator may specify a trigger threshold quantitatively (e.g., 5 cm H_2O below baseline). Once the trigger variable signals the start of inspiration, there is always a short delay before flow to the patient starts. This delay is called the *response time* and is secondary to the signal-processing time and the mechanical inertia of the drive mechanisms. It is important for the ventilator to have a short response time to maintain optimal synchrony with patient inspiratory effort.

Target Variable

Here *target* means restricting the magnitude of a variable during inspiration. A *target variable* is one that can reach and maintain a preset level *before* inspiration ends (i.e., it does not end inspiration). Pressure, flow, or volume can be target variables and actually all can be active for a single breath (e.g., using the P_{max} feature on a Dräger ventilator). Note that time cannot be a target variable because specifying an inspiratory time would cause inspiration to end, violating the preceding definition. Astute readers may notice that in the past I have used the term *limit* where here I have used *target.* This was done to be consistent with the International Standards Organization's use of the term *limit* as applying to alarm situations only.

Clinicians often confuse target variables with cycle variables. To *cycle* means "to end inspiration." A cycle variable always ends inspiration. A target variable does not terminate inspiration; it only sets an upper bound for pressure, volume, or flow (Fig. 2-3).

Cycle Variable

The inspiratory phase always ends when some variable reaches a preset value. The variable that is measured and used to end inspiration is called the *cycle variable.* The cycle variable can be pressure, volume, flow, or time. Manual cycling is also available on some ventilators.

When a ventilator is set to pressure cycle, it delivers flow until a preset pressure is reached, at which time inspiratory flow stops and expiratory flow begins. The most common application of pressure cycling on mechanical ventilators is for alarm settings.

When a ventilator is set to volume cycle, it delivers flow until a preset volume has passed through the control valve. By definition, as soon as the set volume is met, inspiratory flow stops and expiratory flow begins. If expiration does not begin immediately after inspiratory flow stops, then an inspiratory hold has been set, and the ventilator is, by definition,

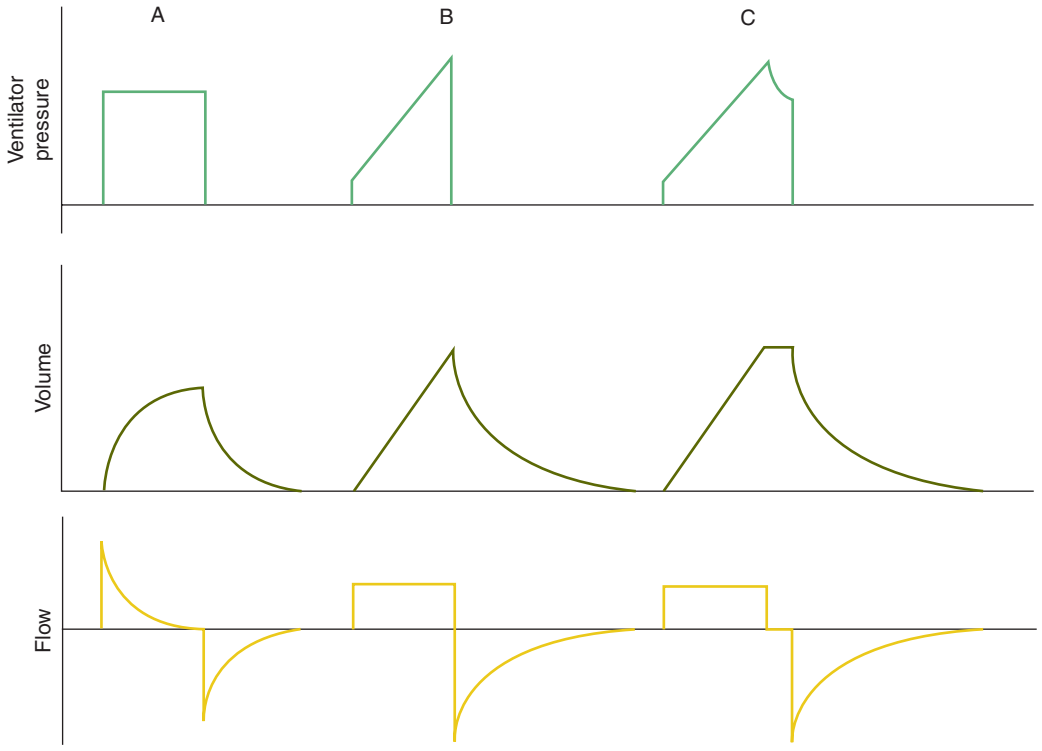

FIGURE 2-3 This figure illustrates the distinction between the terms *target* and *cycle.* **A.** Inspiration is pressure-targeted and time-cycled. **B.** Flow is targeted, but volume is not, and inspiration is volume-cycled. **C.** Both volume and flow are targeted, and inspiration is time-cycled. (Reproduced, with permission, from Chatburn.[6])

time cycled (see Fig. 2-3). Note that the volume that passes through the ventilator's output control valve is never exactly equal to the volume delivered to the patient because of the volume compressed in the patient circuit. Some ventilators use a sensor at the Y-connector (such as the Dräger Evita 4 with the neonatal circuit) for more accurate tidal volume measurement. Others measure volume at some point inside the ventilator, and the operator must know whether the ventilator compensates for compressed gas in its tidal volume readout.

When a ventilator is set to flow cycle, it delivers flow until a preset level is met. Flow then stops, and expiration begins. The most frequent application of flow cycling is in the pressure-support mode. In this mode, the control variable is pressure, and the ventilator provides the flow necessary to meet the inspiratory pressure target. In doing so, flow starts out at a relatively high value and decays exponentially (assuming that the patient's respiratory muscles are inactive after triggering). Once flow has decreased to a relatively low value (such as 25% of peak flow, typically preset by the manufacturer), inspiration is cycled off. Manufacturers often set the cycle threshold slightly above zero flow to prevent inspiratory times from getting so long that patient synchrony is degraded. On some ventilators, the flow-cycle threshold may be adjusted by the operator to improve patient synchrony. Increasing the flow-cycle threshold decreases inspiratory time and vice versa.

Time cycling means that expiratory flow starts because a preset inspiratory time interval has elapsed.

Baseline Variable

The baseline variable is the parameter controlled during expiration. Although pressure, volume, or flow could serve as the baseline variable, pressure control is the most practical and is implemented by all modern ventilators. Baseline or expiratory pressure is always measured and set relative to atmospheric pressure. Thus, when we want baseline pressure to equal atmospheric pressure, we set it to zero. When we want baseline pressure to exceed atmospheric pressure, we set a positive value, called *positive end-expiratory pressure* (PEEP).

MODES OF VENTILATION

The general goals of mechanical ventilation are to promote safety, comfort, and liberation (Table 2-2).[1] Specific objectives under these goals include ensuring adequate gas exchange, avoiding ventilator induced lung injury, optimizing patient-ventilator synchrony, and minimizing the duration of ventilation. The preset pattern of patient-ventilator interaction designed to achieve these objectives is referred to as a *mode* of ventilation. Specifically, a mode can be classified according to the outline in Table 2-3.[2]

TABLE 2-2: GOALS AND OBJECTIVES OF MECHANICAL VENTILATION

1. Promote safety
   a. Optimize ventilation–perfusion of the lung
      i. Maximize alveolar ventilation
      ii. Minimize shunt
   b. Optimize pressure–volume curve
      i. Minimize tidal volume
      ii. Maximize compliance
2. Promote comfort
   a. Optimize patient–ventilator synchrony
      i. Maximize trigger–cycle synchrony
      ii. Minimize auto-PEEP
      iii. Maximize flow synchrony
      iv. Coordinate mandatory and spontaneous breaths
   b. Optimize work demand versus work delivered
      i. Minimize inappropriate shifting of work from ventilator to patient
3. Promote liberation
   a. Optimize the weaning experience
      i. Minimize adverse events
      ii. Minimize duration of ventilation

Control Variable

I have already mentioned that pressure, volume, or flow can be controlled during inspiration. When discussing modes I will refer to inspiration as being pressure-controlled or volume-controlled. Ignoring flow control is justified because when the ventilator controls volume directly (i.e., using a volume-feedback signal), flow is controlled indirectly, and vice versa (i.e., mathematically, volume is the integral of flow, and flow is the derivative of volume).

There are clinical advantages and disadvantages to volume and pressure control. To keep within the scope of this chapter, we can just say that volume control results in a more stable minute ventilation (and hence more stable blood gases) than pressure control if lung mechanics are unstable. On the other hand, pressure control allows better synchronization with the patient because inspiratory flow is not constrained to a preset value. Although the ventilator must control only one variable at a time during inspiration, it is possible to begin a breath-in pressure control and (if certain criteria are met) switch to volume control or vice versa (referred to as dual targeting, described in "Targeting Schemes" below).

Breath Sequence

The *breath sequence* is the pattern of mandatory or spontaneous breaths that the mode delivers. A *breath* is a positive airway flow (inspiration) relative to baseline, and it is paired (by size) with a negative airway flow (expiration), both associated with ventilation of the lungs. This definition excludes flow changes caused by hiccups or cardiogenic oscillations. It allows, however, the superimposition of, for example, a spontaneous breath on a mandatory breath or vice versa. The flows are paired by size, not necessarily by timing. In airway pressure-release ventilation, for example, there is a large inspiration (transition from low pressure to high pressure) possibly followed by a few small inspirations and expirations, followed finally by a large expiration (transition from high pressure to low pressure). These comprise several small spontaneous breaths superimposed on one large mandatory breath. During high-frequency oscillatory ventilation, in contrast, small mandatory breaths are superimposed on larger spontaneous breaths.

A *spontaneous breath,* in the context of mechanical ventilation, is a breath for which the patient determines both the timing and the size. The start and end of inspiration may be determined by the patient, independent of any machine settings for inspiratory time and expiratory time. That is, the patient both triggers and cycles the breath. On some ventilators, the patient may make short, small spontaneous efforts during a longer, larger mandatory breath, as in the case of *airway pressure-release ventilation.* It is important to make a distinction between spontaneous breaths and assisted breaths. An *assisted breath* is one for which the ventilator does some work for the patient, as indicated by an increase in airway pressure (i.e., P_{vent}) above baseline during inspiration or below baseline during expiration. For example, in the *pressure-support mode,* each breath is assisted because airway pressures rise to the *pressure-support* setting above PEEP (i.e., $P_{vent} > 0$). Each breath is also spontaneous because the patient both triggers and cycles the breath. The patient may cycle the breath in the *pressure-support* mode by actively exhaling, but

even if the patient is passive at end-inspiration, the patient's resistance and compliance determine the cycle point and thus the size of the breath for a given *pressure-support* setting. In contrast, for a patient on continuous positive airway pressure, each breath is spontaneous but unassisted. Breaths are spontaneous because the patient determines the timing and size of the breaths without any interference by the ventilator. Breaths during continuous positive airway pressure are not assisted because airway pressure is controlled by the ventilator to be as constant as possible (i.e., $P_{vent} = 0$). Understanding the difference between assisted and unassisted spontaneous breaths is very important clinically. When making measurements of tidal volume and respiratory rate for calculation of the rapid-shallow breathing index, for example, the breaths must be *spontaneous* and *unassisted.* If they are assisted (e.g., with pressure support), an error of 25% to 50% may be introduced.

A *mandatory breath* is any breath that does not meet the criteria of a spontaneous breath, meaning that the patient has lost control over the timing and/or size. Thus, a mandatory breath is one for which the start or end of inspiration (or both) is determined by the ventilator, independent of the patient; that is, the machine triggers and/or cycles the breath. It is possible to superimpose a short mandatory breath on top of a longer spontaneous breath, as in the case of high-frequency oscillatory ventilation.

Having defined spontaneous and mandatory breaths, there are three possible breath sequences, designated as follows:

- *Continuous spontaneous ventilation (CSV).* All breaths are spontaneous.
- *Intermittent mandatory ventilation (IMV).* Spontaneous breaths are permitted between mandatory breaths. When the mandatory breath is triggered by the patient, it is commonly referred to as *synchronized IMV.* Because the trigger variable can be specified in the description of phase variables, I will use IMV instead of synchronized IMV to designate general breath sequences.
- *Continuous mandatory ventilation (CMV).* Spontaneous breaths are not permitted between mandatory breaths, as the intent is to provide a mandatory breath for every patient inspiratory effort. CMV originally meant that every breath was mandatory. The development of the "active exhalation valve," however, made it possible for the patient to breathe spontaneously during a mandatory pressure-controlled breath on some ventilators. In fact, it was always possible for the patient to breathe spontaneously during pressure-controlled mandatory breaths on infant ventilators. *The key distinction between CMV and IMV is that with CMV, the ventilator attempts to deliver a mandatory breath every time the patient makes an inspiratory effort* (unless a mandatory breath is already in progress). This means that during CMV, if the operator decreases the ventilator rate, the level of ventilator support is unaffected as long as the patient continues making inspiratory efforts. With IMV, the rate setting directly affects the number of mandatory breaths and hence the level of ventilator support. Thus, CMV is normally viewed as a method of "full ventilator support," whereas IMV is usually viewed as a method of partial ventilator support. Of course, actual "full ventilatory support" can only be achieved if the patient is making no inspiratory efforts, for example, is paralyzed, but the term is often used loosely to mean supplying as much support as possible for a given patient condition.

Given the two ways to control inspiration (i.e., pressure and volume) and the three breath sequences (i.e., CMV, IMV, or CSV), there are five possible breathing patterns; volume control (VC)-CMV, VC-IMV, pressure control (PC)-CMV, PC-IMV, PC-CSV (see Table 2-2). VC-CSV is not possible because volume control implies that inspiration ends after a preset tidal volume is delivered, hence violating the patient cycling criterion of a spontaneous breath.

Targeting Schemes

Targeting schemes are feedback control systems used by mechanical ventilators to deliver specific ventilatory patterns.[1] The targeting scheme is a key component of a mode classification system. Before we can describe specific targeting schemes used by ventilators, we must first appreciate the basic concepts of engineering control theory.

The term *closed-loop control* refers to the use of a feedback signal to adjust the output of a system. Ventilators use closed-loop control to maintain consistent pressure and flow waveforms in the face of changing patient/system conditions. This is accomplished by using the output as a feedback signal that is compared to the operator-set input. The difference between the two is used to drive the system toward the desired output. For example, pressure-control modes use airway pressure as the feedback signal to control gas flow from the ventilator. Figure 2-4 is a schematic of a general

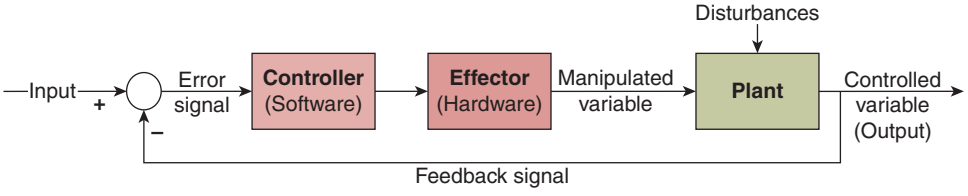

FIGURE 2-4 Generalized control circuit (see text for explanation). The "plant" in a control circuit for mechanical ventilation is the patient. (Reproduced with permission from Chatburn RL. Mireles-Cabodevila E, Closed loop control of mechanical ventilation. *Respir Care.* 2011;56(1): 85–98.)

control system. The input is a reference value (e.g., operator preset inspiratory pressure) that is compared to the actual output value (e.g., instantaneous value of airway pressure). The difference between those two values is the error signal. The error signal is passed to the controller (e.g., the software control algorithm). The controller converts the error signal into a signal that can drive the effector (e.g., the hardware) to cause a change in the manipulated variable (e.g., inspiratory flow). The relationship between the input and the output of the controller is called the transfer function in control theory. Engineers need to understand the transfer function in terms of complex mathematical equations. Clinicians, however, need only understand the general operation of the function in terms of how the mode affects the patient's ventilatory pattern, and we will use that frame of reference in defining targeting schemes. The "plant" in Figure 2-4 refers to the process under control. In our case, the plant is the patient and the delivery circuit connecting the patient to the ventilator. The plant is the source of the "noise" that causes problems with patient–ventilator synchrony. At one extreme, a paralyzed patient and an intact delivery circuit pose little challenge for a modern ventilator to deliver a predetermined ventilatory pattern, and thus synchrony is not an issue. At the opposite extreme is a patient with an intense, erratic respiratory drive and a delivery circuit with leaks (e.g., around an uncuffed endotracheal tube) making patient–ventilator synchrony virtually impossible. The challenge for both clinicians and engineers is to develop technology and procedures for dealing with this wide range of circumstances.

The plant alters the manipulated variable to generate the feedback signal of interest as the control (output) variable. Continuing with the example above, the manipulated variable is flow, but the feedback control variable is pressure (i.e., ventilator flow times plant impedance equals airway pressure), as in pressure-control modes.

Closed-loop control can also refer to the use of feedback signals to control the overall pattern of ventilation, beyond a single breath, such as the use of end-tidal carbon dioxide tension as a feedback signal to control minute ventilation.

The process of "setting" or adjusting a ventilation mode can be thought of as presetting various target values, such as tidal volume, inspiratory flow, inspiratory pressure, inspiratory time, frequency, PEEP, oxygen concentration, and end-tidal carbon dioxide concentration. The term *target* is used for two reasons. First, just like in archery, a target is aimed at but not necessarily hit, depending on the precision of the control system. An example is setting a target value for tidal volume and allowing the ventilator to adjust the inspiratory pressure over several breaths to finally deliver the desired value. In this case, we could more accurately talk about delivering an average target tidal volume over time.

The second reason for using *target* is because the term *control* is overused and we need it to preserve some fundamental conventions regarding modes such as *volume control* versus *pressure control.* From this use of the term *target,* we can logically refer to the control system transfer function (relationship between the input and the output of the controller) as a targeting scheme. The history of these schemes clearly shows an evolutionary trend toward increasing levels of automation. In fact, we can identify three groups of targeting schemes based on increasing levels of autonomy: manual, servo, and automatic. Manual targeting schemes require the operator to adjust all the target values. Servo targeting schemes are unique in that there are no static target values; rather, the operator sets the parameters of a mathematical model that drives the ventilator's output to follow a dynamic signal (like power steering on an automobile). Automatic targeting schemes enable the ventilator to set some or all of the ventilatory targets, using either mathematical models of physiologic processes or artificial-intelligence algorithms.

The basic concept of closed-loop control has evolved into at least six different ventilator targeting schemes (set-point, dual, servo, adaptive, optimal, and intelligent). These targeting schemes are the foundation that makes possible several dozen apparently different modes of ventilation. Once we understand how these control types work, many of the apparent differences are seen to be similarities. We then avoid a lot of the confusion surrounding ventilator marketing hype and begin to appreciate the true clinical capabilities of different ventilators.

SET-POINT

In set-point targeting, the operator sets specific target values and the ventilator attempts to deliver them (Fig. 2-5). The simplest examples for volume-control modes are tidal volume and inspiratory flow. For pressure-control modes, the operator may set inspiratory pressure and inspiratory time or cycle threshold.

DUAL

As it relates to mechanical ventilation, volume control means that inspired volume, as a function of time, is predetermined by the operator before the breath begins. In contrast, pressure control means that inspiratory pressure as a function of time is predetermined. "Predetermined" in this sense means that either pressure or volume is constrained to a specific mathematical form. In the simple case where either pressure or flow are preset constant values (e.g., set-point targeting, as explained above), we can say that they are the independent

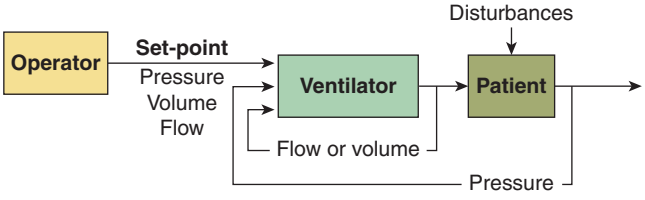

FIGURE 2-5 Set-point targeting. (Reproduced, with permission, from Chatburn RL. Computer control of mechanical ventilation. *Respir Care.* 2004;49:507–515.)

variables in the equation of motion. The equation of motion for the respiratory system is a general mathematical model of patient–ventilator interaction:

$$P(t) = EV(t) + R\dot{V}(t) \quad (4)$$

where $P(t)$ is inspiratory pressure as a function of time (t), E is respiratory-system elastance, $V(t)$ is volume as a function of time, R is respiratory-system resistance, and $\dot{V}$ is flow as a function of time. Thus, for example, if pressure is the independent variable, then both volume and flow are dependent variables, indicating pressure control. If volume is the independent variable, then pressure is the dependent variable, indicating volume control. Because volume is the integral of flow, if $\dot{V}$ is predetermined, then so is $V(t)$. Therefore, for simplicity, we include the case of flow being the independent variable as a form of volume control.

Only one variable (i.e., pressure or volume) can be independent at any moment, but a ventilator controller can switch between the two during a single inspiration. When this happens, the targeting scheme is called dual set-point control or dual targeting. There are two basic ways that ventilators have implemented dual targeting. One way is to start inspiration in volume control and then switch to pressure control if one or more preset thresholds are met (e.g., a desired peak airway pressure target). An example of such a threshold is the operator-set P_{max} in volume control on the Dräger Evita XL ventilator. The other form of dual targeting is to start inspiration in pressure control and then switch to volume control (e.g., if a preset tidal volume has not been met when flow decays to a preset value). This was originally described as "volume-assured pressure-support ventilation,"[13] but is currently only available as a mode called "Volume Control Assist Control with Machine Volume" in the CareFusion Avea ventilator.

Dual targeting is an attempt to improve the synchrony between patient and ventilator. This can be seen in the equation of motion if a term representing the patient inspiratory force (muscle pressure or P_{mus}) is added:

$$P(t) = EV(t) + RV(t) - P_{mus}(t) \quad (5)$$

With set-point targeting in volume control modes, volume and flow are preset. Therefore, if the patient makes an inspiratory effort (i.e., $P_{mus}(t) > 0$), then the equation dictates that transrespiratory-system pressure, $P(t)$, must fall. Because work is the result of both pressure and volume delivery (i.e., work = $\int Pdv$), if pressure decreases, the work the ventilator does on the patient decreases and hence we have asynchrony of work demand on the part of the patient versus work output on the part of the ventilator.

With set-point pressure control, transrespiratory pressure is preset. Consequently, if the patient makes an inspiratory effort, both volume and flow increase. With constant pressure and increased volume, work per liter for the breath stays constant. Although this gives better work synchrony than does volume control, it is not ideal. Nevertheless, merging of volume and pressure control using a dual targeting scheme provides the safety of a guaranteed minimum tidal volume with the patient comfort of flow synchrony provided by pressure control.

SERVO

The term *servo* was coined by Joseph Farcot in 1873 to describe steam-powered steering systems. Later, hydraulic "servos" were used to position antiaircraft guns on warships. Servo control specifically refers to a control system that converts a small mechanical motion into one requiring much greater power, using a feedback mechanism. As such, it offers a substantial advantage in terms of creating ventilation modes capable of a high degree of synchrony with patient breathing efforts. That is, ventilator work output can be made to match patient work demand with a high degree of fidelity. We apply the name *servo control* to targeting schemes in which the ventilator's output automatically follows a varying input. This includes proportional-assist ventilation (PAV; Fig. 2-6),[14] automatic tube compensation (ATC),[15] and neurally adjusted ventilatory assist (NAVA),[16] in which the airway pressure signal not only follows but amplifies signals that are surrogates for patient effort (i.e., volume, flow, and diaphragmatic electrical signals). Note that the term *servo control* has been loosely used since it was coined to refer to any type of general feedback control mechanism, but I am using it in a very specific manner, as it applies to ventilator targeting schemes.

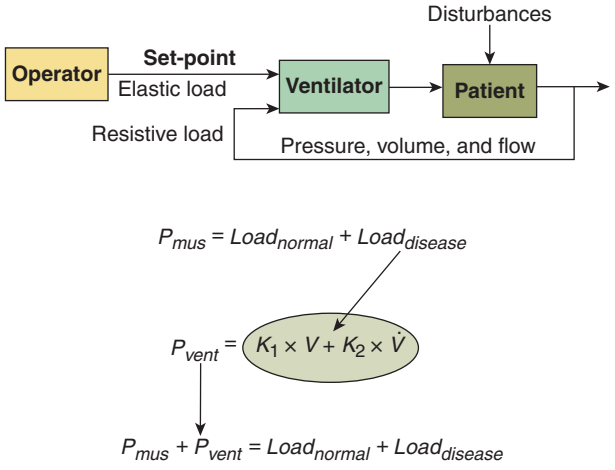

FIGURE 2-6 Servo targeting is the basis for the proportional-assist mode. In this mode, the operator sets targets for elastic and resistive unloading. The ventilator then delivers airway pressure in proportion to the patient's own inspiratory volume and flow. When the patient's muscles have to contend with an abnormal load secondary to disease, proportional assist allows the operator to set amplification factors (K_1 and K_2) on the feedback volume and flow signals. By amplifying volume and flow, the ventilator generates a pressure that supports the abnormal load, freeing the respiratory muscles to support only the normal load caused by the natural elastance and resistance of the respiratory system. (Reproduced, with permission, from Chatburn RL. Computer control of mechanical ventilation. *Respir Care.* 2004;49:507–515.)

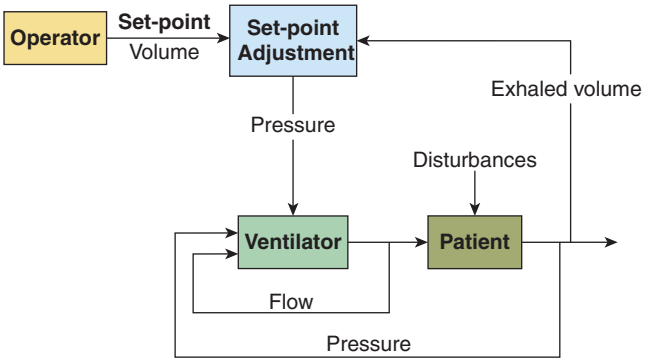

FIGURE 2-7 Adaptive targeting. Notice that the operator has stepped back from direct control of the within-breath parameters of pressure and flow. Examples of adaptive targeting are pressure-regulated volume control (PRVC) on the Siemens ventilator and autoflow on the Dräger Evita 4 ventilator. (Reproduced, with permission, from Chatburn RL. Computer control of mechanical ventilation. *Respir Care.* 2004;49: 507–515.)

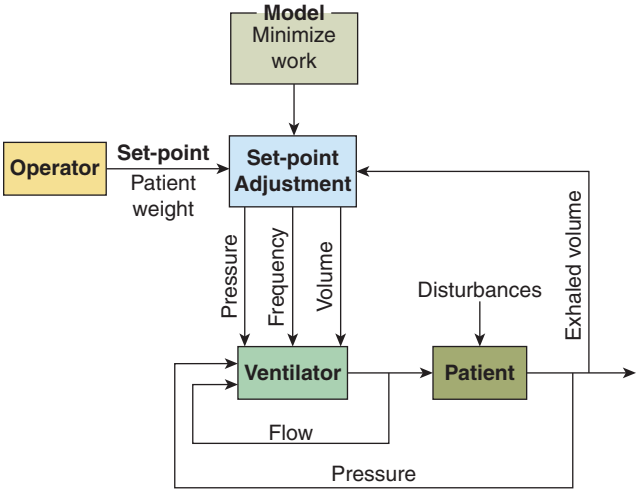

FIGURE 2-8 Optimal targeting. A static mathematical model is used to optimize some performance parameter, such as work of breathing. The only commercially available form of optimal targeting is the adaptive-support ventilation (ASV) mode on the Hamilton Galileo ventilator. (Reproduced, with permission, from Chatburn RL. Computer control of mechanical ventilation. *Respir Care.* 2004;49:507–515.)

ADAPTIVE

An adaptive targeting scheme involves modifying the function of the controller to cope with the fact that the system parameters being controlled are time varying. As it applies to mechanical ventilation, adaptive targeting schemes allow the ventilator to set some (or conceivably all) of the targets in response to varying patient conditions. Modern intensive care unit ventilators may use adaptive flow targeting as a more accurate way to deliver volume control modes than set-point targeting. For example, the Covidien PB 840 ventilator automatically adjusts inspiratory flow between breaths to compensate for volume compression in the patient circuit and thus achieving an average target tidal volume equal to the operator-set value.[17] Aside from this application of adaptive targeting, there are four distinct approaches to basic adaptive targeting, which are represented by the mode names *pressure-regulated volume control* (inspiratory pressure automatically adjusted to achieve an average tidal volume target, Fig. 2-7), *mandatory rate ventilation* (inspiratory pressure automatically adjusted to maintain a target spontaneous breath frequency), *adaptive flow/adaptive I-time* (inspiratory time and flow automatically adjusted to maintain a constant inspiratory time-to-expiratory time ratio of 1:2), and *mandatory minute ventilation* (automatic adjustment of mandatory breath frequency to maintain a target minute ventilation).

OPTIMAL

Optimal targeting is an advanced form of adaptive targeting.[18] Optimal targeting in this context means that the ventilator controller automatically adjusts the targets of the ventilatory pattern to either minimize or maximize some overall performance characteristic (Fig. 2-8). Adaptive-support ventilation (ASV) on the Hamilton ventilators is the only commercially available mode to date that uses optimal targeting. This targeting scheme was first described by Tehrani in 1991[20] and was designed to minimize the work rate of breathing, mimic natural breathing, stimulate spontaneous breathing, and reduce weaning time.[20] The operator inputs the patient's weight. From that, the ventilator estimates the required minute alveolar ventilation, assuming a normal dead space fraction. Next, an optimum frequency is calculated based on work by Otis et al[21] that predicts a frequency resulting in the least mechanical work rate:[20]

$$f = \frac{-1 + \sqrt{1 + 4\pi^2 RC_E \left(\frac{MV - fV_D}{V_D}\right)}}{2\pi^2 RC_E} \qquad (6)$$

where MV is predicted minute ventilation (L/min) based on patient weight and the setting for percent of predicted MV to support, V_D is predicted dead space (L) based on patient weight, RC_E is the expiratory time constant calculated as the slope of the expiratory flow volume curve and f is the computed optimal frequency (breaths/min). The target tidal volume is calculated as MV/f. The ASV controller uses the Otis equation to set the tidal volume (Fig. 2-8). As with simple adaptive pressure targeting, the inspiratory pressure within a breath is controlled to achieve a constant value and between breaths the inspiratory pressure is adjusted to achieve a target tidal volume. Unlike simple adaptive pressure targeting, however, the target is not set by the operator; instead, it is estimated by the ventilator in response to changes in respiratory-system mechanics and patient effort. Individual pressure-targeted breaths may be mandatory (time triggered and time cycled) or spontaneous (flow triggered and flow cycle).

ASV adds some expert rules that put safety limits on frequency and tidal volume delivery and reduce the risk of auto-PEEP. In that sense, this mode may be considered an intelligent targeting scheme, or more appropriately, a hybrid system (i.e., using a mathematical model and artificial intelligence).

INTELLIGENT

Intelligent targeting systems are another form of adaptive targeting schemes that use artificial-intelligence techniques.[22] The most convincing proof of the concept was presented by East et al,[23] who used a rule-based expert system for ventilator management in a large, multicenter, prospective, randomized trial. Although survival and length of stay were not different between human and computer management, computer control resulted in a significant reduction in multiorgan dysfunction and a lower incidence and severity of lung overdistension injury. The most important finding, however, was that *expert knowledge can be encoded and shared successfully with institutions that had no input into the model.* Note that the expert system did not control the ventilator directly, but rather made suggestions for the human operator. In theory, of course, the operator could be eliminated.

There is only one ventilator mode commercially available to date in the United States with a targeting scheme that relies entirely on a rule-based expert system (Fig. 2-9). That mode is SmartCare/PS on the Dräger Evita XL ventilator. This mode is a specialized form of pressure support that is designed for true (ventilator led) automatic weaning of patients. The SmartCare/PS controller uses predefined acceptable ranges for spontaneous breathing frequency, tidal volume, and end-tidal carbon dioxide tension to automatically adjust the inspiratory pressure to maintain the patient in a "respiratory zone of comfort."[23]

The SmartCare/PS system divides the control process into three steps. The first step is to stabilize the patient within the "zone of respiratory comfort" defined as combinations of tidal volume, respiratory frequency, and end tidal CO_2 values defined as acceptable by the artificial-intelligence program. There are different combinations depending on whether the patient has chronic obstructive pulmonary disease or a neuromuscular disorder. The second step is to progressively decrease the inspiratory pressure while making sure the patient remains in the "zone." The third step tests readiness for extubation by maintaining the patient at the lowest level of inspiratory pressure. The lowest level depends on the type of artificial airway (endotracheal tube vs. tracheostomy tube), the type of humidifier (heat and moisture exchanger vs. a heated humidifier), and the use of automatic tube compensation. Once the lowest level of inspiratory pressure is reached, a 1-hour observation period is started (i.e., a spontaneous breathing trial) during which the patient's breathing frequency, tidal volume, and end-tidal CO_2 are monitored. Upon successful completion of this step, a message on the screen suggests that the clinician "consider separation" of the patient from the ventilator. This method for automatic weaning reduces the duration of mechanical ventilation and intensive care unit length of stay in a multicenter randomized controlled trial.[24,25] The advantage of artificial intelligence, however, may be less noticeable in environments where natural intelligence is plentiful. Rose et al recently concluded that "Substantial reductions in weaning duration previously demonstrated were not confirmed when the SmartCare/PS system was compared to weaning managed by experienced critical care specialty nurses, using a 1:1 nurse-to-patient ratio. The effect of SmartCare/PS may be influenced by the local clinical organizational context."[26]

The ultimate in ventilator targeting system to date is the artificial neural network (Fig. 2-10).[27] Again, this experimental system does not control the ventilator directly but acts as a decision-support system. What is most interesting is that *the neural network is capable of learning,* which offers significant advantages over static mathematical models and even expert rule-based systems.

Neural nets are essentially data-modeling tools used to capture and represent complex input–output relationships. A neural net learns by experience the same way a human brain does, by storing knowledge in the strengths of internode connections. As data-modeling tools, they have been used in many business and medical applications for both diagnosis and forecasting.[28] A neural network, like an animal brain, is made up of individual neurons. Signals (action potentials) appear at the unit's inputs (synapses). The effect of each signal may be approximated by multiplying the signal by some number or weight to indicate the strength of the signal. The weighted signals then are summed to produce

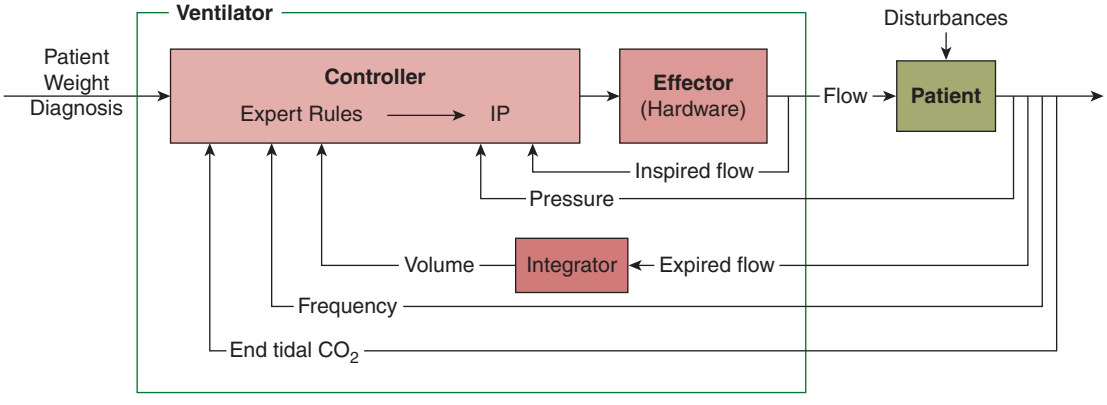

FIGURE 2-9 An intelligent targeting system for automatically adjusting pressure support levels (e.g., SmartCare/PS). IP, inspiratory pressure. (Reproduced, with permission, from Chatburn RL, Mireles-Cabodevila E. Closed loop control of mechanical ventilation. *Respir Care.* 2011;56(1):85–98.

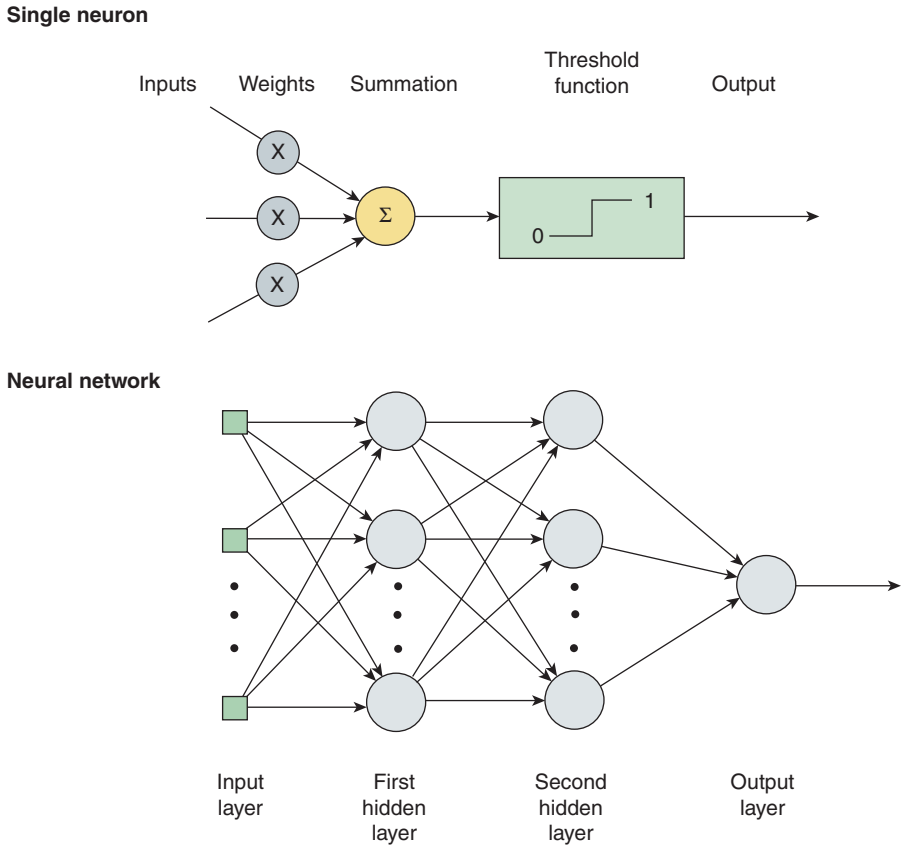

FIGURE 2-10 Neural network structure. A single neuron accepts inputs of any value and weights them to indicate the strength of the synapse. The weighted signals are summed to produce an overall unit activation. If this activation exceeds a certain threshold, the unit produces an output response. A network is made up of layers of individual neurons. (Reproduced, with permission, from Chatburn RL. Computer control of mechanical ventilation. *Respir Care.* 2004;49:507–515.)

an overall unit activation. If this activation exceeds a certain threshold, the unit produces an output response. Large numbers of neurons can be linked together in layers (see Fig. 2-10). The nodes in the diagram represent the summation and transfer processes. Note that each node contains information from all neurons. As the network learns, the weights change, and thus the values at the nodes change, affecting the final output.

In summary, ventilator control schemes display a definite hierarchy of evolutionary complexity. At the most basic level, control is focused on what happens within a breath. We can call this *manual control,* and there is a very direct need for operator input of static set-points. The next level up is what we can call *automatic control.* Here, set-points are dynamic in that they may be adjusted automatically over time by the ventilator according to some model of desired performance. The operator is somewhat removed in that inputs are entered at the level of the model and take effect over several breaths instead of at the level of individual breath control. Finally, the highest level so far is what might be considered *intelligent control.* Here, the operator can be eliminated altogether. Not only dynamic set-points but also dynamic models of desired performance are permitted. There is the possibility of the system learning from experience so that the control actually spans between patients instead of just between breaths.

Mode Classification

When Mushin et al wrote the classic book on automatic ventilation of the lungs,[10] the emphasis was on classifying ventilators and there were very few modes on each device. These devices have undergone a tremendous technological evolution during the intervening years. As a result, there are now more than 170 names of modes on ventilators in the United States alone, with as many as two dozen available on a single device. The proliferation of names makes education of end users very difficult, potentially compromising the quality of patient care. In addition, although there may be more than 170 mode names, these are not uniquely different modes. Consequently, the emphasis today in describing ventilators must be on classifying modes, shifting awareness from names to tags. Much has been written on the subject,[2,5,29–31] and this section gives a brief overview of the development and application of a ventilator mode taxonomy.

You can easily appreciate the motivation for classifying modes, just as we do animals or plants (or cars or drugs) because of their large number and variety. The logical basis for a mode taxonomy, however, is not apparent without some consideration. This basis has become a teaching system I have developed and tested and is founded on ten simple constructs (or aphorisms), each building on the previous one to yield a practical taxonomy. These aphorisms summarize many of the ideas discussed previously in this chapter, and there is even some evidence that they are recognized internationally by clinicians.[32] In simplified form, the aphorisms are as follows:

1. *A **breath** is one cycle of positive flow (inspiration) and negative flow (expiration).* The purpose of a ventilator is to assist breathing. Therefore, the logical start of a taxonomy is to define a breath. Breaths are defined such that during mechanical ventilation, small artificial breaths may be superimposed on large natural breaths or vice versa.
2. *A breath is **assisted** if pressure rises above baseline during inspiration or falls during expiration.* A ventilator assists breathing by doing some portion of the work of breathing. This occurs by delivering volume under pressure.
3. *A ventilator assists breathing using either **pressure control** (PC) or **volume control** (VC).* The equation of motion is the fundamental model for understanding patient–ventilator interaction and hence modes of ventilation. The equation is an expression of the idea that only one variable can be predetermined at a time; pressure or volume (flow control is ignored for simplicity and for historical reasons, and because controlling flow directly will indirectly control volume and vice versa).
4. *Breaths are classified according to the criteria that **trigger** (start) and **cycle** (stop) inspiration.* A ventilator must know when to start and stop flow delivery for a given breath. Because starting and stopping inspiratory flow are critical events in synchronizing patient–ventilator interaction, and because they involve uniquely different operator-influenced factors, they are distinguished by giving them different names.
5. *Trigger and cycle criteria can be either patient or machine initiated.* A major design consideration in creating modes is the ability to synchronize breath delivery with patient demand and at the same time to guarantee breath delivery if the patient is apneic. Therefore, understanding patient–ventilator interaction means understanding the difference between machine and patient trigger and cycle events.
6. *Breaths are classified as **spontaneous** or **mandatory** based on both the trigger and cycle criteria.* A spontaneous breath arises without apparent external cause. Thus, it is patient triggered and patient cycled. Any machine involvement in triggering or cycling leads to a mandatory breath. Note that the definition of a spontaneous breath is independent of the definition of an assisted or unassisted breath.
7. *Ventilators deliver only three basic **breath sequences**: CMV, IMV, and CSV.* The two breath classifications logically lead to three possible breath sequences that a mode can deliver. CSV implies all spontaneous breaths; IMV allows spontaneous breaths to occur between mandatory breaths and CMV does not.
8. *There are only five basic **ventilatory patterns**: VC-CMV, VC-IMV, PC-CMV, PC-IMV, and PC-CSV.* All modes can be categorizes by these five patterns. This provides enough practical detail about a mode for most clinical purposes.
9. *Within each ventilatory pattern there are several variations that can be distinguished by their **targeting scheme(s)**.* When comparing modes or evaluating the capability of a ventilator, more detail is required than just the ventilatory pattern. Modes with the same pattern can be distinguished by describing the targeting schemes they use. There are at present only six basic targeting schemes: set-point, dual, servo, adaptive, optimal, and intelligent.
10. *A **mode of ventilation** is classified according to its control variable, breath sequence, and targeting scheme(s).* A practical taxonomy of ventilatory modes is based on just four levels of detail: the control variable (pressure or volume), the breath sequence (CMV, IMV, or CSV), the targeting scheme used for primary breaths (CMV and CSV), and, if applicable, secondary breaths (IMV).

In teaching these constructs to respiratory therapists and physicians, most educators would agree that knowing a concept and applying it are two different skills. As with any taxonomy, learning the definitions and mastering the heuristic thinking required to actually categorize specific cases requires further guidance and some practice. Say, for example, your task is to compare the capabilities of two major intensive care unit ventilator models for a large capital purchase. Memorizing the ten aphorisms may not translate into the ability to classify the modes offered on these two ventilators as a basis for comparison. To facilitate that skill, I created the three tools shown in Figures 2-11 and 2-12 and in Table 2-4. Using these tools you can create a simple spreadsheet that defines and compares the modes on any number of ventilators. Table 2-5 is an example of such a table for the Covidien PB 840 ventilator and the Dräger Evita XL ventilator. When implemented as a spreadsheet with built-in data-sorting functions, the table becomes a database with several major uses:

1. A "Rosetta Stone" that can be used to translate from mode name to mode classification and vice versa. In this way modes can be identified that are functionally identical but have different proprietary names.
2. A tool for engineers to describe performance characteristics of individual named modes. Information like this should be available to users in the ventilator's manual.
3. A system for clinicians to compare and contrast the capabilities of various modes and ventilators.
4. A paradigm for educators to use in teaching the basic principles of mechanical ventilation.

One can imagine the utility of an expanded database containing the classification of all modes on all commercially available ventilators.

VENTILATOR ALARM SYSTEMS

As with other components of ventilation systems, ventilator alarms have increased in number and complexity. Fortunately, the classification system I have been describing can be expanded to include alarms as well (see Table 2-1).

MacIntyre[33] has suggested that alarms also be categorized by the events that they are designed to detect. Level 1 events include life-threatening situations, such as loss of input power or ventilator malfunction (e.g., excessive or no flow of gas to the patient). The alarms in this category should be mandatory (i.e., not subject to operator

P, pressure; *V*, volume; *F*, flow; *T*, time; *R*, resistance; *E*, elastance; *MV*, minute volume; *Edi*, electrical activity of diaphragm; *WB Target*, within-breath preset parameters of the pressure, volume, or flow waveform; *BB Target*, between breath targets modify WB targets or overal ventiltory pattern; *Cycle*, end of inspiration; *NA,* not available as operator preset, ventilator determines value if applicable.

low impedance, low resistance and/or elastance;
high impedance, high resistance and/or elastance;

TABLE 2-5: SPREADSHEET EXAMPLE OF HOW MODES ON TWO COMMON ICU VENTILATORS WOULD BE CLASSIFIED

The spreadsheet could be sorted any number of ways (e.g., using AutoFilter drop-down dialogs) to compare the ventilators on various capabilities (e.g., all modes with adaptive pressure targeting). The spreadsheet also functions as a mode translator, giving the different proprietary names for identical modes.

CMV, continuous mandatory ventilation; *CSV,* continuous spontaneous ventilation; *IMV,* intermittent mandatory ventilation.

choice), redundant (i.e., multiple sensors and circuits), and noncanceling (i.e., alarm continues to be activated, even if the event is corrected, and must be reset manually). Level 2 events can lead to life-threatening situations if not corrected in a timely fashion. These events include such things as blender failure, high or low airway pressure, autotriggering, and partial patient circuit occlusion. They also may include suspicious ventilator settings such as an inspiratory-to-expiratory timing (I:E) ratio greater than 1:1. Alarms for level 2 events may not be redundant and may be self-canceling (i.e., alarm inactivated if event ceases to occur). Level 3 events are those that affect the patient–ventilator interface and may influence the level of support provided. Examples of such events are changes in patient compliance and resistance, changes in patient respiratory drive, and auto-PEEP. Alarm function at this level is similar to that of level 2 alarms. Level 4 events reflect the patient condition alone rather than ventilator function. As such, these events usually are detected by stand-alone monitors, such as oximeters, cardiac monitors, and blood-gas analyzers. Some ventilators, however, are able to incorporate the readings of a capnograph in their displays and alarm systems.

THE FUTURE

Almost 20 years ago, Warren Sanborn predicted that ventilators today would "… report the patient's metabolic state; manage oxygen delivery; calculate cardiac output, synchronize breath delivery with cardiac cycle to maximize cardiac output…and perform all these functions automatically or at least presenting consensus-based advisory messages to the practitioner…."[17] Some of these ideas were never developed commercially. Some were tried and abandoned. Some, have evolved beyond Warren's broad vision.

There are three basic ways to improve ventilators in the future. First, just like computer games, ventilators need to improve the operator interface constantly. Yet very little research has been done to call attention to problems with current displays.[34,35] We have come a long way from using a crank to adjust the stroke of a ventilator's piston to set tidal volume. The operator interface must provide for three basic functions: allow input of control and alarm parameters, monitor the ventilator's status, and monitor the ventilator–patient interaction status. We have a long way to go before the user interface provides an ideal experience with these functions.

Second, the weak link in the patient–ventilator system is the patient circuit. We buy a $35,000 ventilator with state-of-the-art computer control, and then we connect it to the patient (priceless) with a $1.98 piece of plastic tubing that is subject to filling with condensate from a heated humidifier whose design has not changed appreciably in 20 years. The resistance and compliance of the delivery circuit make flow control and volume delivery more difficult. It is like buying a Ferrari and putting wooden wheels on it. In the future, water vapor should be treated like any other desirable inhaled gas constituent (e.g., air, oxygen, helium, or nitric oxide) and metered from within the ventilator. The inspiratory part of the patient circuit should be a sterile, insulated, permanent part of the ventilator right up to the patient connection, which can be a disposable tip for cleaning purposes. The gas should be delivered under high pressure as a jet to provide not only conventional pressure, volume, and flow waveforms but also high-frequency ventilation. The jet also can be used to provide a counterflow PEEP effect, eliminating any need for an exhalation–valve system. The disposable tip could be designed to house disposable sensors and would be the only part of the circuit to be exposed to the patient's exhaled gas. If ventilator manufacturers saw themselves as providers of the entire system, instead of letting third parties deal in plastic connecting tubing, I think we would see a huge evolutionary step in ventilator performance, better patient outcomes, and potential savings in labor costs for providers.

Third, the most exciting area for development probably is in the intelligence that will be built into future ventilator control circuits. The real challenge in closed-loop control of ventilation is defining, measuring, and interpreting the appropriate feedback signals. If we stop to consider all the variables a human operator assesses, the problem looks insurmountable. Not only does a human consider a wide range of individual physiologic variables, but there are the more abstract evaluations of such things as metabolic, cardiovascular, and psychological states. Add to this the various environmental factors that may affect operator judgment, and we get a truly complex control problem (Fig. 2-13).

I would like to speculate now about a response to this challenge. The ideal control strategy would have to start out with basic tactical control of the individual breath. Next, we add longer-term strategic control that adapts to changing load characteristics. Mathematical models could provide the basic parameters of the mode, whereas expert rules would place limits to ensure lung protection.

Next, we sample various physiologic parameters and use fuzzy logic to establish the patient's immediate condition. This information is passed on to a neural network, which would then select the best response to the patient's condition.

The neural network ideally would have access to a huge database comprised of both human expert rules and actual patient responses to various ventilator strategies. This arrangement would allow the ventilator not only to learn from its interaction with the current patient but also to contribute to the database.

Finally, the database and this ventilator could be networked with other intelligent ventilators to multiply the learning capacity exponentially (Fig. 2-14). Whatever the future brings, it seems clear that ventilators will have more intelligence built in to increase patient safety and decrease the time required to provide care.

SUMMARY AND CONCLUSION

Mechanical ventilators have become so complex that a system of classification is necessary to communicate intelligently about them. The theoretical basis for this classification system is a mathematical model of patient–ventilator interaction known as the *equation of motion for the respiratory system*. From this model we deduce that as far as an individual inspiration is concerned, any conceivable ventilator can be classified as either a pressure, volume, or flow controller (and in rare cases, simply an inspiratory-expiratory time controller). An individual breath is shaped by the phase variables that determine how the breath is triggered (started), targeted (sustained), and cycled (stopped).

A *mode* of ventilation can be characterized using a four-level taxonomy: (a) control variable, that is, pressure or volume according to the equation of motion; (b) the breath sequence, that is, CMV, IMV, or CSV; (c) targeting scheme for primary breaths; and (d) targeting scheme for secondary breaths. The trend in ventilator targeting schemes has been from basic manual control (within-breath control requiring operator input of static set-points), to more advanced automatic control (between-breath control of set-points that are adjusted automatically by the ventilator with minimal operator input), to the highest level of intelligent control (in which the operator theoretically may be eliminated altogether in favor of artificial-intelligence systems capable of learning).

3

BASIC PRINCIPLES OF VENTILATOR DESIGN

Robert L. Chatburn
Eduardo Mireles-Cabodevila

THE VENTILATOR AS A "BLACK BOX"

A mechanical ventilator is an automatic machine designed to provide all or part of the work the body must do to move gas into and out of the lungs. The act of moving air into and out of the lungs is called breathing, or, more formally, ventilation.

The simplest mechanical device we could devise to assist a person's breathing would be a hand-driven, syringe-type pump that is fitted to the person's mouth and nose using a mask. A variation of this is the self-inflating, elastic resuscitation bag. Both of these require one-way valve arrangements to cause air to flow from the device into the lungs when the device is compressed, and out from the lungs to the atmosphere as the device is expanded. These arrangements are not automatic, requiring an operator to supply the energy to push the gas into the lungs through the mouth and nose. Thus, such devices are not considered mechanical ventilators.

Automating the ventilator so that continual operator intervention is not needed for safe, desired operation requires three basic components:

1. A source of input energy to drive the device;
2. A means of converting input energy into output energy in the form of pressure and flow to regulate the timing and size of breaths; and
3. A means of monitoring the output performance of the device and the condition of the patient.

There was a time when you could take a handful of simple tools and do routine maintenance on your car engine. About that time the average clinician could also completely disassemble and reassemble a mechanical ventilator as a training exercise or to perform repairs. In those days (the late 1970s), textbooks[1] describing ventilators understandably paid much attention to the individual mechanical components and pneumatic schematics. In fact, this philosophy was reflected to some extent in previous editions of this book. Today, both cars and ventilators are incredibly complex mechanical devices controlled by multiple microprocessors running sophisticated software (Fig. 3-1). Figure 3-2 shows the pneumatic schematic of a current intensive care ventilator. All but the most rudimentary maintenance of ventilators is now the responsibility of specially trained biomedical engineers. Our approach to describing ventilator design has thus changed from a focus on individual components to a more generalized model of a ventilator as a "black box," that is, a device for which we supply an input and expect a certain output and whose internal operations are largely unknowable, indeed, irrelevant, to most clinical operators. What follows, then, is only a brief overview of the key design features of mechanical ventilators with an emphasis on input power requirements, transfer functions (pneumatic and electronic control systems), and outputs (pressure, volume, and flow waveforms). The rest of the chapter focuses on the interactions between the operator and the ventilator

FIGURE 3-2 Pneumatic schematic of the Dräger Infinity V500 intensive care ventilator. **A.** Gas-mixture and gas-metering assembly. Gas from the supply lines enters the ventilator via the gas-inlet connections for oxygen and air (*1,2*). Two nonreturn valves (*3,4*) prevent one gas from returning to the supply line of the other gas. Mixing takes place in the tank (*7*) and is controlled by two valves (*5,6*). Inspiratory flow is controlled by a third valve (*8*). **B.** Inspiratory unit consists of safety valve (*9*) and two nonreturn valves (*10,11*). In normal operation, the safety valve is closed so that inspiratory flow is supplied to the patient's lungs (*12*). During standby, the safety valve is open and enables spontaneous inspiration by the emergency breathing valve (*11*). The emergency expiratory valve (*10*) provides a second channel for expiration when the expiratory valve (*13*) is blocked. **C.** Expiratory unit consists of the expiratory valve (*13*) and a nonreturn valve (*14*). The expiratory valve is a proportional valve and is used to adjust the pressure in the patient circuit. In conjunction with the spring-loaded valve of the emergency air outlet (*10*), the nonreturn valve (*14*) prevents pendulum breathing during spontaneous breathing. **D.** Expiratory flow sensor. **E.** Barometric pressure sensor. Conversion of mass flow to volume, body temperature and pressure saturated (*BTPS*) requires knowledge of ambient pressure. **F.** Pressure measurement assembly. Pressure in the patient circuit is measured with two independent pressure sensors (*18,20*). **G.** Calibration assembly. The pressure sensors are regularly zero calibrated by connection to ambient pressure via the two calibration valves (*17,19*). **H.** Oxygen sensor. **I.** Medication nebulizer assembly. (the operator interface), and between the ventilator and the patient (the patient interface).

Inputs

Mechanical ventilators are typically powered by electricity or compressed gas. Electricity, either from wall outlets (e.g., 100 to 240 volts AC, at 50/60 Hz) or from batteries (e.g., 10 to 30 volts DC), is used to run compressors of various types. Batteries are commonly used as the primary power source in the home-care environment but are usually reserved for patient transport or emergency use in hospitals. These sources provide compressed air for motive power as well as air for breathing. Alternatively, the power to expand the lungs is supplied by compressed gas from tanks, or from wall outlets in the hospital (e.g., 30 to 80 pounds per square inch [psi]). Some transport and emergency ventilators use compressed gas to power both lung inflation and the control circuitry. For these ventilators, knowledge of gas consumption is critical when using cylinders of compressed gas.

The ventilator is generally connected to separate sources of compressed air and compressed oxygen. In the United States, hospital wall outlets supply air and oxygen at 50 psi, although most ventilators have internal regulators to reduce this pressure to a lower level (e.g., 20 psi). This permits the delivery of a range of oxygen concentrations to support the needs of sick patients. Because compressed gas has all moisture removed, the gas delivered to the patient must be warmed and humidified so as to avoid drying out the lung tissue.

Conversion and Control

The input power of a ventilator must be converted to a predefined output of pressure and flow. There are several key systems required for this process. If the only power input is electrical, the ventilator must use a compressor or blower to generate the required pressure and flow. A compressor is a machine for moving a relatively low flow of gas to a storage container at a higher level of pressure (e.g., 20 psi). A blower is a machine for generating relatively larger flows of gas as the direct ventilator output with a relatively moderate increase of pressure (e.g., 2 psi). Compressors are generally found on intensive care ventilators whereas blowers are used on home-care and transport ventilators. Compressors are typically larger and consume more electrical power than blowers, hence the use of the latter on small, portable devices.

FLOW-CONTROL VALVES

To control the flow of gas from a compressor, ventilator engineers use a variety of flow-control valves, from very simple to very complex. The simplest valve is just a fixed orifice flow resistor that permits setting a constant flow to the external

FIGURE 3-3 CareFusion Infant Flow SiPAP device.

tubing that conducts the gas to the patient, called the *patient circuit*. Such devices are used in small transport ventilators and automatic resuscitators. Manually adjusted variable-orifice flow meters have been used in simple infant ventilators in the past (e.g., Bourns BP-200) and are currently used in the Infant Flow SiPAP device (CareFusion, Minneapolis, MN), as shown in Figure 3-3. The advent of inexpensive microprocessors in the 1980s led to development of digital control of flow valves that allow a great deal of flexibility in shaping the ventilator's output pressure, volume, and flow waveforms (Fig 3-4).[2] Such valves are used in most of the current generation of intensive care ventilators.

Directing flow from the source gas into the patient requires the coordination of the output flow-control valve and an expiratory valve or "exhalation manifold" (Fig. 3-5). In the simplest case, when inspiration is triggered on, the output control valve opens, the expiratory valve closes, and the only path left for gas is into the patient. When inspiration is cycled off, the output valve closes and the exhalation valve opens, flow from the ventilator ceases and the patient exhales out through the expiratory valve (see Fig. 3-2). The most sophisticated ventilators employ a complex interaction between the output flow-control valve and the exhalation valve, such that a wide variety of pressure, volume, and flow waveforms may be generated to synchronize the ventilator output with patient effort as much as possible.

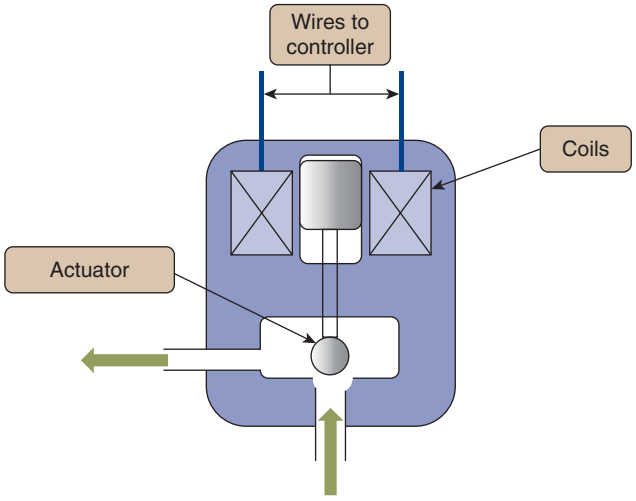

FIGURE 3-4 Schematic of an output flow-control valve.

FIGURE 3-6 Small, pneumatically powered transport ventilator using a pneumatic control system. (Reproduced, with permission, from CAREvent, O-Two Medical Technologies, Ontario, Canada.)

CONTROL SYSTEMS

In the simplest terms, the control system of a ventilator is comprised of components that generate the signals that operate the output valve and the exhalation manifold to obtain the desired output waveforms and modes of ventilation. Control systems may be based on mechanical, pneumatic, fluidic, or electronic components. Mechanical components include levers, pulleys, cams, and so on.[3] Pneumatic control circuits use gas pressure to operate diaphragms, jet entrainment devices, pistons, and other items. Use of lasers to create micro channels for gas flow has enabled miniaturization of ventilator control circuits that are powered entirely by gas pressure to create small, but sophisticated, ventilators for transport, such as the CAREvent (O-Two Medical Technologies) shown in Figure 3-6. Fluidic circuits are analogs of electronic logic circuits.[4] Just as an electronic logic circuit uses electricity, the fluidic circuit uses a very small gas flows to generate signals that operate switches and timing components. Both pneumatic and fluidic control systems are immune to failure from electromagnetic interference, such as around magnetic resonance imaging equipment. Examples of simple pneumatic and fluidic ventilator control circuits have been illustrated elsewhere.[5] By far, the majority of ventilators use electronic control circuits with microprocessors to manage the complex monitoring (e.g., from pressure and flow sensors) and control (valves) functions of modern ventilators used in almost every health care environment.

What makes one ventilator so different from another has as much to do with the control system software as it does with the hardware. The control software determines how the ventilator interacts with the patient; that is, the modes available. Thus, a discussion about control systems is essentially a discussion about mode capabilities and classifications. Chapter 2 describes the specific design principles of ventilator control systems in detail.

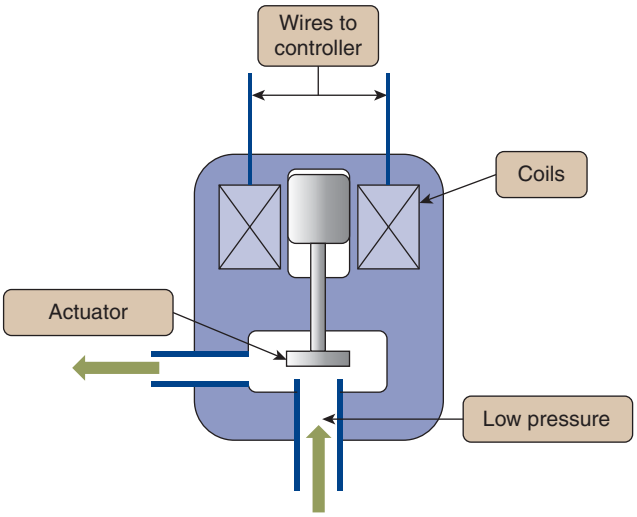

FIGURE 3-5 Schematic of an exhalation valve.

Outputs

Just as the study of cardiology involves the use of electrocardiograms and blood pressure waveforms, the study of mechanical ventilation requires an understanding of output waveforms. The waveforms of interest are the pressure, volume, and flow.

IDEALIZED PRESSURE, VOLUME, AND FLOW WAVEFORMS

Output waveforms are conveniently graphed in groups of three. The horizontal axis of all three graphs is the same and has the units of time. The vertical axes are in units of pressure, volume, and flow. For the purpose of identifying

characteristic waveform shapes, the specific baseline values are irrelevant. What is important is the relative magnitudes of each of the variables and how the value of one affects or is affected by the value of the others.

Figure 3-7 illustrates the typical waveforms available on modern ventilators. These waveforms are idealized; that is, they are precisely defined by mathematical equations and are meant to characterize the operation of the ventilator's control system. As such, they do not show the minor deviations, or "noise," often seen in waveforms recorded during actual ventilator use. This noise can be caused by a variety of extraneous factors such as vibration and flow turbulence. Of course, scaling of the horizontal and vertical axes can affect the appearance of actual waveforms considerably. Finally, the waveforms in Figure 3-7 do not show the effects of the resistance and compliance of the patient circuit.

No ventilator is an ideal pressure, volume, or flow controller, and ventilators are designed to only approximate a particular waveform. Idealized waveforms as shown in Figure 3-7 are, nevertheless, helpful because they are used commonly in other fields (e.g., electrical engineering), which makes it possible to use mathematical procedures and terminology that already have been established. For example, a standard mathematical equation is used to describe the most common ventilator waveforms for each control variable. This known equation may be substituted into the equation of motion, which is then solved to get the equations for the other two variables. Once the equations for pressure, volume, and flow are known, they are easily graphed. This is the procedure that was used to generate the graphs in Figure 3-7.

EFFECTS OF THE PATIENT CIRCUIT

The pressure, volume, and flow the patient actually receives are never precisely the same as what the clinician sets on the ventilator. Sometimes these differences are caused by instrument inaccuracies or calibration error. More commonly, the patient delivery circuit contributes to discrepancies between the desired and actual patient values. This is so because the patient circuit has its own compliance and resistance. Thus, the pressure measured inside a ventilator upstream of the patient always will be higher than the pressure at the airway opening because of patient circuit resistance. In addition, the volume and flow coming out of the ventilator's exhalation manifold will exceed those delivered to the patient because of the compliance of the patient circuit.

Exactly how the mechanical properties of the patient circuit affect ventilator performance depends on whether they are connected in series or in parallel with the patient. It turns out that the resistance of the patient circuit is connected in series whereas the compliance is modeled as a parallel connection. To understand this, we first make the simplifying assumption that we can examine the patient circuit's resistance separate from its compliance. It is intuitively obvious that the same flow of gas that comes from the ventilator travels through the circuit tubing as through the patient's airway opening. We also can see that the pressure drop across the patient circuit will be different from that across the respiratory system because they have different resistances. By a definition we borrow from electronics, when two circuit components share the same flow but have different pressure drops, they are connected in series. This

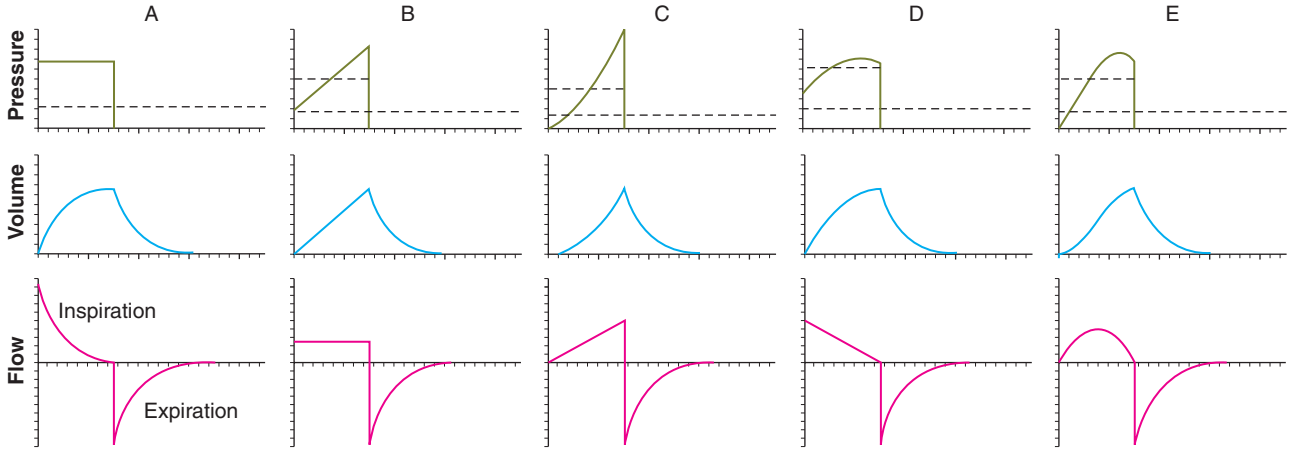

FIGURE 3-7 Idealized ventilator output waveforms. **A.** Pressure-controlled inspiration with a rectangular pressure waveform. **B.** Volume-controlled inspiration with a rectangular flow waveform. **C.** Volume-controlled inspiration with an ascending-ramp flow waveform. **D.** Volume-controlled inspiration with a descending-ramp flow waveform. **E.** Volume-controlled inspiration with a sinusoidal flow waveform. The *short dashed lines* represent mean inspiratory pressure, and the *long dashed lines* represent mean pressure for the complete respiratory cycle (i.e., mean airway pressure). Note that mean inspiratory pressure is the same as the pressure target in A. These waveforms were created as follows: (a) defining the control waveform using a mathematical equation (e.g., an ascending-ramp flow waveform is specified as flow = constant × time), (b) specifying the tidal volume for flow-control and volume-control waveforms, (c) specifying the resistance and compliance, (d) substituting the preceding information into the equation of motion for the respiratory system, and (e) using a computer to solve the equation for the unknown variables and plotting the results against time. (Reproduced, with permission, from Chatburn RL. *Fundamentals of Mechanical Ventilation.* Cleveland Heights, OH: Mandu Press; 2003:143.)

means that the patient circuit resistance, however small, adds to the total resistive load seen by the ventilator. Thus, in a volume-controlled breath, the peak inspiratory pressure is higher, and in a pressure-controlled breath, the tidal volume and peak flow are lower. In practice, the effect of patient circuit resistance is usually ignored because it is so much lower than the resistance of the respiratory system.

Now consider the patient circuit compliance. The effective compliance of the patient circuit is a combination of the tubing compliance and the compressibility of the gas inside it. As the ventilator delivers the breath to the patient, pressure at the airway opening rises relative to atmospheric pressure, which is the driving force for flow into the lungs. The patient circuit is connected between the ventilator and the airway, so the pressure it experiences across its walls is the same as that experienced by the respiratory system (remember that we are ignoring its resistance now, so we can ignore any pressure drop between the ventilator outlet and the airway opening). The volume change of the patient circuit tubing is different from that of the respiratory system because the compliance of the circuit is different. Because the patient circuit and the respiratory system fill with different volumes during the same inspiratory time, the flows they experience are different (remember that flow = volume ÷ time). Again borrowing a definition from electronics, if two circuit components share the same pressure drop but different flows, they are connected in parallel. Because they are in parallel, the two compliances are additive, so the total compliance is greater than either component.

Patient circuit compliance sometimes can be greater than respiratory system compliance and thus can have a large effect on ventilation. It must be accounted for either automatically by the ventilator or manually by increasing the tidal volume. For example, when ventilating neonates, patient circuit compliance can be as much as three times that of the respiratory system, even with small-bore tubing and a small-volume humidifier. Thus, when trying to deliver a preset tidal volume during volume-controlled ventilation, as little as 25% of the set volume will be delivered to the patient, with 75% compressed in the patient circuit. The compliance of the patient circuit can be determined by occluding the tubing at the patient *Y*, delivering a small volume under flow control (using zero positive end-expiratory pressure [PEEP]), and noting the resulting pressure. Using a short inspiratory hold will make it easier to read the pressure. Then compliance is calculated as before, by dividing the volume by the pressure. Once the patient circuit compliance is known, the set tidal volume can be corrected using the following equation:

$$V_{delivered} = \frac{V_{set}}{1+(C_{PC}/C_{RS})} \tag{1}$$

where $V_{delivered}$ is the tidal volume delivered to the patient, V_{set} is the tidal volume setting on the ventilator, C_{PC} is the patient circuit compliance, and C_{RS} is the respiratory system compliance.

We can get a more intuitive understanding of this equation if we put in some values. Suppose, for example, that we use the perfect patient circuit that has zero compliance. Substituting zero for C_{PC}, we get

$$\begin{aligned} V_{delivered} &= \frac{V_{set}}{1+(C_{PC}/C_{RS})} = \frac{V_{set}}{1+(0/C_{RS})} \\ &= \frac{V_{set}}{1+0} = \frac{V_{set}}{1} = V_{set} \end{aligned} \tag{2}$$

which shows that there is no effect on the delivered tidal volume. Suppose now that C_{PC} is as large as C_{RS} (i.e., $C_{PC} = C_{RS}$). Now we have

$$V_{delivered} = \frac{V_{set}}{1+(C_{PC}/C_{RS})} = \frac{V_{set}}{1+1} = \frac{V_{set}}{2} \tag{3}$$

in which case, half the volume from the ventilator goes to the patient, and the other half is compressed in the patient circuit. Some ventilators automatically compensate for gas lost to the patient circuit.[2]

The effect of the patient circuit is more troublesome during volume-controlled modes than during pressure-controlled modes. This is so because during volume control, the ventilator meters out a specific volume of gas, and unless it measures flow at the airway opening, it has no way of knowing how much goes to the patient and how much goes to the patient circuit. In contrast, during pressure-controlled modes, the ventilator simply meters out a set pressure change no matter where the gas goes. Because the respiratory system and the patient circuit compliance are in parallel, they both experience the same driving pressure (peak inspiratory pressure minus end-expiratory pressure), so tidal volume delivery is affected very little. The only effect might be that the patient circuit compliance may tend to increase the pressure rise time, which would tend to decrease peak flow and tidal volume slightly.

Another area where patient circuit compliance causes trouble is in the determination of auto-PEEP. There are several methods for determining auto-PEEP. One method to determine auto-PEEP during mechanical ventilation is to create an expiratory hold manually (i.e., delay the next inspiration) until static conditions prevail throughout the lungs (i.e., no flow anywhere in the lungs). The pressure at this time (total PEEP) minus the applied PEEP is an estimation of global auto-PEEP. Note that auto-PEEP may vary throughout the lungs depending on the distribution of lung disease and may not reflect pressure behind collapsed areas in patients with severe flow limitation. Auto-PEEP is an index of the gas trapped in the system at end expiration secondary to an insufficient expiratory time:

$$\text{measured auto-PEEP} = \frac{V_{trapped}}{C_{total}} \tag{4}$$

where $V_{trapped}$ is the volume of gas trapped in the patient and the patient circuit at end-expiration (above that associated with applied PEEP), and C_{total} is the total compliance of the

respiratory system and the patient circuit. The problem is that we want auto-PEEP to reflect the gas trapped in the patient, not in the circuit. If we know the compliances of the patient circuit and the respiratory system, we can correct the measured auto-PEEP as follows:

$$\text{true auto-PEEP} = \frac{C_{RS} + C_{PC}}{C_{RS}} \times \text{measured auto-PEEP} \quad (5)$$

where true auto-PEEP is that which exists in the lungs, measured auto-PEEP is the amount of end-expiratory pressure in equilibration with the lungs and the patient circuit, C_{RS} is the respiratory system compliance, and C_{PC} is the patient circuit compliance. If the ventilator displays auto-PEEP on its monitor, check the ventilator's operating manual to see whether or not the auto-PEEP calculation is corrected for patient circuit compliance. The larger C_{PC} is relative to C_{RS}, the larger will be the error. Again, the error will be most noticeable in pediatric and neonatal patients.

THE OPERATOR INTERFACE

The operator interaction with the ventilator mainly happens through the ventilator display. The display or interface has evolved in parallel with the ventilators. The key to this evolution are the technological advances in the last three decades.[2] The microprocessors, the digital displays, and the interactive screens have all permeated from other technological advances into the ventilator world. There are still remnants of the evolutionary process. In their initial ventilator generations, the interface had no or minimal manifestation of the interaction with the patient. The operator would enter the ventilator settings by using knobs or buttons that regulated simple functions (pressure, flow, or time). The results of these changes were evaluated in the patient clinical response, and occasionally through simple pressure analog displays. Some ventilators still use these type of displays (e.g., CareFusion 3100A high-frequency oscillator and Puritan Bennett LP-10, Fig. 3-8).

Most of the ventilators produced in the last decade have advanced displays, including liquid crystal displays and color touch screens with one or more multipurpose knobs or buttons. This allows the user to scroll through different menus and to select and activate the selections (e.g., Hamilton G5 ventilator, Fig. 3-9). The operator can customize the screen to the operator's needs. Current ventilators allow graphical displays of alarms, settings, respiratory system calculations, and measurements. The ventilator display evolution has not necessarily resulted in easier management of the ventilator. These advances brought issues with the amount of information displayed, the actions taken with that information, and the ease of use of certain interfaces.[6] As the level of sophistication has increased, we have been able to increase the number of ventilation parameters monitored. This requires a new level of training and understanding of human behavior. For example, a mode of ventilation may be preferentially chosen based on the amount of alarms it triggers,[7] or its ease of use.[6,8]

FIGURE 3-8 Puritan Bennett LP-10 home-care ventilator. (Image with permission from Nellcor Puritan Bennett LLC, Boulder, Colorado, doing business with Covidien.)

Operator Inputs

The operator input refers to parameters or settings entered by the operator of the ventilator. Each mode of ventilation has particular features, some of which can be adjusted by the operator. We describe here the most common adjustable parameters. The effect of each parameter on the lung is better understood under the light of the equation of motion (see Chapter 2).[9,10] A change of one parameter will lead to changes in others (i.e., in volume control, for the same respiratory characteristics changing the tidal volume will cause a change in peak airway pressure). Furthermore, knowing the basic construction and characteristics of a

FIGURE 3-9 G5 ventilator. (Reproduced with permission from Hamilton Medical, AG.)

mode of ventilation (volume vs. pressure control breaths) or the breath sequence (mandatory vs. spontaneous) will help understand how the setting will affect the ventilator output (see Chapter 2).

The operator input is presented below in the order that follows the progression of a breath; starting with the gas inhaled, to triggering, targeting, cycling, and baseline variables.

Inspired Gas Concentration

A mechanical ventilator has the capacity of delivering different mixtures of gas. Most ventilators allow the administration of specific concentrations of oxygen. A few allow the administration of helium, nitric oxide, or anesthesia gases.

OXYGEN

Oxygen is the most common gas administered to patients undergoing mechanical ventilation. The oxygen percentage in the inspired gas (FI_{O_2}) can be regulated in most ventilators by means of a direct adjustment of a specific control (21% to 100%). However, this is not true for all ventilators. For example, some home ventilators (e.g., LP-10 or the LTV 1150, Pulmonetic, CareFusion) use a connection to a low-pressure oxygen source to the ventilator or the patient circuit. The following formula can calculate the flow of oxygen to achieve a desired oxygen concentration:

$$O_2 \text{ required} = \frac{f \times V_T \times (\text{desired } FIo_2 - 0.21)}{0.79} \qquad (6)$$

where O_2 required is 100% oxygen flow in L/min, f is the breathing frequency in breaths/min, V_T is the tidal volume in liters and the FI_{O_2} is the patient O_2 concentration desired in decimal format (i.e., 30% = 0.3). An oxygen analyzer should be used to confirm the measurements. It must be recognized that changes in oxygen flow, breathing rate, or tidal volume will change the FI_{O_2}.

When transporting the critically ill patient, availability of oxygen supplies for the mechanically ventilated patient is crucial. Size and weight of cylinders makes transport difficult and presents an increased risk of fire. Branson et al. have described a solution using a portable oxygen concentrator (SeQual Eclipse II) paired with the Impact 754 and Pulmonetics LTV-1200 ventilators.[11]

For the rest of the current mechanical ventilators, the ventilator adjusts the mixture of air and oxygen to achieve the desired FIo_2. The mixing of air is achieved by an internal or external blender. A blender may use proportioning valves that regulate the flow of air and oxygen to a mixing changer (Fig. 3-10). It is similar to the mechanism used to mix hot and cold water in a shower—the more oxygen needed, the larger the opening for oxygen and the smaller it is for air. To work properly, the blender requires a constant pressure within the working ranges of the device.

Most current ventilators have oxygen sensors to monitor the FI_{O_2}. The oxygen sensor gives feedback to the operator to adjust the mixture, or alarms if there is a discrepancy between the set and delivered FI_{O_2}. The oxygen sensors detect changes in electrical current, which is proportional to the oxygen concentration. The most common techniques are: (a) paramagnetic, (b) polarographic, and (c) galvanic.[12]

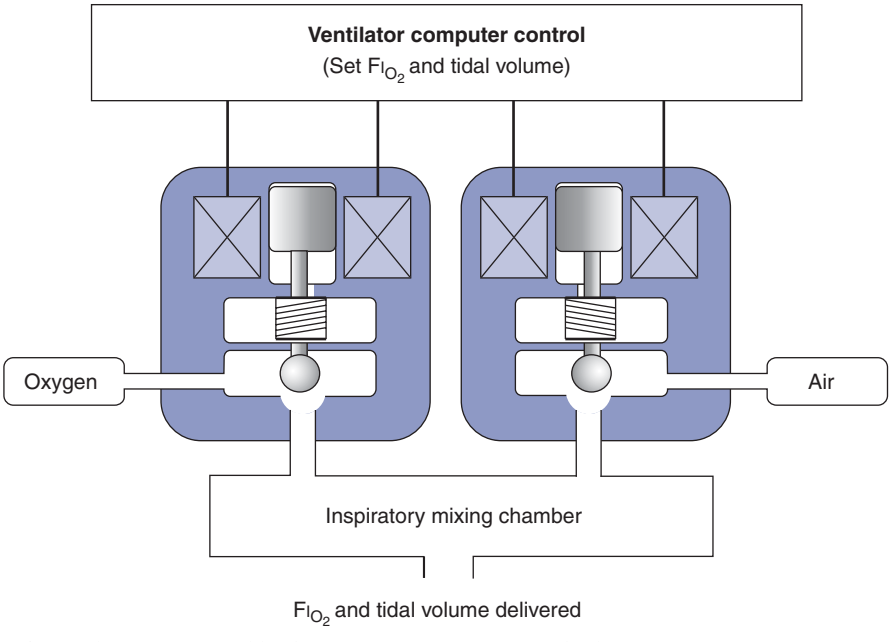

FIGURE 3-10 Schematic of a ventilator air–oxygen blending system using proportional valves.

TABLE 3-1: PROPERTIES OF PURE GASES AND AIR

Gas	Thermal Conductivity (κ) (μcal · cm · s · °k)	viscosity (η) (Micropoises)	Density (ρ) (g/L)
Helium (He)	352.0	188.7	0.1785
Nitrogen (N_2)	58.0	167.4	1.251
Oxygen (O_2)	58.5	192.6	1.429
Air	58.0	170.8	1.293

HELIOX

Mixtures of helium and oxygen (heliox, HeO_2) instead of air and oxygen are occasionally used to help patients on mechanical ventilation with obstructive airway diseases. Helium is less dense than air (Table 3-1).[13] The decrease in density interferes with flow measurements, inspiratory and expiratory valve accuracy, and gas mixing.[14] Several studies have evaluated the performance of mechanical ventilators delivering heliox[14–16] and have shown that heliox does affect the performance of the ventilator. The interference of heliox is more evident in volume-control modes than in pressure-control modes.[14,17] In pressure-control mode, the ventilator targets a set inspiratory pressure and the delivered tidal volume is dependent only on the mechanical properties of the respiratory system. The time constant may decrease but the delivered volume should be the same as for nonheliox gas delivery. In volume-control mode, delivered volume may be larger than, smaller than, or the same as expected depending on the design of the ventilator.[14] Only a few ventilators (Maquet Servo *i* with heliox option, Hamilton G5 with heliox option, and the Viasys Avea with comprehensive model) are designed and calibrated for heliox delivery. Otherwise, the operator needs to be aware of the specific ventilator performance and correction formulas and factors[14] such that potentially hazardous conditions do not develop.

NITRIC OXIDE

Inhaled nitric oxide (NO) is used as selective pulmonary vasodilator for patients with pulmonary hypertension, life-threatening hypoxia, or right-heart failure. Different devices to deliver NO have been described in the literature. Most of them were custom made and required the use of mixing chambers, stand-alone NO/nitric dioxide monitors, and manual titration of the gas flow. The large amount of custom-made devices led to inconsistent administration of NO.[18] In 1998, the American Society for Testing Materials (ASTM) committee on anesthetic and respiratory equipment developed a standard to provide a minimum degree of safety of the devices used to deliver NO. The recommendation was to use a NO administration apparatus, and a NO/nitrogen dioxide analyzer. The Food and Drug Administration (FDA) enforces this recommendation, and so far, only one device is approved in the United States. The INOvent (Ikaria Inc, Clinton, NJ) delivery system uses a closed-loop scheme to measure and deliver NO in proportion to the inspiratory flow from the ventilator. NO is injected in the proximal limb of the inspiratory circuit, and measured close to the connection between the patient circuit and the endotracheal tube. Two portable systems are available—INO Max DS (Ikaria) and AeroNOx (PulmoNOx, Alberta, CA). As these devices are not universally available, the following formula[19] can be used to calculate the NO flow rate required to achieve a desired concentration of NO when injected in the inspiratory limb at a constant gas flow,

$$Q_{NO} = \left(\frac{C_{NOset}}{C_{NOcyl} - C_{NOset}}\right) \times Q_V \qquad (7)$$

where Q_{NO} is the flow rate of nitric oxide in L/min, C_{NOset} is the desired NO concentration in parts per million (ppm), C_{NOcyl} is the NO concentration in the cylinder in ppm (usually 800 ppm) and the Q_V is the ventilator gas flow.

The formula is accurate for constant flow systems. This presents a major problem when used with intermittent breaths (as most modes of ventilation) the patient will receive variable amounts of NO (a "bolus" with each mechanical breath).[20] Furthermore, whenever the ventilator settings or the patient breathing pattern changes, the NO delivery will change. Finally, the use of NO will alter the gas delivery of the ventilator. For example, the INOvent system will add gas to and extract gas from the delivered breath. At 80 ppm it adds 10% more gas, although it also withdraws 230 mL/min through the gas-sampling port. Thus, the oxygen delivered will decrease, and the tidal volume may increase. The changes seem to be small (unless you see it in pediatric proportions), but it may affect the ventilator's performance. Furthermore, as a flow of gas is introduced, the flow-triggering performance may be affected.

Trigger Variables

A ventilator-assisted breath can be started (triggered) by the machine or the patient. A machine-triggered breath is defined by the start of the inspiratory phase *independent*

of any signal from the patient. The operator typically sets a breath frequency for machine-triggered breaths. A patient-triggered breath is one for which inspiration is started solely by a signal from the patient. The key operator set variable for patient triggering is sensitivity, or the magnitude of the patient signal required to initiate inspiratory flow. The patient signal can be obtained from measuring the airway pressure, flow, volume, electromyogram (EMG),[21] abdominal motion (Graseby capsule[22]), thoracic impedance,[23] or any other measurable signal of respiratory activity.[24] Most intensive care ventilators measure pressure and flow (volume is integrated from flow) at the circuit. There are only a few ventilators that use other sources of signaling, diaphragmatic EMG (Servo *i* NAVA), thoracic impedance (Sechrist SAVI), and abdominal motion (Infant Star STAR SYNC, which is no longer commercially available).[24,25]

Ventilator triggering characteristics can be evaluated using different metrics.[23,26–28] The most sophisticated device for evaluating ventilator performance is the ASL lung simulator (IngMar Medical Ltd., Pittsburgh, PA). This device can simulate both passive lung mechanics (e.g., resistance and compliance) as well as patient inspiratory and expiratory effort. It can display and record pressure, volume, and flow signals, and calculate a wide variety of performance metrics. Figure 3-11 shows an example of these waveforms with specific reference points for calculating performance metrics (from operator's manual for software version 3.2). Using these reference points we can define the following key trigger metrics: P_{min} (maximum pressure drop relative to PEEP during the trigger phase), pressure-time product ($\int Paw–PEEP\,dt$ from start of effort to return of airway pressure [Paw] to PEEP), patient trigger work ($\int Paw–PEEP\,dv$ from start of effort to return of Paw, to PEEP), and time to trigger (period from the start of effort to the return of Paw to PEEP).

TIME

Time is measured by the internal ventilator processor. The next breath is time triggered (in the absence of a patient trigger event) when the expiratory time has reached the threshold to maintain a set respiratory rate (e.g., if the set rate is 10 breaths per minute and the inspiratory time is set at 1 second, then the expiratory time is 5 seconds). Some modes allow the user to set the inspiratory and expiratory time [e.g., airway pressure release ventilation (APRV) and biphasic], thus fixing the inspiratory-to-expiratory timing (*I:E*) ratio and respiratory rate. In an effort to improve patient–ventilator interactions, the ventilator may synchronize the mandatory breath with the patient's triggering signal if it falls within a threshold. The classic example is synchronized intermittent mandatory ventilation (SIMV). More recently APRV, as programmed in the Evita XL, delivers a machine breath if the patient trigger signal falls within 25% of the triggering time.[29] Time triggering is also found as a safety mechanism. The operator or manufacturer enters a time after which the apnea alarm will trigger the delivery of a preset breath after a preset time is reached.

PRESSURE

The patient inspiratory effort causes a drop in pressure in the airway and the circuit. Inspiration starts when pressure falls below the preset "sensitivity" threshold. The site of measurement will have an impact on the performance of the device. Pressure signals travel at the speed of sound, approximately 1 ft/ms.[30] The farther the sensor is from the signal source, the longer the potential time delay. The closest measurements can be done in the trachea. Tracheal pressure measurements reflect actual airway pressure as the endotracheal tube resistance is bypassed. When used for ventilator

TABLE 3-2: ADVANTAGES AND DISADVANTAGES OF THE DIFFERENT CIRCUIT PRESSURE-SENSING SITES

Advantages	Disadvantages
A. Exhalation port: Well protected from mechanical abuse. During mechanical inhalation, accurately reads pressure at the Y. During inhalation, increases in inspiratory or expiratory circuit resistance do not compromise inspiratory flow output, except for manyfold increases.	Requires protection from moisture of exhaled gas. During spontaneous inspiration, underestimates pressure generated at the Y to trigger the ventilator. During exhalation, underestimates pressure at the Y. During exhalation, increases in expiratory circuit resistance compromise expiratory flow. Hence, system requires well-maintained expiratory filter to ensure that expiratory circuit resistance remains low.
B. Inhalation port: Well protected from mechanical abuse. Does not require protection from moisture or additional filters. During exhalation, accurately reads pressure at the Y as long as the inspiratory circuit remains patient. During inhalation, increases in expiratory circuit resistance do not compromise inspiratory-flow output.	During mechanical inhalation, overestimates pressure at the Y. During spontaneous inspiration, underestimates pressure generated at the Y to trigger the ventilator. During inhalation, increases in inspiratory circuit resistance compromise inspiratory flow output. For example, factors such as selection of humidifier and type of patient circuit yield varying patient inspiratory efforts for fixed ventilator settings.
C. Patient Y: During inhalation and exhalation, accurately reads both inspiratory and expiratory pressures. Pressure readings reflect relative condition of inspiratory and expiratory circuits.	Susceptible to mechanical abuse. Requires a separate pressure-sensing tube, which is prone to occlusion, blockage, and disconnection, all of which prevent sensing of patient effort.

Source: Modified, with permission, from Sassoon CSH. Mechanical ventilator design and function: the trigger variable. *Respir Care*. 1992;37:1056–1069.

triggering, tracheal pressure sensing results in decreased work of breathing.[31–33] However, tracheal pressure measurements are not routinely done and require special equipment (endotracheal tube with monitoring port) and no current ventilator uses it to routinely trigger the ventilator.

The other sites of pressure measurement are the patient circuit Y or at the inspiratory or expiratory ports, each with its advantages and disadvantages (Table 3-2). Trigger performance will also be affected by the presence of humidifiers, filters, water condensation, patient circuit and exhalation valves. These will most often dampen, or rarely amplify, the pressure signal. Clinically, the presence of a dampened signal will require a larger pressure change (higher work of breathing) to reach the trigger threshold. On the contrary, presence of water in the pressure tubing may cause oscillation, which can falsely trigger mechanical breaths.

The trigger pressure sensitivity is usually set at 0.5 to 1.5 cm H_2O below the baseline pressure. Common practice is to increase the sensitivity (i.e., decrease the pressure drop) until autotriggering occurs and then reduce sensitivity until the autotriggering just stops.[30] Note that each ventilator comes with predetermined manufacturer set values and can be adjusted.

FLOW

Flow triggering is based on the detection of a change in a constant, small, baseline (bias) flow through the patient circuit. The operator sets a flow sensitivity threshold. When the change in flow reaches the threshold, a breath is delivered. The changes in flow are detected at the expiratory valves or by a flow sensor in the patient circuit. The ventilator measures the flow from the ventilator and from the patient. In a closed circuit, the two flow values should remain equal in the absence of patient effort. When the patient makes an inspiratory effort, the expiratory flow drops, creating a difference between the inspiratory and expiratory flow values. When the difference in values reaches the preset sensitivity threshold, a breath is delivered. Some systems (Puritan Bennett, 7200) allow the operator to set both the bias flow and the trigger sensitivity. Newer devices set the bias flow according to the operator selected value for the triggering sensitivity. For example, the Puritan Bennett 840 sets the flow 1.5 L/min above the selected sensitivity, and the Hamilton G5 automatically sets the bias flow equal to two times the set sensitivity threshold. As a backup, if flow sensor is kinked or taken out of line, an internal pressure trigger of −2 cm H_2O is used until the flow sensor is "online" again.

Flow change may be detected by placing a sensor just before the endotracheal tube. The close proximity to the patient may enhance triggering. It, however, exposes the sensor to secretions and moisture, which may affect its performance. Flow triggering seems more efficient than pressure triggering in terms of work of breathing.[34] This, however, seems of no particular clinical relevance in the presence of appropriately set pressure triggering.[35] Flow sensing may cause autotriggering secondary to noninspiratory flow changes. The flow change can happen in either the ventilator circuit (leak in the circuit or endotracheal tube) or the patient (cardiogenic oscillations or bronchopleural fistula).[36,37]

A novel approach to flow triggering is offered on the Dräger Infinity V500 ventilator in the APRV mode. Rather than setting a T-low time to determine the time triggering of each mandatory breath, the operator may set a percent of peak *expiratory* flow as the trigger threshold.

VOLUME

A breath may be triggered when a preset volume is detected as the result of a patient inspiratory effort. This is similar to

flow triggering but using volume has the theoretical advantage of being less susceptible to signal noise (i.e., integrating flow to get volume cancels out some noise because of flow oscillations). Volume triggering is rare in ventilators but can be found on the Dräger Babylog VN500 infant ventilator.

DIAPHRAGMATIC SIGNAL

The ideal approach to coordinate a mechanical ventilator with the patient inspiratory effort would be to use the neural output of the respiratory center. Direct measurement of the respiratory center output is currently not possible. The phrenic nerve has been used as a trigger signal in animal models,[38,39] but not in humans. The only available clinical approach is measurement of the diaphragmatic electrical activity (Edi). Because the Edi is an electric signal, it easily becomes contaminated by the electrical activity of the heart, the esophagus, and other muscles.[21] More importantly, the Edi requires an intact respiratory center, phrenic nerve, neuromuscular junction, and assumes that the diaphragm is the primary inspiratory muscle (e.g., rather than accessory muscles of ventilation).

The only clinically available system that uses diaphragmatic signal trigging is the neurally adjusted ventilatory assistance (NAVA) system. An esophageal catheter is used to measure the Edi. The sensitivity is set by entering a value above the background electrical noise. The trigger value is set in microvolts and represents the change in the electrical signal rather than an absolute value.[40] The default setting is 0.5 microvolts, but it can be adjusted from 0 to 2 microvolts. As a backup trigger signal in the absence of a measurable Edi, NAVA uses flow or pressure triggering, whichever happens first.

OTHER SIGNALS

The BiPAP Vision (Respironics Inc., Murrysville, PA) uses a triggering mechanism called *shape-signal*. The ventilator microprocessor generates a new flow signal, which is offset from the actual flow by 0.25 L/s and delays it for 300 milli seconds. The delay causes the flow shape signal to be slightly behind the patient's flow rate. The mechanical breath is triggered when a sudden decrease in expiratory flow from an inspiratory effort crosses the shape signal.[41]

The Sechrist SAVI system (Sechrist Industries, Anaheim, CA) is the only mode available that uses transthoracic electrical impedance to trigger the ventilator.[25] The thoracic impedance is obtained by placing two chest leads, one in the anterior axillary line on the right and the other in the posterior axillary line on the left. The sensors are placed high enough to avoid costal and subcostal retractions. The chest sensors measure the electrical impedance across the human body. As a breath occurs, the transthoracic impedance changes as a result of a different ratio of air-to-fluid in the thorax. The triggering threshold can be adjusted. The cardiac cycle may also cause interference with the signal.[22,25]

Target Variables

During inspiration, the variable limiting the magnitude of any parameter is called the target variable (previously known as the limit of the control variable, but the term *limit* is now reserved for alarm and safety conditions rather than control settings).[42]A target is a predetermined goal of ventilator output. Targets can be viewed as the parameters of the targeting scheme (see Chapter 2). *Within-breath targets* are the parameters of the pressure, volume, or flow waveform. Examples of within-breath targets include inspiratory flow or pressure rise time (set-point targeting), inspiratory pressure and tidal volume (dual targeting), and constant of proportionality between inspiratory pressure and patient effort (servo targeting). *Between-breath targets* serve to modify the within-breath targets and/or the overall ventilatory pattern. Between-breath targets are used with more advanced targeting schemes, where targets act over multiple breaths. A simple example of a between-breath target is to compare actual exhaled volume to a preset between-breath tidal volume so as to automatically adjust the within-breath constant pressure or flow target for the next breath. Examples of between-breath targets and targeting schemes include average tidal volume (for adaptive targeting), percent minute ventilation (for optimal targeting), and combined partial pressure of carbon dioxide, volume, and frequency values describing a "zone of comfort" (for intelligent targeting).

PRESSURE

The ventilator uses microprocessors to control the delivery of pressure. The pressure can be delivered with any pressure profile and in response to many signals. Currently, most modes of ventilation in which inspiratory pressure is targeted deliver the pressure rapidly and attempt to maintain the pressure constant throughout the inspiratory phase (square waveform). This means that the performance of the ventilator depends on the delivery of the pressure waveform and any departure from the ideal waveform leads to differences in performance between ventilators.[43,44]

Inspiratory Pressure. The pressure rise during inspiration associated with volume and flow delivery is set by the operator (pressure control–continuous mandatory ventilation) or closed-loop algorithms (e.g., pressure-regulated volume control). Care should be exercised while setting the ventilator or reading the literature as there is significant variability between ventilator manufacturers and peer-reviewed literature in the definitions and nomenclature related to inspiratory pressures.[43] The main problem stems from what historically has been used to define the inspiratory pressure. For example, in the same ventilator, for

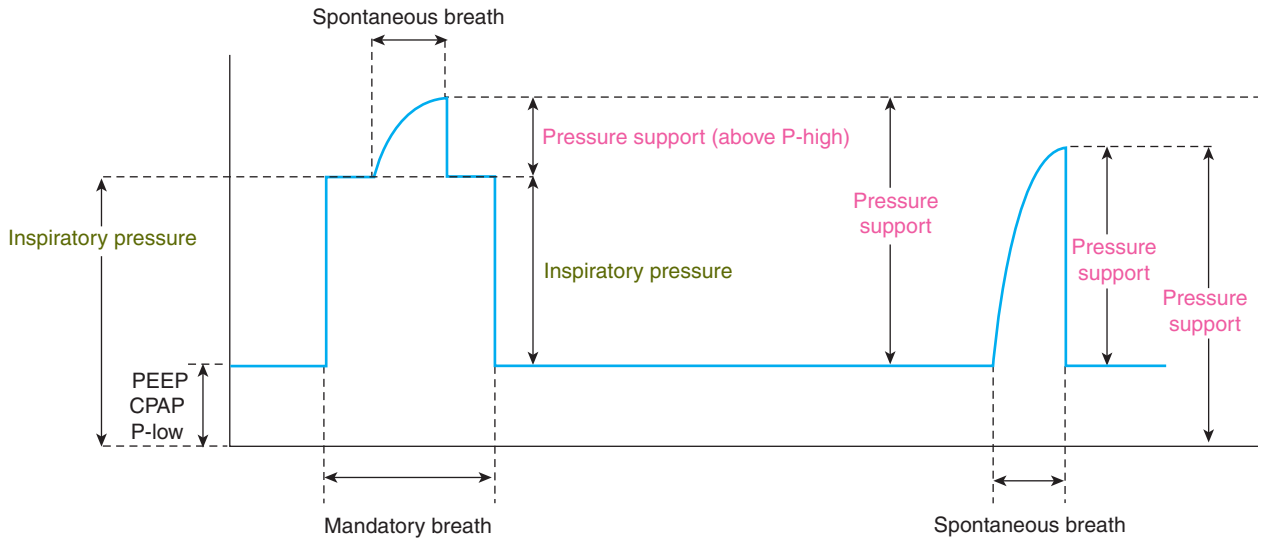

FIGURE 3-12 Idealized airway pressure waveform showing various conventions used for pressure parameters. Note that there are two ways to define inspiratory pressure for mandatory breaths (*green*) and four ways to define inspiratory pressure (i.e., pressure support) for spontaneous breaths (*red*). *CPAP*, continuous positive airway pressure; *PEEP*, positive end-expiratory pressure; *P-high*, high pressure; *P-low*, low pressure. (Reproduced, with permission, from Chatburn RL, Volsko TA. Documentation issues for mechanical ventilation in pressure-control modes. *Respir Care.* 2010;55(12):1705–1716.)

pressure control–continuous mandatory ventilation breaths the peak inspiratory pressure is stated in reference to the set end-expiratory pressure (PEEP), but for APRV the peak inspiratory pressure is stated in reference to the atmospheric pressure. To compound the confusion, on some ventilators the value of pressure support is set relative to PEEP (e.g., Drager Evita XL, Puritan Bennett 840), on others (LTV 950) pressure support is set relative to the atmospheric pressure (i.e., atmospheric pressure = zero airway pressure), and on at least one ventilator (BiVent in Servo *i*) pressure support may be set relative to inspiratory pressure (P-high). Figure 3-12 illustrates the two different ways used to define inspiratory pressure and the four different ways to define pressure support. Figure 3-13 illustrates the proposed solution to this problem.[43] In this proposal, the term *inspiratory pressure* is defined as the set change in airway pressure during inspiration relative to set end-expiratory airway pressure during pressure-control modes.

On some ventilators, inspiratory pressure rise is set relative to atmospheric pressure rather than set end-expiratory pressure. To distinguish this from inspiratory pressure as defined relative to PEEP, the term *peak inspiratory pressure* has been proposed.[43] In contrast "peak *airway* pressure" is the *measured* peak airway pressure relative to atmospheric pressure. Often, for a good pressure-control system, there is seemingly no difference between set peak inspiratory pressure and measured peak airway pressure on the airway-pressure waveform during pressure-control modes. And even if the operator sees a transient small difference, this is not considered clinically important in most nonalarm cases. This leads clinicians to conceptually oversimplify what they see and make the mistake of assuming inspiratory pressure and peak airway pressure are synonymous. For example, measured peak airway pressure is often higher than set peak inspiratory pressure because of pressure transients from an underdamped pressure-control system or noise from patient movement. The introduction of the so-called active exhalation valve made possible unrestricted spontaneous breaths during the inspiratory phase of a mandatory pressure-control breath. New modes brought new terms. For example, P-high or PEEP high refers to the peak inspiratory pressure above atmospheric pressure in APRV (again, there is no standardization of either terminology or symbology in this mode).

P_{max}. The Drager Evita XL, when set in volume-control modes, allows the operator to set the maximum pressure (P_{max}) that can be achieved during the delivery of a mandatory breath. The goal is to prevent pressure peaks while maintaining the set tidal volume. When the P_{max} is reached during a given inspiration, the ventilator switches from volume control to pressure control (dual targeting) using the P_{max} setting as the inspiratory pressure target. If the set tidal volume cannot be reached in the set inspiratory time, the ventilator will alarm.[45]

Rise Time. The speed with which the airway pressure reaches the set inspiratory pressure is called the *rise time*. (Rise time for flow can be set in the Maquet Servo *i*, but this feature is rare on ventilators.) The rise time may be set by the operator or automatically adjusted based on a computer algorithm (e500, Newport Medical Instruments Inc, Newport Beach, California). The name used to indicate pressure rise time varies by ventilator brand (e.g., inspiratory

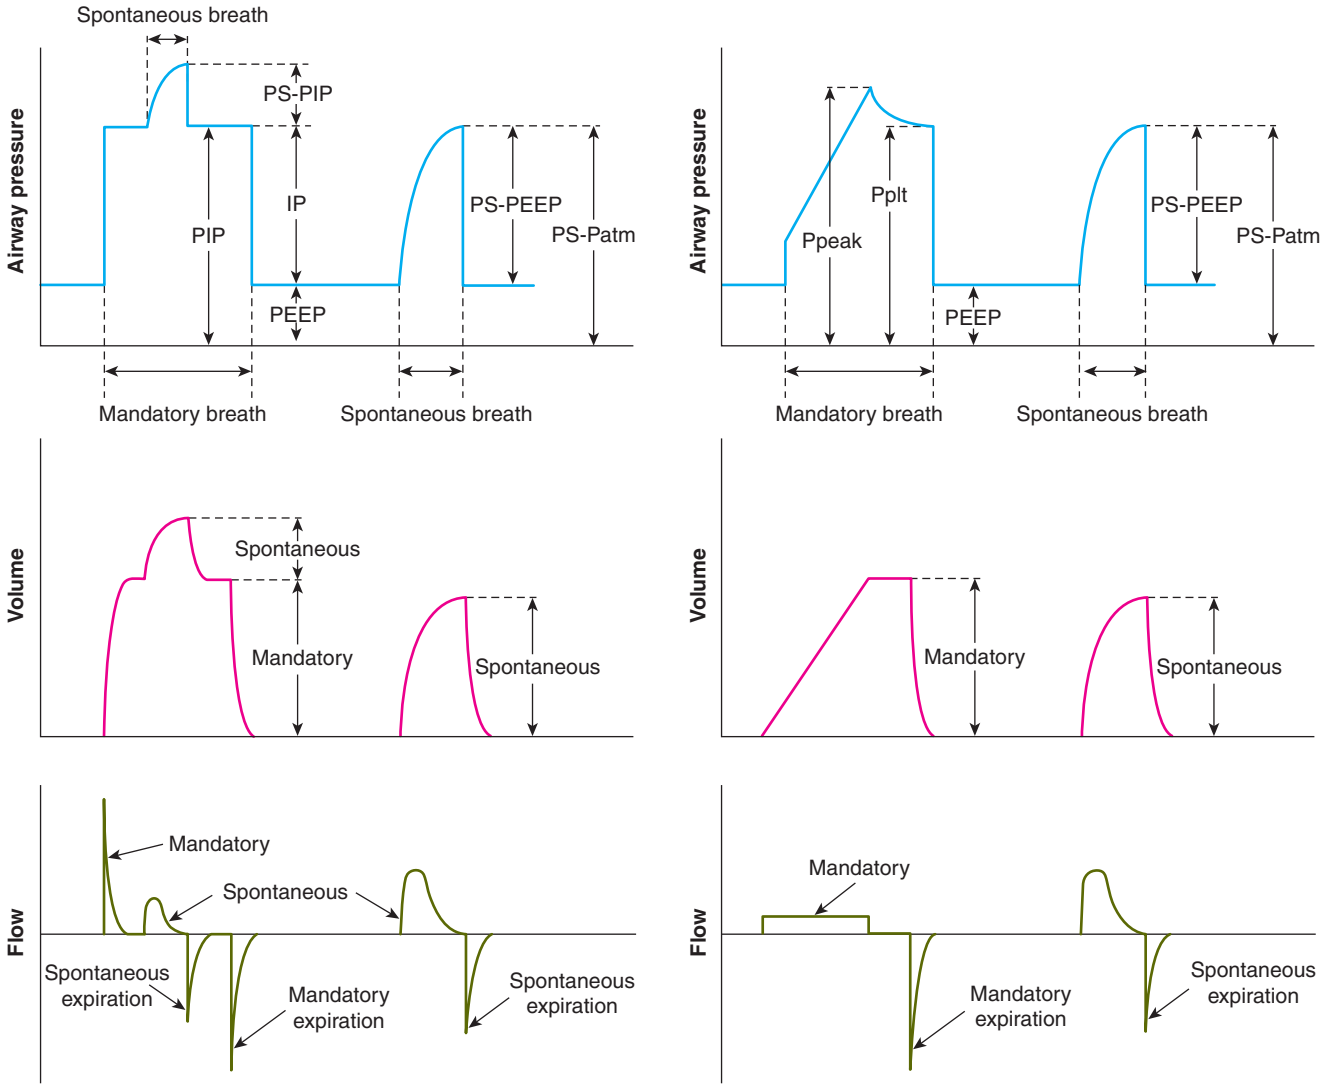

FIGURE 3-13 Idealized pressure, volume, and flow waveforms for pressure control and volume control illustrating the use of proposed conventions for both set and measured airway pressures. *IP*, inspiratory pressure; *PEEP*, positive end-expiratory pressure; *PIP*, peak inspiratory pressure; *Ppeak*, peak pressure; *Pplt*, plateau pressure; *PS-Patm*, pressure support relative to atmospheric pressure; *PS-PEEP*, pressure support relative to positive end expiratory pressure; *PS-PIP*, pressure support relative to peak inspiratory pressure. slope, P-ramp, plateau%, and slope rise time). Adjusting the rise time influences the synchronization between the patient and the ventilator secondary to changes in the initial inspiratory flow rate. The lower the rise time, the faster the pressurization rate[46] and the higher the peak inspiratory flow.[47] A higher initial inspiratory flow rate may decrease the work of breathing but can lead to patient discomfort and worse patient–ventilator synchrony. Conversely, too slow a rise time may result in increased work of breathing and longer mechanical inspiratory time, leading to a dissociation between patient breathing effort and the mechanical breath. That is, the relation between work of breathing, respiratory drive, and comfort with the duration of the rise time is not proportional.[46,48] Because rules for setting an optimal rise time are lacking, based on these studies, both very rapid and slow rise time should be avoided. A more gradual rise may be needed in awake patients (for comfort) or patients with low compliance to prevent pressure overshoot and premature cycling of inspiration (Fig. 3-14).

TIDAL VOLUME

The operator is required to enter a tidal volume in any volume-control mode. This may be a direct setting or an indirect one by setting frequency or minute ventilation. The ventilator will control the tidal volume and the pressure will be the dependent variable. A tidal volume target, however, may also be set when the mode uses adaptive targeting in pressure control (e.g., pressure-regulated volume control [PRVC] on the Maquet ventilators).[49] In such a case, inspiratory pressure

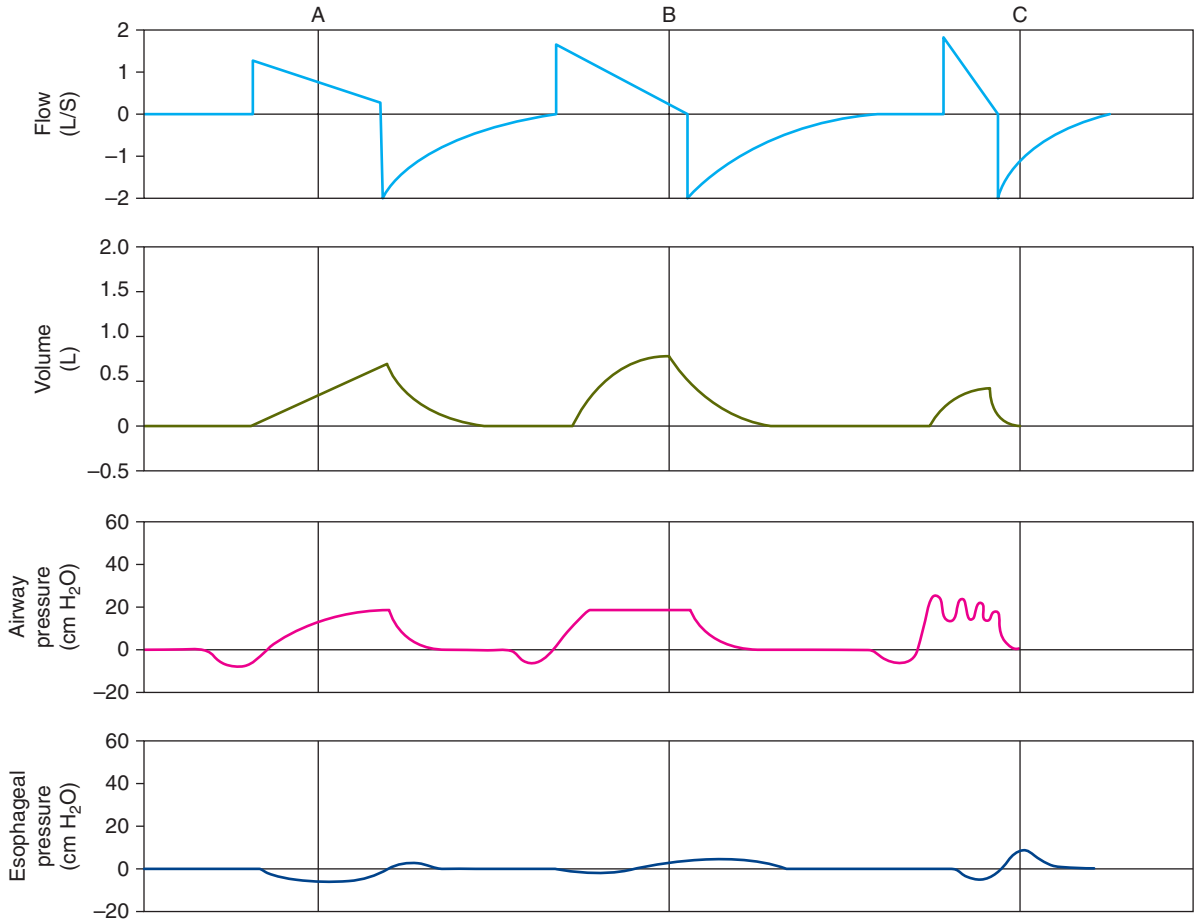

FIGURE 3-14 Examples of different pressure rise times in three breaths in pressure-support mode. **A.** Rise time is set very low, resulting in a lower peak inspiratory flow. **B.** Rise time is set higher, resulting in a higher peak flow and shorter inspiratory time. **C.** Rise time is set very high, resulting in "ringing" of airway pressure signal and peak flow that is uncomfortable to the patient, who exerts an expiratory effort and prematurely terminates inspiration (indicated by the positive deflection of esophageal pressure). (Reproduced, with permission, from Macintyre NR. Patient-ventilator interactions: optimizing conventional modes. *Respir Care*. 2011;56(1):73–81.)

is automatically adjusted between breaths by the ventilator to achieve an average measured tidal volume equal to the operator set target. There are four basic ways ventilators deliver a preset tidal volume (from least used to most commonly used):

1. By measuring the volume delivered and using the signal in a feedback control loop to manipulate the volume waveform.
2. By the displacement of a piston or bellows. An example of this is the Puritan Bennett LP10 home-care ventilator (piston) or some anesthesia ventilators (bellows).
3. By controlling the inspiratory pressure within a breath and automatically adjusting it between breaths to deliver a minimum set tidal volume. The volume delivered is targeted by a closed-loop algorithm, known as adaptive pressure control (see Chapter 2). This targeting scheme is available in most modern critical care ventilators under multiple names (e.g., PRVC, autoFlow, VC+, APV). A common confusion is that this is a volume-control mode, when, by the equation of motion, what is being controlled is pressure during a breath. A caveat with this targeting scheme is that in the presence of the patient's inspiratory efforts, the tidal volume may be higher than set, and the support provided by the ventilator may be inappropriately low.[50,51]
4. By controlling flow, the volume delivered is indirectly controlled. Because flow and volume are inverse functions of time (i.e., volume is the integral of flow and flow is the derivative of volume), controlling one controls the other. In simple ventilators, there is no feedback signal for flow, just a known flow for an adjustable amount of inspiratory time. On more sophisticated ventilators, the operator can regulate the shape of the inspiratory flow waveform. A square waveform will create higher peak airway pressures and will require less time to deliver the set volume (which may result in lower mean airway pressures) than a descending ramp pattern.[52–54] Some ventilators offer one waveform (e.g., the Dräger Evita XL offers only the

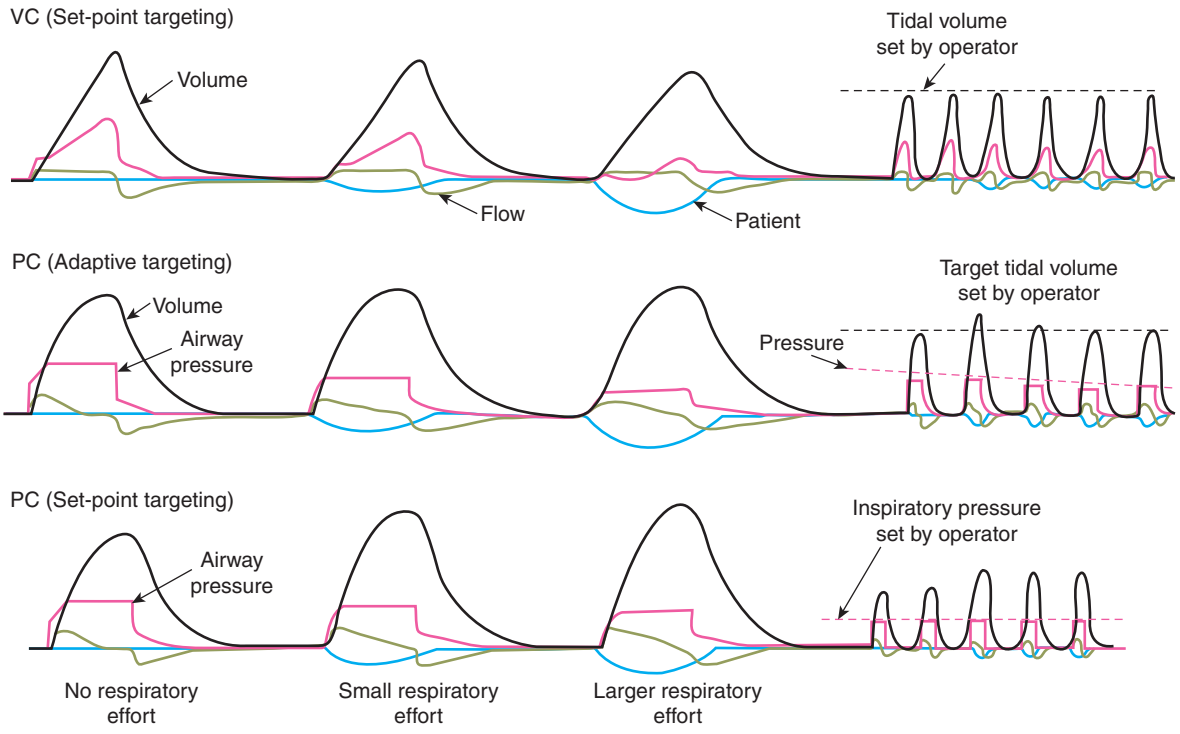

FIGURE 3-15 Volume delivery in volume control (VC) and pressure control (PC) modes using set-point targeting versus pressure control using adaptive targeting. Notice how tidal volume (flow) remains constant in volume control with set-point targeting in the setting of increased patient effort. In adaptive pressure targeting, the inspiratory pressure is adjusted by an algorithm to keep the tidal volume at a target. The tidal volume, however, may be larger if the patient effort is large enough. In set-point pressure targeting, the pressure remains constant, and the tidal volume increases in response to patient effort.

square waveform) others have more (e.g., the Hamilton Veolar offers 50% or 100% descending ramps, sinusoidal, and square).[55] Most current ventilators only provide the square waveform or a descending ramp profile.

Figure 3-15 compares volume delivery between standard volume and pressure control modes versus modes using adaptive pressure control.

MINUTE VENTILATION

In volume-control modes, the minimum minute ventilation is set by entering the tidal volume and respiratory rate. This assures that the patient will receive a minimum amount of ventilatory support. Some modes provide the option to enter a target minute ventilation (as a percent of the calculated minute ventilation for a given ideal body weight, adaptive-support ventilation [ASV]; e.g., Hamilton G5), while others will calculate it from the entered tidal volume and respiratory rate (mandatory minute volume [MMV]; e.g., Dräger Evita XL). The concept of automatically adjusting the ventilator settings to maintain a constant minute volume was first described by Hewlett and Plat in 1977.[56] As implemented, for example, on the Dräger Evita XL ventilator, MMV is a form of volume control–intermittent mandatory ventilation. The operator presets the target minute ventilation by setting tidal volume and frequency. The ventilator then monitors the total minute ventilation as the sum of the minute ventilations generated by mandatory and spontaneous breaths. If the total minute ventilation is below the target value, the mandatory breath frequency will increase. As long, however, as the spontaneous minute ventilation is at least equal to the target value, mandatory breaths will be suppressed. In this way, the proportion of the total minute ventilation generated by spontaneous breaths can range from 0% to 100%. As a result, MMV may be considered a mode of automatic weaning.

Another version of MMV was used on the Hamilton Veolar ventilator (now obsolete); the target minute ventilation was maintained by automatic adjustment of inspiratory pressure (adaptive pressure support). That mode was replaced by ASV on newer Hamilton ventilators.[49] ASV is the only commercially available mode to date that uses optimal targeting. It was first described by Tehrani in 1991.[57] The operator inputs the patient's height and percent of minute ventilation to be supported (25% to 350%). The ventilator then calculates the ideal body weight and estimates the required minute alveolar ventilation assuming a normal dead space fraction. Next, an optimum frequency is calculated based on work by Otis et al[9] that predicts a frequency resulting in the least mechanical work rate. The target tidal volume is calculated as minute ventilation divided by

TABLE 3-3: DETERMINANTS OF MINIMUM AND MAXIMUM MINUTE VENTILATION FOR SOME COMMON MODES

Mode Name	A/C	SIMV	MMV	ASV	Smart Care
Operation	Operator enters a set rate and tidal volume. Patient may trigger breaths above set rate.	Operator enters a set rate and tidal volume. Patient may breath in between mandatory breaths with or without assistance.	Operator enters a set rate and tidal volume. Patient may breath with or without assistance. If his minute ventilation falls below minimum, then mandatory breaths initiate at a set rate.	Adaptive pressure control breaths target tidal volume and rate according to mathematical model.	Pressure support is titrated based on expert rules to achieve the range $etPCO_2$.
Control variable	Volume	Volume	Volume	Pressure	Pressure
Breath sequence	CMV	IMV	IMV	IMV	CSV
Minimum minute ventilation	set $V_T \times$ set f	set $V_T \times$ set f	set $V_T \times$ set f	Targeted by ventilator based on operator-entered body weight.	Targeted by ventilator to maintain "comfort zone" based on V_T, f, and $etPCO_2$.
Maximum minute ventilation	Variable: $V_T \times$ total f	Variable: $V_T \times$ total f	Variable: $V_T \times$ total f	Variable but ventilator will reduce support if patient attempts to increase above estimated minute ventilation requirement.	Variable but ventilator will reduce support if patient attempts to increase above estimated minute ventilation requirement.

Abbreviations: *A/C*, assist/control; *ASV*, adaptive support ventilation; *$etPCO_2$*, end-tidal pressure of carbon dioxide; *f*, ventilatory frequency—total f reflects the sum of machine- and patient-triggered breaths; *MMV*, mandatory minute volume; *SIMV*, synchronized intermittent mandatory ventilation; *V_T*, tidal volume.

respiratory frequency (MV/f). In ASV, there are two breath patterns based on the patient's respiratory effort. If there is no patient effort, the ventilator delivers adaptive pressure-control ventilation; if there is patient effort, the patient receives adaptive pressure support. In both instances, the inspiratory pressure within a breath is controlled to achieve a target tidal volume.[49]

Table 3-3 summarizes the determinants of minimum and maximum minute ventilation for some common modes.

INSPIRATORY FLOW

The inspiratory flow can be adjusted by the operator on most ventilators that provide volume-control modes (see "Tidal Volume" above). In general, the ventilator operator will choose a peak flow and may have some waveform pattern options (e.g., square waveform or descending ramp). Although these settings appear simple, there are several points that may cause differences in performance and interpretation of data. First, the ventilator uses a microprocessor to control the delivery according to the preset tidal volume, inspiratory time, flow pattern, pressure limits, and ventilator-specific algorithms. During the breath, the flow delivery is adjusted according to a closed-loop feedback mechanism and proprietary software.[2] The consequence is a difference in performance among ventilator brands, even in the same mode.[27] Second, the interface may add confusion. For example, in the Dräger Evita XL, while on volume control, the operator will need to set the inspiratory flow, the inspiratory time, and tidal volume, whereas on the Hamilton G5, the options are customizable in three different ways! (Hopefully, all conducive to the same output.) The operator can enter (a) the *I:E* and the percent pause in inspiration, (b) the peak inspiratory flow and inspiratory time, or (c) the percent inspiratory time and plateau pause time. Underscoring that knowledge of the device used is essential. Finally, to add to the confusion, there are incorrect conclusions that sometimes permeate practice:

1. *In pressure-control mode, the flow is controlled as a descending ramp*. In a pressure-controlled breath, the volume and the flow are the manifestation of the respiratory system characteristics (resistance and compliance) and the patient's respiratory effort. If the patient is passive (no respiratory effort), the flow will decay exponentially (see Fig. 3-7, *A*). If the patient has a respiratory effort, the flow pattern will be variable, according to the characteristics of the patient effort, the ventilator settings (inspiratory pressure, pressurization algorithm, triggering, etc.), and the respiratory system characteristic. The only way to have a standard descending ramp is to select that waveform and have the computer control the flow delivery in volume control.

2. *The "autoflow" function adjusts the flow in a volume-controlled breath to the patient's demand.* Autoflow is available in Dräger Evita ventilators. It appears as an add-on for three modes of volume-control ventilation (controlled mechanical ventilation [CMV] or intermittent positive-pressure ventilation [IPPV], SIMV, and MMV). This "add on" is defined in the manual as automatic regulation of the inspiratory flow adjusted to the changes in lung conditions and to the spontaneous breathing demands.[58,59] What this "add on" does is turn the mode from a volume-control mode to an adaptive pressure-control mode. This is the same as being on PRVC on the Maquet ventilators. They all automatically adjust the inspiratory pressure to achieve a target tidal volume and because this is a pressure-controlled breath, the flow will be variable (see "Tidal Volume" above).

The inspiratory flow setting has importance at different levels. The work of breathing is related to the peak flow and the pressurization rate. The balance between patient and ventilator work of breathing will be affected by the inspiratory flow setting. In regards to cycling, high flows can lead to high peak inspiratory pressures (peak inspiratory pressure [PIP] is directly proportional to resistance, the higher the flow, the higher the PIP), which may lead to reaching the pressure or flow-cycling threshold and ending the breath prematurely.[59] But a more practical issue is this: does the flow-wave shape itself have any effect on patient outcome? Like most other questions about ventilator settings affecting patient outcome, after more than 30 years of research on this particular subject we still do not know the answer.

Studies from the early 1960s to early 1980s produced conflicting results, prompting Al-Saady and Bennett to design a better-controlled study, keeping tidal volume, minute ventilation, and *I:E* ratio constant.[60] They discovered that compared to a constant inspiratory flow, a descending ramp flow (what they and many subsequent authors have called "decelerating flow") resulted in a lower peak airway pressure, total respiratory resistance, work of inspiration, dead space-to-tidal volume ratio, and alveolar–arterial oxygen tension gradient. They also noted an increase in compliance and partial pressure of arterial oxygen (Pa_{O_2}) with no changes in partial pressure of arterial carbon dioxide (Pa_{CO_2}) or any hemodynamic variables. In 1991, Rau et al compared peak and mean airway pressure for seven different inspiratory flow waveforms (including square, ascending and descending ramps, and sinusoidal) under three different lung model conditions.[54] For all models, the descending ramp flow waveform produced the lowest peak and the highest mean airway pressures, whereas the ascending ramp produced the opposite: the highest peak and lowest mean values. When compliance was low, mean airway pressure increased as peak airway pressure increased. When resistance was high, peak airway pressure was more affected by the peak flow setting than the waveform setting.

In 1996, Davis et al[52] tested the hypothesis that a descending ramp flow waveform is responsible for improvements in gas exchange during pressure-control ventilation for acute lung injury. They compared volume control with a square or descending ramp waveform to pressure control with a square pressure waveform. Both pressure control and volume control with a ramp waveform provided better oxygenation at lower peak airway pressure and higher mean airway pressure compared to volume control with the square-flow waveform.

Polese et al[61] compared square, sinusoidal, and descending ramp flow waveforms in patients after open heart surgery. They found that Pa_{O_2} and Pa_{CO_2} were not affected by changes in waveform. Peak airway pressure was highest with the sinusoidal waveform while mean airway pressure and total work of breathing were least with the square waveform. Yang et al[53] applied square, sine, and descending ramp flow waveforms to patients with chronic obstructive pulmonary disease (COPD) and found that the descending ramp reduced inspiratory pressure, dead space-to-tidal volume ratio, and Pa_{CO_2}, but increased alveolar–arterial oxygen tension difference with no change in arterial oxygenation or hemodynamic variables.

Our own experience is that many clinicians prefer the descending ramp flow waveform when using volume control modes, with the observation that patients tend to be more comfortable, perhaps because of the higher flow earlier in the inspiratory phase.

Figure 3-16 illustrates an algorithm that can be used to adjust inspiratory flow to improve patient–ventilator synchrony.[62]

PERCENT SUPPORT

Proportional-assist ventilation (PAV)[63] delivers pressure-control breaths with a servo targeting scheme (see Chapter 2).[49] The pressure applied is a function of patient effort: the greater the inspiratory effort, the greater is the increase in applied pressure (Fig. 3-17). The form of PAV implemented on the Dräger Evita XL ventilator (called proportional pressure support) requires the operator to input desired assistance values for elastance and resistance. PAV implemented on the Puritan Bennett 840 ventilator (called PAV +) uses a different algorithm. It automatically calculates the resistance of the artificial airway, and combines resistance and elastance such that the operator enters only a single value representing the percentage work of breathing to be supported.[64] The design differences between proportional pressure support and PAV + lead to significant performance differences.[65]

NEURALLY ADJUSTED VENTILATORY SUPPORT LEVEL

NAVA is a mode that applies airway pressure proportionately to patient effort based on the voltage recorded from diaphragmatic activity. The "NAVA level" is the constant

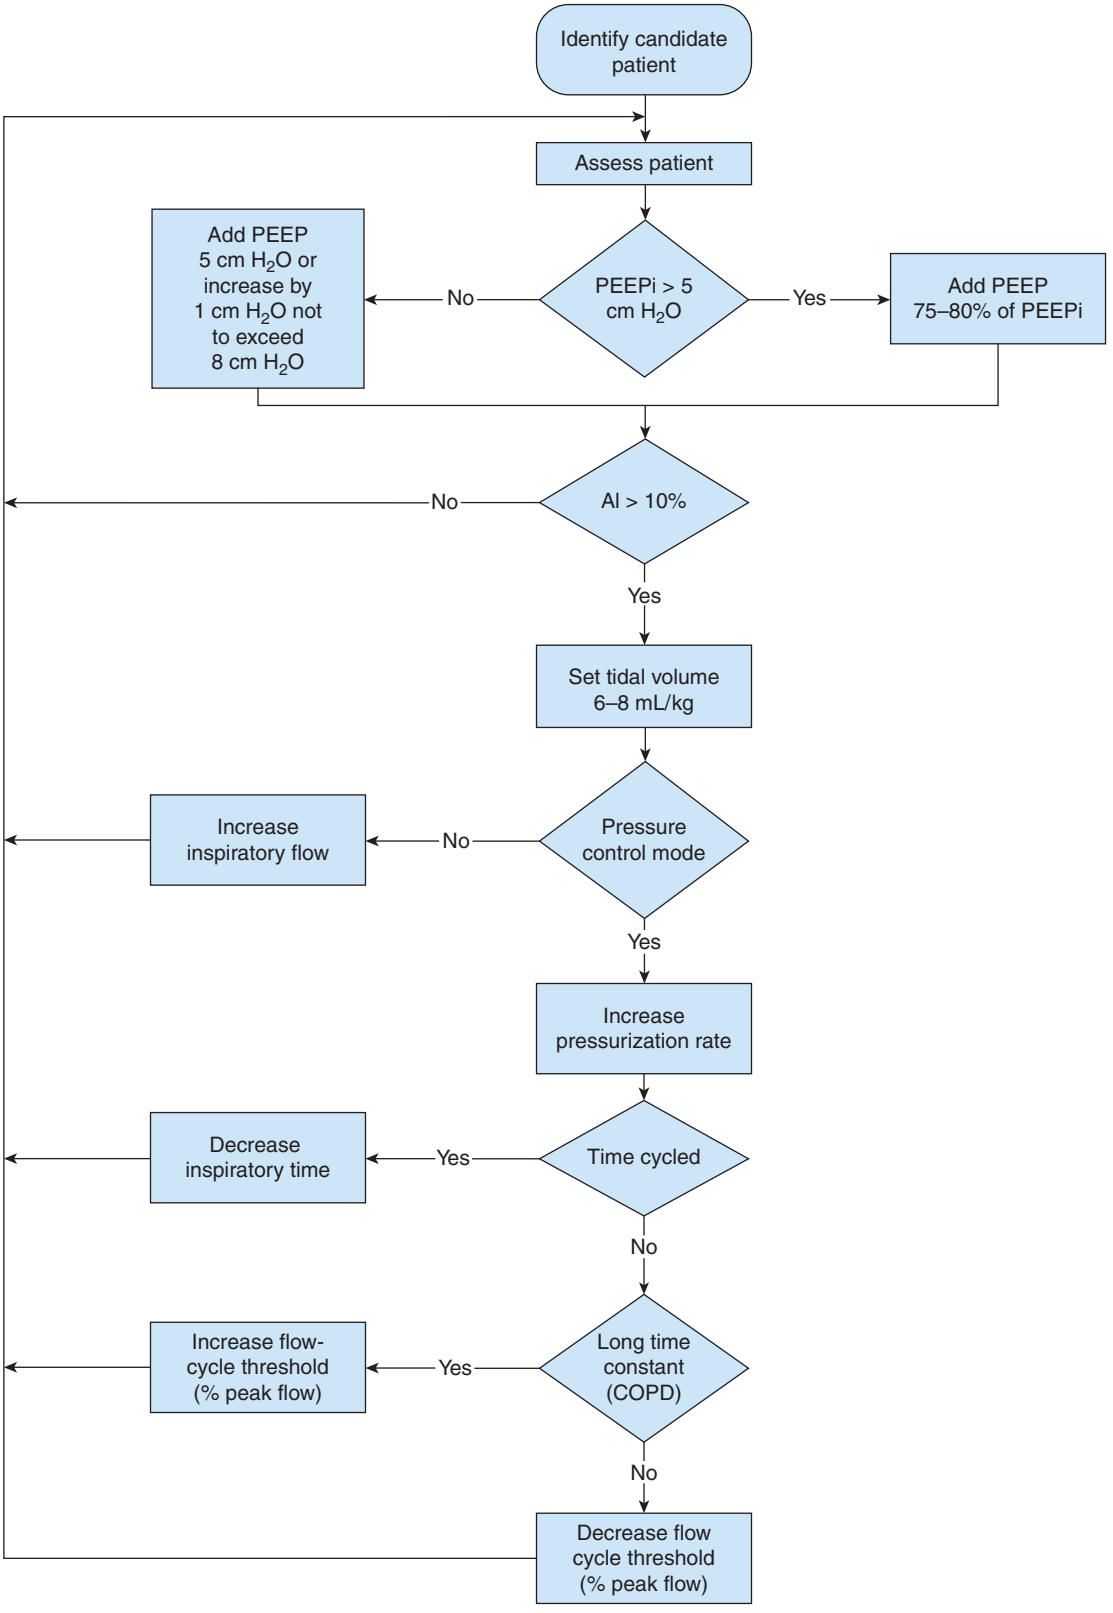

FIGURE 3-16 Algorithm for improving patient–ventilator synchrony. *AI*, asynchrony index, percent of inspiratory efforts that failed to trigger a breath; *COPD*, chronic obstructive pulmonary disease; *PEEPi*, intrinsic PEEP (aka auto-PEEP). (Modified from, with permission, Sassoon CSH. Triggering of the ventilator in patient-ventilator interactions. *Respir Care.* 2011;56(1):39–48.)

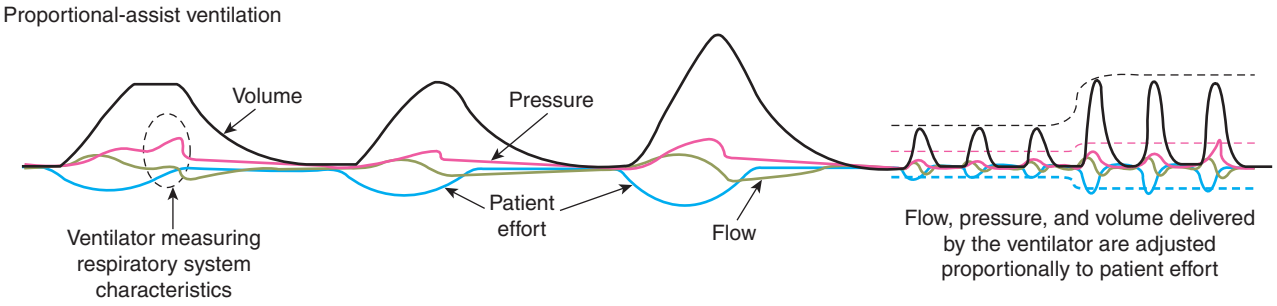

FIGURE 3-17 Pressure, volume, and flow waveforms for proportional assist ventilation.

of proportionality (gain) between voltage and airway pressure. The operator enters the NAVA level, then the ventilator delivers pressure equal to the product of gain and the Edi. In simple terms, it states how much pressure the patient will receive for each microvolt of diaphragmatic activity:

$$Paw(t) = Edi(t) \times \text{NAVA level} \quad (8)$$

where $Paw(t)$ is the airway pressure (cm H_2O) as a function of time (t), $Edi(t)$ is the electrical activity of the diaphragm as a function of time (t), in microvolts (μV), and the NAVA level is the operator-set level of support in cm H_2O/μV. The range is 0 to 30 cm H_2O/μV.

The NAVA level is set according to the operator ventilation goals, level of inspiratory pressure support, tidal volume, apparent patient work of breathing, or respiratory rate. Recently, Roze et al[66] proposed using the maximum Edi during a spontaneous breathing trial to help set the NAVA level (Fig. 3-18). By titrating the NAVA level to the a target Edi, the goal is to avoid excessive diaphragmatic unloading as well as respiratory muscle fatigue.

AUTOMATIC TUBE COMPENSATION

Automatic tube compensation (ATC) is a mode that compensates for the flow-dependent pressure drop across an endotracheal tube during inspiration and expiration. It is thus intended to reduce or eliminate the resistive work of breathing imposed by the artificial airway. ATC is an add-on feature on several ventilators. When ATC is activated, the ventilator supplies airway pressure in proportion to the square of flow times, a gain factor that is determined by the size of the endotracheal tube. Because flow is positive during inspiration and negative during expiration, ATC pressure either adds to inspiratory pressure or subtracts from expiratory pressure (Fig. 3-19). Some ventilators calculate and display tracheal pressure as airway pressure minus ATC pressure. ATC can be used alone or added to the ventilating pressure in pressure-control modes. Interestingly, the way ATC was implemented in the intensive care unit ventilators is different from the original concept, where negative pressure could be applied during exhalation.[67,68]

Cycle Variables

The inspiratory phase of a mechanical breath ends (cycles off) when a threshold value for a measured variable is reached. This variable is called the *cycle variable*, and it ends the inspiratory time. Cycling is characterized by the initiation of expiratory flow. The cycle variable may be preset (by the operator or the ventilator manufacturer), or automatically defined by the ventilator. Many different signals are used, for example, time, volume, pressure, flow, diaphragmatic signal, and thoracic impedance.

INSPIRATORY TIME

Inspiratory time is defined as the period from the start of inspiratory flow to the start of expiratory flow. Inspiratory time has two components; inspiratory flow time (period when inspiratory flow is above zero) and inspiratory pause time (period when flow is zero). In pressure-controlled or volume-controlled breaths, the inspiration is cycled (terminated) when the set inspiratory time elapses. In spontaneous modes of ventilation (NAVA, PAV, pressure support), the inspiratory time is dependent on the patient's own neurally determined inspiratory time, level of support, cycling rule (flow, pressure, time, diaphragm activity), and safety rules (maximum set inspiratory time).

Inspiratory time is usually an operator-entered input but some modes of ventilation can automatically set it and change it based on expert rules and closed-loop feedback algorithms. Two notable algorithms are ASV and Adaptive I-Time. In ASV (Hamilton G5), the inspiratory time is automatically set at one expiratory time constant (of the measured respiratory system characteristics and it is never shorter than 0.5 second or longer than 2 seconds). In the Adaptive Flow and Adaptive I-Time in the Versamed iVent (GE Healthcare, Madison, WI), the ventilator automatically adjusts the inspiratory time and inspiratory flow to maintain a target *I:E* ratio of 1:2 and deliver the operator-set tidal volume.[49]

In volume-control modes, there are four possibilities for setting inspiratory time:

1. Operator sets tidal volume and inspiratory flow: inspiratory time is equal to the tidal volume divided by mean inspiratory flow.

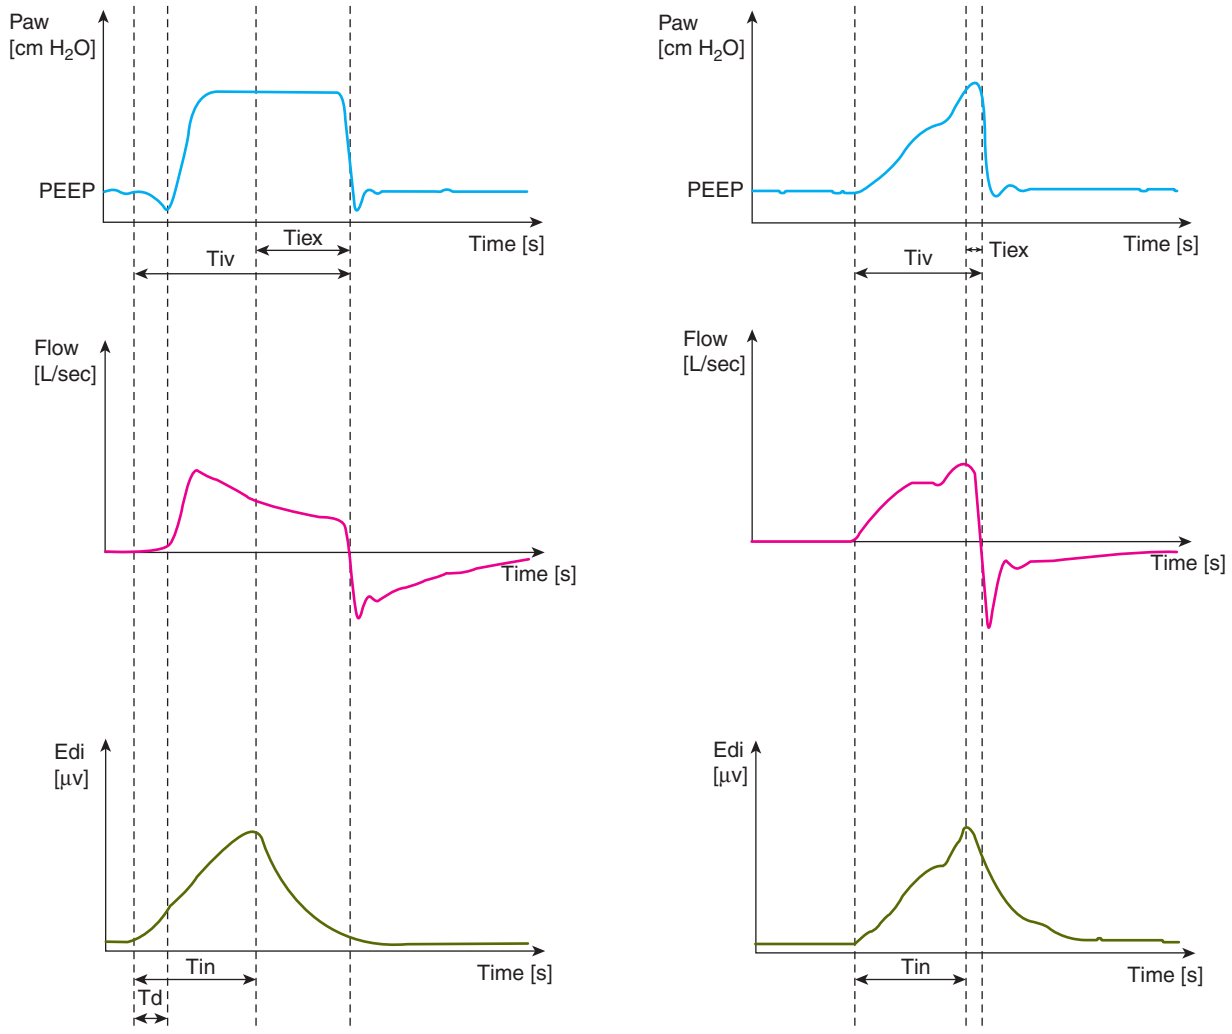

FIGURE 3-18 Airway pressure, flow, and electrical diaphragmatic activity curves in pressure support (left) and in neurally adjusted ventilatory assist (right). *Edi*, electrical activity of the diaphragm; *PEEP*, positive end-expiratory pressure, *Td*, trigger delay; *Tiex*, inspiratory time in excess; *Tin*, neural inspiratory time; *Tiv*, ventilator pressurization time. FIGURE 3-19 Pressure waveforms illustrating automatic tube compensation (ATC). (Modified, with permission, from Dräger Medical AG & Co. KG. *Infinity V500 Operator's Manual.* Luebeck, Germany.)

2. Operator sets tidal volume and inspiratory time: mean inspiratory flow is equal to the tidal volume divided by the inspiratory time.
3. Operator sets tidal volume, inspiratory flow, and inspiratory time: if the inspiratory time is longer than the inspiratory flow time (set tidal volume divided by set flow), then an inspiratory hold is created and the pause time is equal to the inspiratory time minus the inspiratory flow time. For example, if the tidal volume is 600 mL (0.6 L) and the set inspiratory flow is 60 L/min (1L/s) then the inspiratory flow time is (0.6/1 = 0.6 s). Now, if the operator also sets the inspiratory time to 1 s, an inspiratory pause is created and it lasts 1.0 – 0.6 = 0.4 s.
4. On some ventilators, the operator sets pause time directly.

In pressure-control modes, the operator presets the inspiratory time directly for mandatory breaths. Thus, prolonging the inspiratory time causes the ventilator to decrease the expiratory time, possibly resulting in air trapping, larger tidal volumes, or cycle asynchrony. One must remember that the effect on tidal volume of the inspiratory time in a pressure-control breath will depend on the respiratory system characteristics (i.e., the time constant). Thus, a patient with a long time constant (high compliance and/or high resistance) will require a longer inspiratory time to achieve full pressure equilibration, cessation of flow, and complete tidal volume delivery.

Figure 3-16 illustrates an algorithm that can be used to adjust inspiratory time to improve patient–ventilator synchrony.[62]

Inspiratory Pause. The inspiratory pause is the period during which flow ceases but expiration has not begun (see inspiratory time). The expiratory valves are closed during this period. The inspiratory pause time is part of the inspiratory time. It is also named plateau time (PB 840, Covidien, Mansfield MA), Pause time (Servo i, Maquet,) or Pause (G5, Hamilton Medical). When set directly, pause time may be entered in seconds or as a percentage of the inspiratory time. When it is activated, most ventilators will display a plateau pressure (i.e., static inspiratory hold pressure). Increasing the inspiratory pause time will increase the mean airway pressure and thus the time the lung is exposed to volume and pressure. This may have a positive effect on oxygenation and ventilation by increasing mixing time and decreasing dead space.[69,70]

I:E Ratio and Duty Cycle. *I:E* is the ratio of inspiratory time to expiratory time (Fig. 3-20).

$$I{:}E = T_I : T_E = \frac{T_I}{T_E} \tag{9}$$

The *I:E* can also be described as the duty cycle or percent inspiration. In engineering, the duty cycle is defined as the time spent in active state as a fraction of the total time. In mechanical ventilation, the active state is the inspiratory time, and the total time is the sum of the inspiratory and expiratory times. It is expressed as a percentage. The larger the percentage, the longer the inspiratory time in relation to the total cycle time.

$$Duty\ Cycle = \frac{T_I}{T_I + T_E} \times 100 \tag{10}$$

One can convert one to the other by the following formula:

$$I : E = \frac{Duty\ Cycle}{100 - Duty\ Cycle} \tag{11}$$

Example: A duty cycle of 50% is an *I:E* of 1:1, a duty cycle of 33% is an *I:E* 1:2.

The relevance of *I:E* is highlighted in the context of the time constant. The time constant is a measure of how quickly the respiratory system can passively fill or empty in

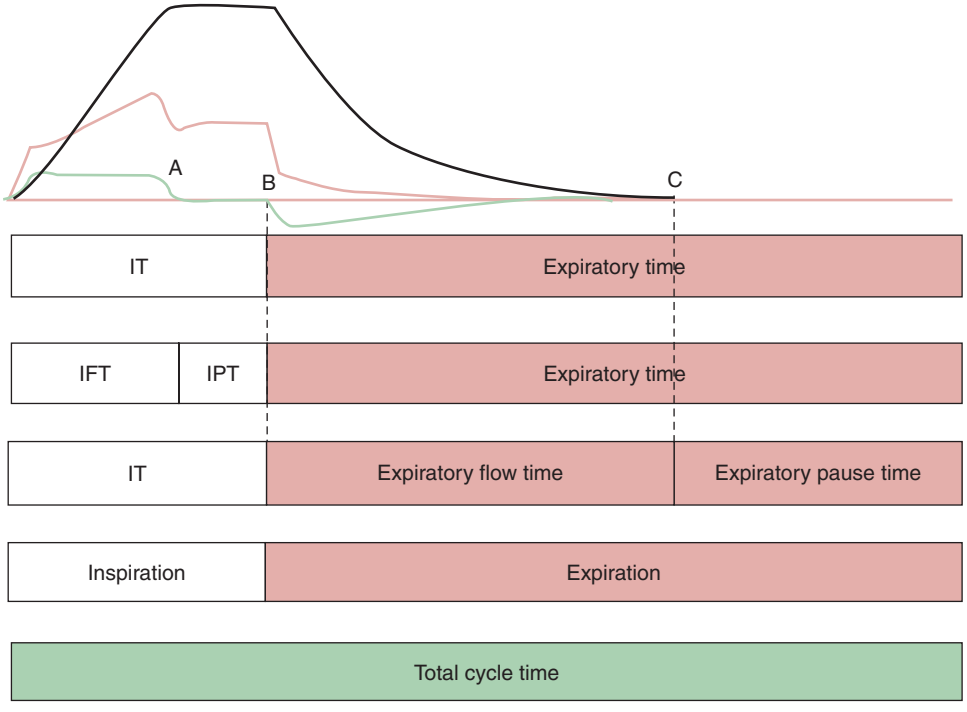

FIGURE 3-20 Divisions of the inspiratory and expiratory periods. A volume-controlled breath is depicted. **A.** End of inspiratory flow. **B.** Start of expiratory flow. **C.** End of expiratory flow. *IFT*, Inspiratory flow time; *IPT*, inspiratory pause time; *IT*, inspiratory time.

TABLE 3-4: EFFECT OF LUNG CONDITION ON TIME CONSTANT AND EXPIRED VOLUME

	Expiratory Time (s)			Expiration		
Time Constant	Normal Lung	ARDS	COPD	Tidal Volume Remaining (mL)	Tidal Volume Exhaled	Tidal Volume Remaining
0	0	0	0	500	0	100
1	0.780	0.510	1.000	184	63%[a]	37%
2	1.560	1.020	2.000	68	86%	14%
3	2.340	1.530	3.000	25	95%	5%
4	3.120	2.040	4.000	9	98%	2%
5	3.900	2.550	5.000	3	99%	1%

Abbreviations: *ARDS*, acute respiratory distress syndrome; *COPD*, chronic obstructive pulmonary disease.
[a]The exact value is $(1 - e^{-1}) \times 100\%$.

response to a step change in transrespiratory pressure.[23] It is calculated as the product of resistance and compliance. The value obtained is the time that takes to achieve 63% of steady state. This percent change remains a constant, regardless of the combination of resistance and compliance. It follows that *each* time constant will lead to a 63% decrease or increase in volume. In Table 3-4, one can see the difference among time constants for different lung conditions. In COPD, the time constant is longer so the time required for exhalation is longer than for patients with acute respiratory distress syndrome. This table demonstrates the effect of the time constant during passive exhalation using previously published[71] expiratory time constants for three conditions (normal lung was 0.78 seconds, for acute respiratory distress syndrome 0.51 seconds, and for COPD 1 second). In this example, expiration starts from a lung volume of 500 mL above functional resting capacity. When expiratory time equals one time constant, 63% of the tidal volume will be exhaled, leaving 37% of the tidal volume yet to be exhaled.

The *I:E* ratio can be an operator-entered value, or just displayed as a calculated value based on common scenarios for mandatory breaths:

- Preset *I:E* ratio and frequency.
- Preset inspiration time (T_I in seconds) and frequency (breaths/min). The frequency sets the ventilatory period ($1/f$) and the expiratory time is the period minus T_I:

$$I{:}E = T_I{:}\,[(60 \div rate) - T_I] \tag{12}$$

- Expiratory time and inspiratory time are fixed:

$$I{:}E = T_I{:}\,T_E \tag{13}$$

Note: some ventilators will synchronize inspiration and/or expiration of a mandatory breath if the patient effort is detected in a trigger/cycle window (e.g., SIMV or APRV), which may alter the *I:E* from the expected value based on settings.

PRESSURE

Pressure cycling occurs when the ventilator reaches a preset peak airway pressure. Pressure cycling is most often a safety feature (i.e., an alarm setting) with current modes of ventilation. When a preset high-pressure alarm threshold is crossed, the ventilator will cycle the ventilator. The goal is to prevent the patient from exposure to hazardous pressures. Pressure cycling without an alarm is the normal operational state for some devices (e.g., VORTRAN automatic resuscitator).

VOLUME

Volume cycling occurs when a preset volume is reached. This occurs when the operator sets a tidal volume in volume-control modes. Volume cycling implies that inspired volume is monitored by the ventilator's control system during inspiration and compared to a threshold value (the set tidal volume). But on some ventilators, despite the setting of a tidal volume, the actual cycle variable is time, that is, the time it takes to deliver the set tidal volume with the set inspiratory flow. Manufacturers seldom make this distinction clear in the operator's manual.

Volume cycling can also be found as a default safety feature. In PAV + (Covidien PB 840 ventilator), one of the cycling criteria is volume. Once the operator-preset high inspired tidal volume limit is reached, the ventilator cycles the breath and alarms.

FLOW

Flow cycling occurs when a preset flow or percentage of the peak flow is reached for pressure-control breaths. Flow cycling is most commonly found with the pressure-support mode but can be added as an "advanced setting" in other pressure-control modes on at least one ventilator (Avea, CareFusion). The flow-cycling threshold preset by the operator has been given many names: expiratory trigger sensitivity (Hamilton ventilators); trigger window (Engstrom Ohmeda); inspiratory termination peak inspiratory flow (Dräger Evita XL); expiratory threshold (Newport); flow termination (Pulmonetics LTV ventilators); PSV cycle (Avea, CareFusion); inspiratory cycle off (Servo *i*, Maquet); Ecycle (V200 respironics); and E sens (PB 840, Puritan Bennett).

During a breath in the pressure-support mode, the ventilator provides enough initial flow to achieve the set inspiratory pressure. The initial flow is high and then decays exponentially. Some ventilators have a preset default value for flow cycling (range: 5% to 30% of peak inspiratory flow); others allow the operator to adjust it (range: 1% to 80% of peak inspiratory flow). Only one device (e500, Newport Medical, Costa Mesa, CA) has automatic adjustment of the flow-cycling criteria. This device has a proprietary algorithm called FlexCycle. It will change the cycle criterion from 10% to 50% of peak flow based on measurements of airway pressure, the expiratory time constant, and expert-based rules applied through a closed-loop system.[72]

A default cycle criterion of 25% to 30% of the peak flow seems inappropriate as a "fit all" measure. The goal of adjusting the flow-cycling criterion is to avoid expiratory asynchrony.[59] In expiratory asynchrony, the ventilator ends inspiration before or after the patient inspiratory effort. We must remember that flow is a manifestation of the respiratory system characteristics, respiratory muscle effort (inspiratory and expiratory) and the integrity of the lung-ventilator circuit. If the respiratory system has a prolonged time constant, a standard flow-termination criterion may be inappropriate as it will prolong inspiration. That may be the case for patients with COPD, where the standard criterion of 25% may be too low, and lead to expiratory asynchrony and increased work of breathing.[73,74] Finally, a leak in the ventilator circuit (mask) or in the patient (endotracheal cuff or a bronchopleural fistula) may lead to lack of decay in the flow curve and thus asynchrony.[72]

Figure 3-16 illustrates an algorithm that can be used to adjust the flow-cycle threshold to improve patient–ventilator synchrony.[62]

DIAPHRAGMATIC SIGNAL

One goal of mechanical ventilation is to improve the patient–ventilator synchrony. In a perfect setting, the beginning and end of an assisted breath would be correlated with the neural signal driving the inspiratory muscles. In conventional ventilation that is rarely the case.[75] NAVA attempts to achieve this goal with the use of an electromyogram signal obtained from the diaphragm (Edi). As diaphragmatic activity decreases, so does the amplitude of the Edi curve. When it decreases below 70% of the peak signal (or 40% when the peak value is low), inspiration is cycled off. As a safety feature there is also a time-cycling mechanism. Piquilloud et al compared NAVA versus pressure support with the usual cycling criteria and found a significant improvement in expiratory synchrony (see Fig. 3-18).[76]

Baseline Variables

The baseline variables are the variables controlled during the expiratory time. Expiratory time is the period from the beginning of expiratory flow to the initiation of inspiratory flow. Flow and volume are not directly controlled during this period on any current ventilator. The most common value controlled is pressure relative to atmospheric pressure (zero-gauge pressure).

Positive End-Expiratory Pressure

The PEEP is established by the ventilator exhalation valve. A common source of confusion is the term continuous positive airway pressure versus PEEP. Continuous positive airway pressure is generally considered to be a mode on mechanical ventilators (or a mode of treatment for sleep apnea), whereas PEEP is the elevation of the baseline pressure during any mode of ventilation and is generally a setting for a mode. Until recently, the selection of PEEP has been a relatively arbitrary process and the meaning of "optimum PEEP" is debatable.[77] Now, Hamilton Medical has developed the INTELLiVENT system for the G5 ventilator that uses an algorithm for automatic targeting of PEEP and FIo_2. A closed-loop algorithm based on expert rules defines the response of the ventilator to measured ventilation variables, end-tidal carbon dioxide and pulse oximetry.

P-Low. P-low is one of the settings entered for so-called "bilevel" modes like APRV (Fig. 3-21). P-low is just another name for PEEP. Similar to PEEP, the settings are dependent on the user. There is, however, a large discrepancy with the objective of PEEP. In APRV, P-low is set to zero.[78] The goal is to maintain lung recruitment with the use of auto-PEEP induced by short T-low settings. P-low can also be set based on the biphasic model,[79] where complete exhalation is allowed and P-low is then set with the same goals as PEEP.

Expiratory Time. Expiratory time is defined as the period from the start of expiratory flow to the start of inspiratory flow. As stated above, the expiratory time is commonly dependent on the set inspiratory time, and set respiratory rate. It is rarely a fixed value. This occurs because making it a fixed value would produce, in most modes, changes in the inspiratory phase (inspiratory time, flow, and pressure). The most common exception to this is on ventilators that offer some form of APRV/biphasic pressure-control mode where expiratory time is set as "T-low."

T-Low. With exception of APRV/biphasic, in all the modern modes of ventilation the expiratory time is dependent on the inspiratory time and frequency; it is not an operator-set value. In APRV/biphasic, the operator sets the time spent at lower pressure, that is, exhalation (see Fig. 3-21). T-low can be set by the operator based on the peak expiratory flow,[78] targeting exhaled tidal volume or allowing complete exhalation.[80] Setting T-low sets the time trigger threshold for mandatory breaths. Among the methods described in setting T-low in APRV, targeting percent of peak expiratory flow (%PEF) is perhaps the most promoted method. The goal is to set the T-low short enough to avoid full exhalation,

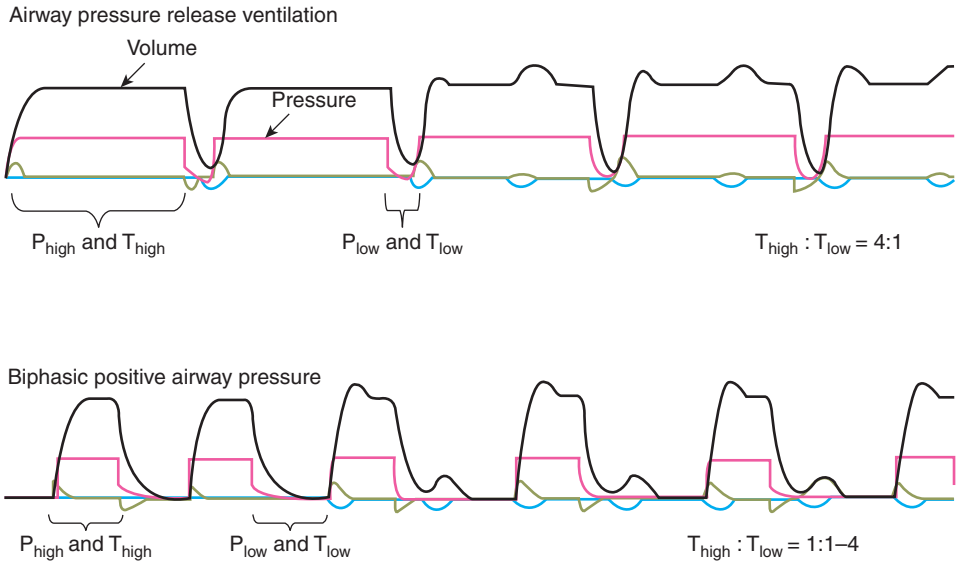

FIGURE 3-21 Differences in P-low and T-low settings for airway pressure release ventilation and biphasic positive airway pressure. Notice the difference in I:E ratio. The operator enters P-high, P-low, T-high, and T-low. The patient may breath spontaneously. Green curves show flow and blue curves show inspiratory effort.

thereby generating air trapping.[29] Adjusting T-low on the ventilator to manually maintain %PEF at 50% to 75% may be a tedious process, which may seem simple on paper, but in a spontaneously breathing patient can become a true challenge. Newer ventilators, like the Dräger Evita Infinity V500, have attempted to make the process easier by allowing the operator to set a trigger threshold based on a percentage of peak *expiratory* flow.

Alarms

Ventilator alarms bring unsafe events to the attention of the clinician. Events are conditions that require clinician awareness or intervention. Events can be classified according to their level of priority.[81]

Immediately life-threatening events are classified as Level 1. They include conditions like insufficient or excessive gas delivery to the patient, exhalation valve failure, control circuit failure, or loss of power. Level 1 alarm indicators should be mandatory (cannot be turned off by the operator), redundant, and noncanceling.

Level 2 events range from mild irregularities in machine function to dangerous situations that could threaten patient safety if left unattended. Some examples are failure of the air–oxygen blending system, inadequate or excessive PEEP, autotriggering, circuit leak, circuit occlusion, inappropriate *I:E* ratio, and failure of the humidification system. Alarms in this category may be self-canceling (i.e., automatically turned off if the event ceases) and are not necessarily redundant.

Level 3 events indicate changes in the amount of ventilator support provided to the patient consequent to changes in the patient's ventilatory drive or respiratory system mechanics and the presence of auto-PEEP. These events often trigger the same alarms as Levels 1 and 2.

Level 4 events are based entirely on patient condition. They may include events such as changes in gas exchange, dead space, oxygenation, and cardiovascular functions. Ventilators generally monitor these events and external monitors are required for alarms (the exception being exhaled carbon dioxide-level alarms built into the ventilator display).

Currently, ventilators do not display alarm settings as levels of priority. Instead, they tend to lump them all together on one screen that shows alarm limits and controls for changing them (Fig. 3-22). How to set alarm thresholds is a complicated topic that has been studied but for which little information is available regarding mechanical ventilation. The goal is to minimize false alarms and maximize true alarms. A high false alarm rate leads to clinician habituation and can also lead to inappropriate responses. In a recent study of an intensive care unit, 1214 alarms occurred and 2344 tasks were performed. On average, alarms occurred six times per hour; 23% were effective, 36% were ineffective, and 41% were ignored.[82] In another intensive care unit study, alarms occurred at a rate of six per hour. Approximately 40% of the alarms did not correctly describe the patient condition and were classified as technically false; 68% of those were caused by manipulation. Shockingly, only 885 (15%) of all alarms were considered clinically relevant.[83] Although these studies did not address mechanical ventilator alarms specifically, it is not hard to imagine similar results for such a study.

Ventilator alarms are usually set by the operator as either an arbitrary absolute value or a percentage of the current value. Examples would be airway-pressure alarms (high and low) set at the current value plus or minus 5 cm H_2O or low and tidal volume/minute ventilation set at plus or minus 25% of the current value.[81] The problem is that the parameters for which alarms are important, and these three

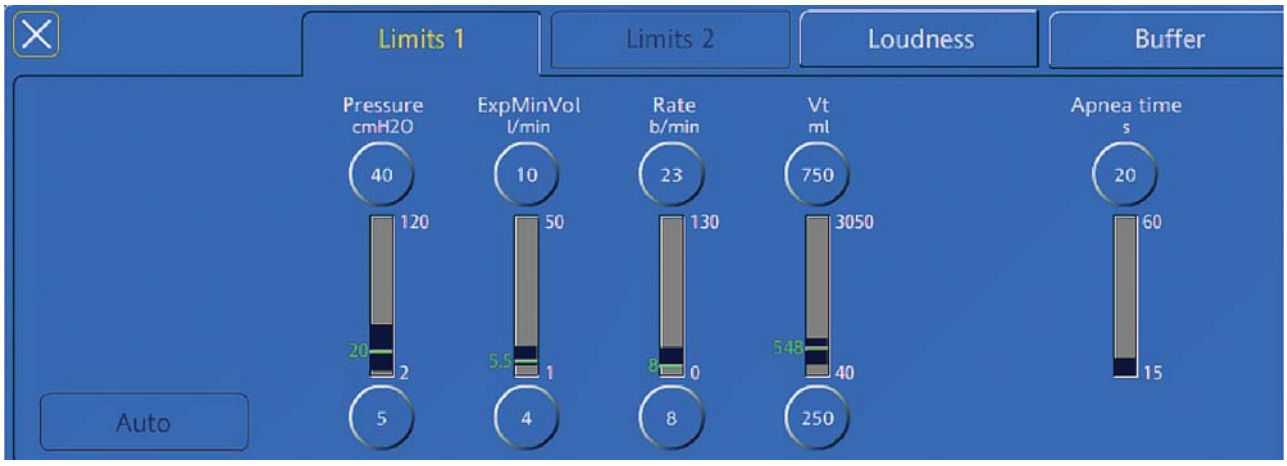

FIGURE 3-22 Alarm screen from the G5 ventilator. (Reproduced, with permission, from Hamilton Medical.)

in particular, are highly variable, with significant portions at extreme values.[84] Thus, limits set as absolute values or percentages may reduce safety for some extreme values while increasing nuisance events for other values. An alternative approach might be a type of "smart alarm," whereby the alarm limits are automatically referenced to the current value of the parameter such that extreme values have tighter limits. Further research is needed to identify optimization algorithms (i.e., minimize both harmful and nuisance events).

VENTILATOR OUTPUTS (DISPLAYS)

Display Types

Ventilator output displays represent the values of monitored parameters that result from the operator settings. There are four basic ways to present the monitored data: as numbers, as waveforms, as trend lines, and in the form of abstract graphic symbols.

NUMERIC VALUES

Data are most commonly represented as numeric values such as FIo_2, peak, plateau, mean and baseline airway pressures, inhaled/exhaled tidal volume, minute ventilation, and frequency. Depending on the ventilator, a wide range of calculated parameters may also be displayed including resistance, compliance, time constant, airway occlusion pressure at 0.1 second (P0.1), percent leak, *I:E* ratio, and peak inspiratory/expiratory flow (Fig. 3-23).

TRENDS

Many ventilators provide trend graphs of just about any parameter they measure or calculate. These graphs show how the monitored parameters change over long periods of time, so that, for example, significant events or gradual changes in patient condition can be identified (Fig. 3-24). In addition, ventilators often provide an alarm log, documenting such things as the date, time, alarm type, urgency level, and events associated with alarms, for example, when activated and when canceled. Such a log could be invaluable in the event of a ventilator failure leading to a legal investigation.

WAVEFORMS AND LOOPS

Many ventilators display waveforms (sometimes called "scalars") of airway pressure, volume, and flow as functions of time. Such displays are useful for identifying the effects of changes in settings or mechanics on the level of ventilation.[85] They are also very useful for identifying sources of patient–ventilator asynchrony, such as missed triggers, flow asynchrony, and delayed or premature cycling.[86] They can also display one variable against another as an *x-y* or "loop" display. The most common loop displays show pressure on the horizontal axis and volume on the vertical axis, or volume on the horizontal axis and flow on the vertical axis. Pressure-volume loop displays are useful for identifying optimum PEEP levels (quasistatic loops only) and over distension. Flow-volume loops are useful for identifying the response to bronchodilators. Figure 3-25 is an example of a composite display showing numeric values, waveforms, and loops.

ADVANCED GRAPHICS

As ventilators have become more complex, their displays have become more confusing and difficult to use. A recent trend is to move away from the traditional display screens in favor of a more integrative approach using creative graphic elements. For example, one study showed that observers detected and treated obstructed endotracheal tubes and auto-PEEP problems faster with graphical rather than conventional displays. They also reported significantly lower subjective workloads using the graphical display.[87]

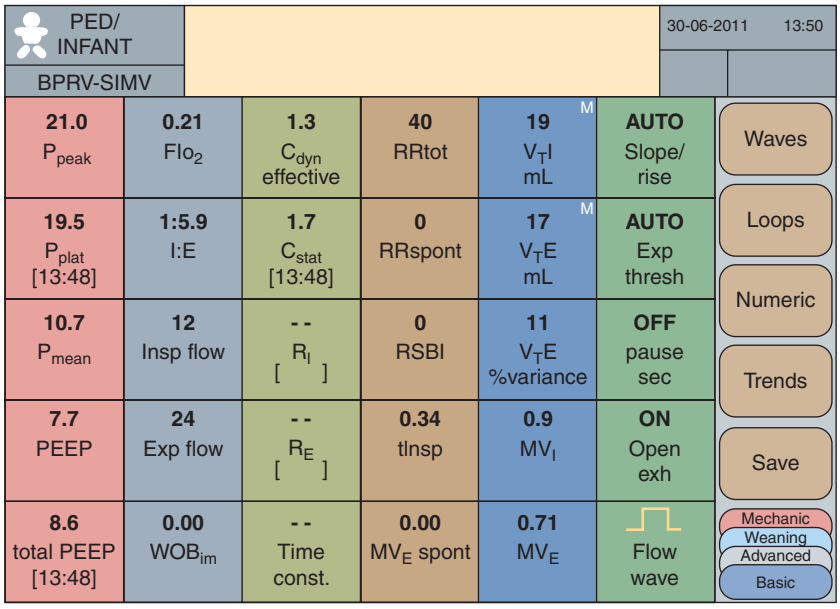

FIGURE 3-23 Digital display of monitored and calculated parameters from the Newport e360 ventilator. (Reproduced, with permission, from Newport Medical.)

Hamilton Medical was the first to make use of innovative picture graphics on their G5 ventilator. They created a graphic representation of the lungs, called a "dynamic lung panel," that visually displays information about resistance and compliance by the shape and color of the lungs and airways (Fig. 3-26). This panel is supplemented by a unique graphic, called the "vent status panel," which displays key parameters (e.g., oxygenation, ventilation, and spontaneous breathing activity). Furthermore, the display shows when each item is in or out of an acceptable zone and for how long. This makes weaning status easy to identify. Preliminary data[88] suggest that this display reduces the time required for clinicians to identify common problems, for example, normal, restrictive, and obstructive lungs; occluded endotracheal tube, right main-stem intubation, pre-spontaneous breathing trial (SBT), SBT in progress, and post-SBT phase.

Dräger Medical recently introduced a similar graphic display called "Smart Pulmonary View." The shapes of the graphic elements quickly indicate relative values of respiratory system resistance and compliance as well as the balance between mandatory and spontaneous breaths (Fig. 3-27). Digital values are also displayed.

THE FUTURE

Better Operator Interfaces

As modes have become more complex, the operator interfaces on ventilators with computerlike displays has become cumbersome. Multiple options for control settings tend to get lost in layers of different screen views. Worse, screen views are often customizable such that if strict control is not exerted by an individual hospital department, each ventilator will be "stylized" by individual operators and chaos will ensue. Clearly, flexibility is a double-edged sword.

Very few studies have been published on ease of use or the problems with current displays. We need to identify optimal ways for ventilator displays to provide three basic functions: to allow input of control and alarm parameters, to monitor the ventilator's status, and to monitor the ventilator–patient interaction status. There is a long way to go before the user interface provides an ideal experience with these functions. This may be a fruitful area of future research.[6,8]

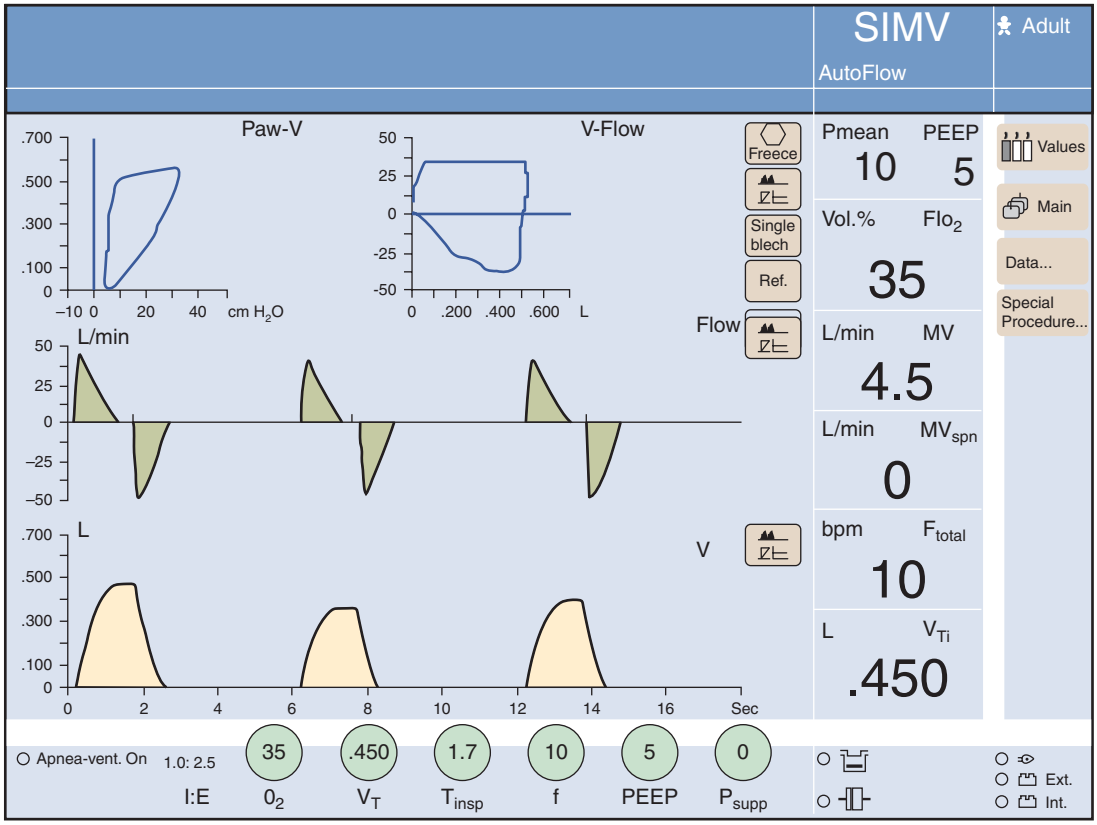

FIGURE 3-25 An example of both scalar and loop displays. (Reproduced with permission from Draeger Medical GmbH, Luebeck, Germany.)

Better Patient Interfaces

The interface between a modern ventilator and the patient is a piece of plastic tubing, that is, the "patient circuit," whose design has not changed much in several decades.

FIGURE 3-26 Example of picture graphic display from the Hamilton G5 ventilator showing the dynamic lung panel and the vent status panel. (Reproduced, with permission, from Hamilton Medical.)

Certainly, humidification systems using heated wires and automatic-temperature control have evolved, but we still are not capable of measuring and directly controlling a primary variable of gas conditioning: humidity. Indeed, after all this effort at evolving humidification systems, there are data to show that simple, unheated circuits provide better humidification of inspired gas.[89] In addition, the compliance of the patient circuit degrades the accuracy of flow delivery and must be "compensated" for by complex mathematical algorithms. It seems to us that a major revolution in patient-interface design would be to simply make the patient circuit a permanent part of the ventilator and treat water molecules the way we treat molecules of oxygen, nitrogen, helium, and nitric oxide. But to do this, ventilator manufacturers would have to merge with humidifier manufacturers and collaborate in systems design rather than seeing the patient circuit and humidifier as devices separate from the ventilator (see Chapter 2).

Better Targeting Systems

Chapter 2 provides a conceptual framework and suggestions for better targeting systems of the future. In essence, evolution in this area involves more and better sensors and the software algorithms required to manage the data they provide. The clear trend here, both in basic research and

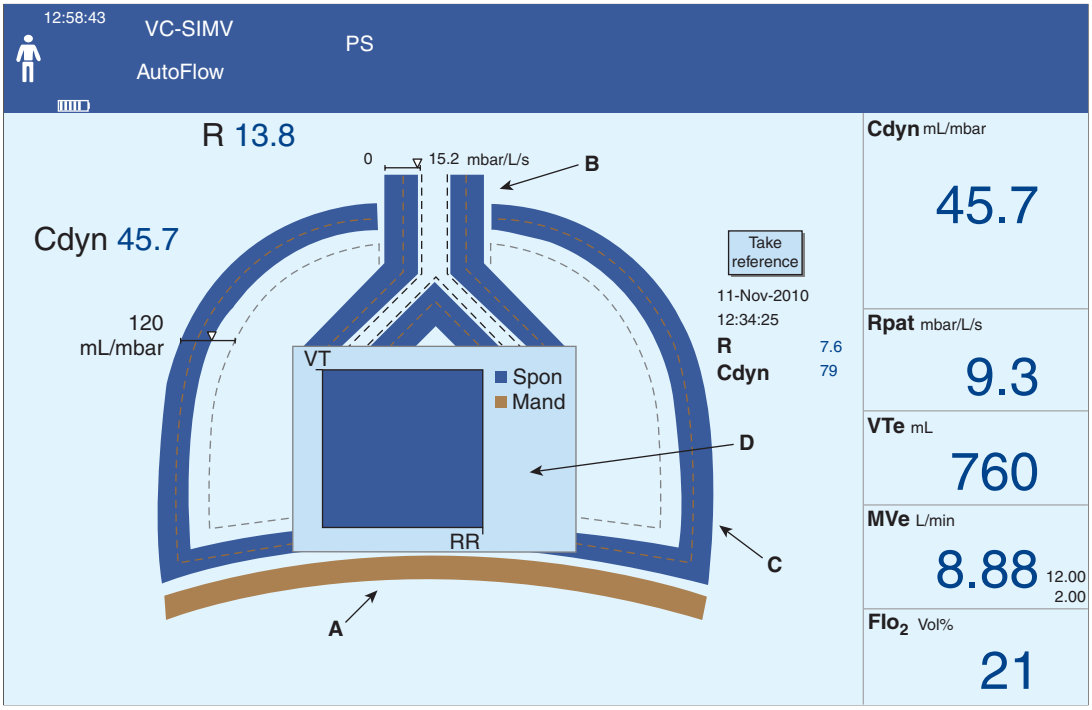

FIGURE 3-27 Example of picture graphic display from the Dräger Evita Infinity V500 ventilator showing the Smart Pulmonary View. **A.** The movement of the diaphragm indicates synchronized mandatory breaths or supported (triggered) breaths. **B.** The blue line around the trachea indicates the resistance R. The higher the resistance, the thicker the line. The numeric value is also displayed. **C.** The blue line around the lungs indicates the compliance Cdyn. The higher the compliance, the thinner the line. The numeric value is also displayed. **D.** Diagram displaying the relationship between spontaneous breathing and mandatory ventilation. The following parameters are displayed in different colors: spontaneous tidal volume (*VT spon*), spontaneous respiratory rate (*RR spon*), mandatory tidal volume (*VT mand*), and mandatory respiratory rate (*RR mand*). (Reproduced, with permission, from Draeger Medical GmbH, Luebeck, Germany.)

commercial applications, is to develop "closed-loop" targeting systems based on mathematical models of physiologic processes, or artificial intelligence, or combinations thereof, with the goal of automating the moment-to-moment adjustment of ventilator output to patient needs. The best example so far is a mode called INTELLiVENT-ASV (G5 ventilator, Hamilton Medical) and is currently available only in Europe.

This mode is an improvement on the optimal targeting scheme that is the basis of the mode called ASV (see Chapter 2). Like ASV, INTELLiVENT-ASV is a form of pressure control intermittent mandatory ventilation using adaptive-pressure targeting to automatically adjust inspiratory pressure to maintain a target tidal volume, which, in turn, is selected by an optimization model. An "optimal" targeting scheme attempts to either maximize or minimize some performance metric.[49] In the case of ASV, the ventilator attempts to select a tidal volume and frequency (for passive ventilation) that minimizes the work rate of ventilation for the patient's particular state of lung mechanics. As the lung mechanics change, the ventilatory pattern changes. ASV requires that the operator input the patient's weight, however, so that the ventilator can calculate an estimated minute ventilation requirement. The operator must also manage PEEP and FIo_2. INTELLiVENT-ASV takes ASV a step further by adding input data from end-tidal CO_2 monitoring and pulse oximetry. These extra data, along with advanced targeting software algorithms, allow the ventilator to automatically select and adjust minute ventilation, PEEP, and FIo_2. This makes INTELLiVENT "… the world's first complete closed-loop ventilation solution that offers automated adjustment of oxygenation and ventilation."[90]

Along with the new targeting systems, this mode also provides a unique operator interface that Hamilton refers to as the "Ventilation Cockpit," an apparent reference to the "autopilot" feature in airplanes. The interface is designed to facilitate understanding complex information in a visually intuitive way. In addition to displaying the usual digital parameters and waveforms, the new mode offers several other screens. The "Dynamic Lung" screen integrates data on lung mechanics, end-tidal carbon dioxide ($P_{ET}CO_2$), and pulse oximetry (SpO_2), and offers a metric called the "heart–lung interaction" index (Fig. 3-28). A graphic element called the "Ventilation Map" plots $P_{ET}CO_2$ against peak airway pressure as shown in Figure 3-29. Another display, the "Oxygenation Map," is very similar to the Ventilation Map: it provides detailed information about the oxygenation status based on the major physiologic input, as measured by pulse oximetry (SpO_2), and the resulting treatment ($PEEP/FIo_2$).

FIGURE 3-28 The operator interface of the Hamilton G5 ventilator with INTELLiVENT-ASV option, called the "Ventilation Cockpit." This screenshot shows the "Dynamic Lung" display including the "Heart–Lung Interaction" index. (Reproduced, with permission, from Chatburn RL. Computer control of mechanical ventilation. *Respir Care.* 2004; 49:507–515.)

Early studies of INTELLiVENT show that compared to ASV, patients ventilated with INTELLiVENT spent more time with optimal ventilation and less time with nonsecure ventilation. In addition, INTELLiVENT delivered lower volumes and pressures for equivalent gas exchange.[91] In another preliminary study, patients managed with INTELLiVENT spent less time with nonsecure and nonoptimal ventilation (3%) compared to conventional ventilation (47%, $P = 0.03$) after cardiac surgery.[92]

We speculate that modes of the future will continue this trend toward automation and include protocols for automatic weaning for various populations of patients. They will provide means for communication with electronic medical records and move us closer to integration of vast amounts of data into useful information for measurable improvements in patient outcomes. This process, however, will present significant challenges to vendors and end users to develop standardized vocabularies, taxonomies, and data transfer protocols in order to assure higher levels of accuracy, security, and usability.

INDICATIONS FOR MECHANICAL VENTILATION

Franco Laghi
Martin J. Tobin

This chapter discusses the indications for mechanical ventilation in adult patients. We focus on patients who are already in the intensive care unit (ICU) or who are considered for transfer to the ICU, that is, patients with new onset of signs and symptoms over minutes or hours. We do not deal with the indications for mechanical ventilation for chronic respiratory failure or in pediatric patients; these subjects are covered in Chapters 23, 18, 33, and 34.

There is a paucity of research—and no clinical trials—on the indications for mechanical ventilation. This situation contrasts with the growing amount of research on the discontinuation of mechanical ventilation. Although it is tempting to apply indices used for predicting the outcome of weaning trials as indices to identify patients who require mechanical ventilation, such an approach has not been tested. It is also probably unwise.

Two factors account for the limited research on indications for mechanical ventilation. First, such patients are extremely ill. Any intervention—such as careful collection of physiologic measurements—that delays institution of ventilation might be viewed as unethical. Second, the nosology of respiratory failure is unsatisfactory (see "Nosology" below). In everyday practice, clinicians do not decide to institute mechanical ventilation because a patient meets certain diagnostic criteria. Instead, clinicians typically decide to institute ventilation based on their assessment of a patient's signs and symptoms. This decision is also grounded on a foundation of solid biomedical theory, specifically principles of pulmonary pathophysiology. Accordingly, we develop our discussion of ventilator indications along these two lines: physical examination and pathophysiologic principles.

OVERALL ASSESSMENT

Clinical presentations that cause a physician to institute mechanical ventilation are protean. They range from patients presenting with frank apnea to patients with clinical signs of increased work of breathing with or without laboratory evidence of impaired gas exchange.[1]

Apnea

Apneic patients, such as those who have suffered catastrophic central nervous system (CNS) damage, need immediate institution of mechanical ventilation. To advocate controlled trials to determine the need for mechanical ventilations in apneic patients is unethical.

Clinical Signs of Increased Work of Breathing

Asthma, chronic obstructive pulmonary disease (COPD), pneumonia, cardiogenic pulmonary edema, and acute respiratory distress syndrome (ARDS) are just a few of the many conditions that cause an increase in work of breathing and, with it, increased energy expenditure by the respiratory muscles.

The energy expenditure of the respiratory muscles can be quantified in terms of pressure-time product[2]—the time integral of the difference between the esophageal pressure tracing and the estimated recoil pressure of the chest wall[3,4] (Fig. 4-1). The pressure-time product of patients in acute respiratory failure is about four times[5–7] the normal value (100 cm H_2O·s/min), and it can be increased sixfold in individual patients.[5,6] The inspiratory pressure-time product can be partitioned into resistive, elastic, and intrinsic positive end-expiratory pressure (PEEP) components (Fig. 4-1).[6] Patients in respiratory distress typically have a 30% to 50% greater inspiratory resistance,[6] 100% greater dynamic elastance,[6] and 100% to 200% greater intrinsic PEEP[5,6] than do similar patients who are not in acute respiratory failure. Inspiratory effort is almost equally divided in offsetting intrinsic PEEP, elastic recoil, and inspiratory resistance.[6] The increase in respiratory effort means that the respiratory muscles account for a much larger fraction of the body's oxygen consumption. In healthy subjects, this fraction is only 1% to 3% of total oxygen consumption. In patients with acute hypoxemic respiratory failure and shock who are undergoing cardiopulmonary resuscitation, the respiratory muscles account for approximately 20% of total oxygen consumption.[8]

Increased work by the respiratory muscles causes respiratory distress. Clinical manifestations of respiratory distress include nasal flaring, retraction of the eyelids, accessory

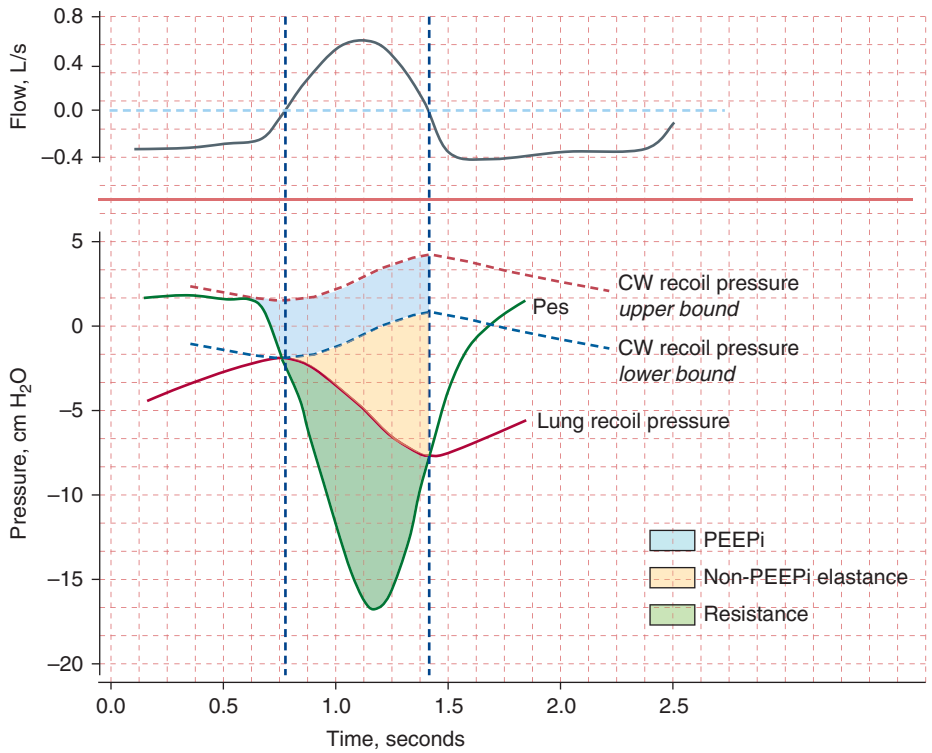

FIGURE 4-1 Flow (*inspiration upward*) and pressure tracings during spontaneous breathing. Recoil pressures of the chest wall (*CW*) and lung are calculated from dynamic elastances of the chest wall and lung, respectively, and lung volume. Inspiratory pressure-time product (PTP) is calculated using the integral of the difference between esophageal pressure (Pes) and CW recoil pressure from the onset of the rapid decrease in Pes to the transition from inspiratory to expiratory flow (upper-bound PTP). The component of PTP caused by intrinsic positive end-expiratory pressure (*PEEPi*) is computed using the integral of the difference between the upper-bound PTP and CW recoil pressure from the onset of rapid decrease in Pes to the transition from inspiratory to expiratory flow (lower-bound PTP). The component of PTP caused by non-PEEPi elastance is computed using the integral of the difference between lung recoil pressure and lower-bound CW recoil pressure from the onset of inspiratory flow to the moment of transition from inspiratory to expiratory flow. The resistive fraction of PTP is computed using the integral of the difference between Pes and lung recoil pressure. The *vertical interrupted lines* represent points for zero flow. (Modified, with permission, from Jubran and Tobin.[6])

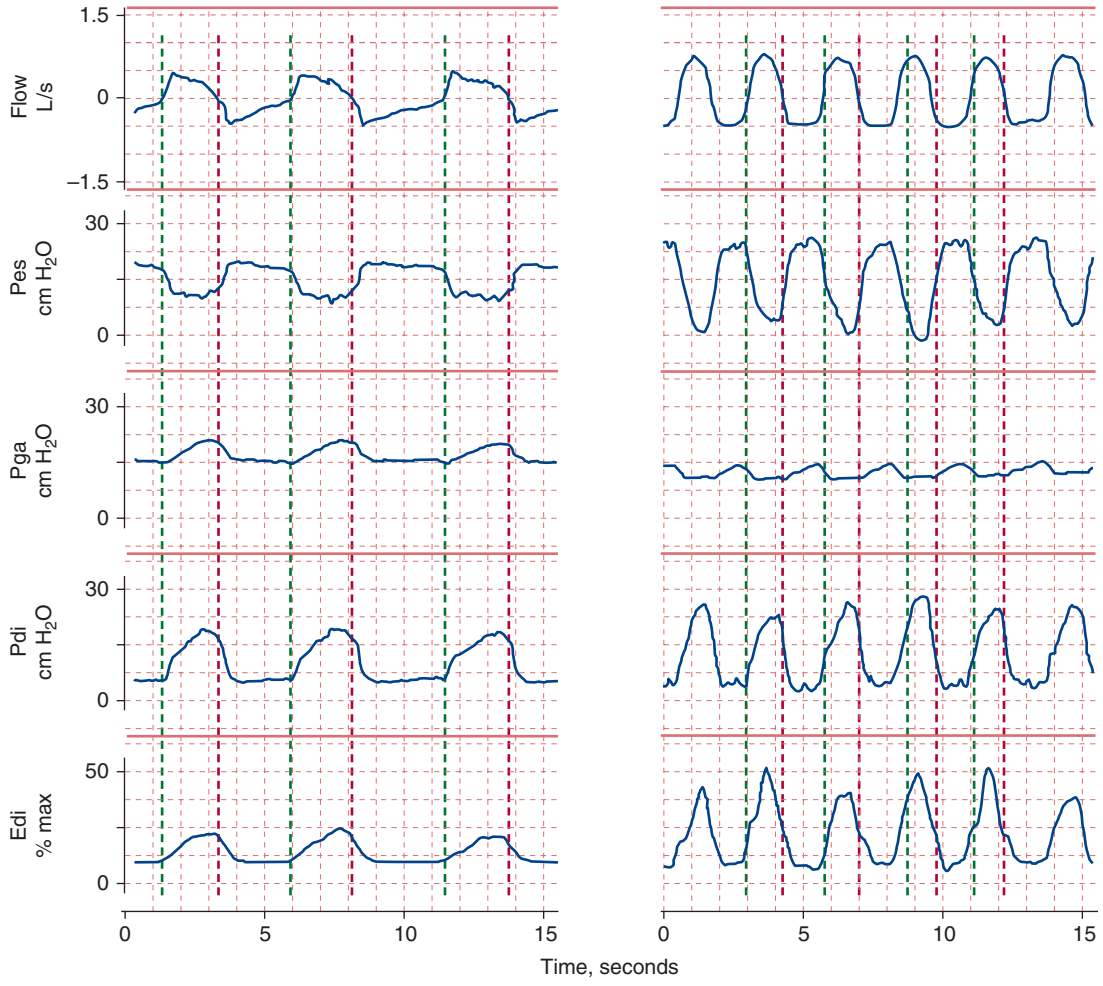

FIGURE 4-2 Respiratory effort during unassisted respiration. Recordings of flow (*inspiration upward*), esophageal (*Pes*), gastric (*Pga*), and transdiaphragmatic (*Pdi*) pressures and electrical activity of the diaphragm (*Edi*) in a stable patient with COPD (*left*) and in a patient with respiratory failure (*right*). The *green vertical lines* indicate the onset of inspiratory flow and the *red vertical lines* indicate the onset of expiratory flow. The excursions in Pes and Edi in the patient in respiratory failure are three times greater than in the stable patient, signifying heightened respiratory motor output. The increase in Pga during exhalation in the patient with respiratory failure signifies expiratory muscle recruitment.

muscle recruitment, expiratory muscle recruitment (Fig. 4-2), tracheal tug, intercostal recession, tachypnea, tachycardia, hypertension or hypotension, diaphoresis, and changes in mental status.

FACIAL SIGNS OF RESPIRATORY DISTRESS

Many intensivists decide to institute mechanical ventilation based on a patient's facial appearance.[9] Gilston has provided an insightful description of many signs that go unstated in reviews on mechanical ventilation.[9] Consider, for example, the mouth. At an early stage of respiratory distress, the mouth opens slightly and to a variable extent during inhalation (Fig. 4-3). At a later stage, the mouth opens throughout the respiratory cycle. Patients may switch to mouth breathing perhaps to decrease respiratory work[9,10] and physiologic dead space ventilation.[9] An open mouth is sometimes seen in patients with a tracheostomy (Fig. 4-4) and in patients receiving ventilator support.[9] The tongue may be seen to jerk in unison with inspiratory efforts.[9]

Some distressed patients also exhibit pursed-lip breathing during exhalation (see Fig. 4-3).[9] In stable, ambulatory patients with COPD, pursed-lip breathing is associated with an increase in tidal volume,[11] a decrease in respiratory rate,[11] and, in patients with severe obstruction, with a decrease end-expiratory lung volume.[12] Pursed-lip breathing can improve the arterial tensions of both carbon dioxide (Pa_{CO_2}) and oxygen (Pa_{O_2}), whereas oxygen uptake ($\dot{V}_{O_2}$) remains unchanged.[11] The latter finding suggests that pursed-lip breathing may allow a decrease in cardiac output without changing tissue oxygenation.[11] Alternatively, if cardiac output does not decrease, pursed-lip breathing may increase mixed venous oxygen saturation, resulting in better tissue oxygenation.[11] Pursed-lip breathing is thought to improve gas exchange by preventing airway collapse. As a result, gas trapping is decreased, resulting in an increase in tidal volume.[11]

FIGURE 4-3 Change in facial appearance during the development and resolution of acute respiratory failure resulting from congestive heart failure and exacerbation of chronic obstructive pulmonary disease. *Left upper panel:* The patient is dyspneic and her mouth is open on inhalation. *Right upper panel:* The patient exhibits pursed-lip breathing on exhalation. Over the ensuing 24 hours, the patient developed hypercapnic respiratory failure and failed a trial of noninvasive ventilation (not shown). *Left lower panel:* The patient is intubated and receiving mechanical ventilation. *Right lower panel:* The patient is successfully extubated 4 days after institution of mechanical ventilation.

A few patients in respiratory distress moan during exhalation. Such moans have been compared with the grunting that is typical of neonates with the respiratory distress syndrome.[9] Grunting results from glottic closure and expiratory muscle recruitment during early exhalation.[13] It is associated with a rise in transpulmonary pressure and oxygenation.[13] If grunting is prevented by tracheal intubation, oxygenation deteriorates.[13] Use of continuous positive airway pressure (CPAP) improves oxygenation and eliminates grunting.[14] The improvement in oxygenation may result from grunting acting as a natural form of PEEP that recruits collapsed alveoli and partially overcomes inequalities in gas distribution caused by differing time constants. Of course, grunting also can arise with disease outside the thorax, such as with an acute abdomen.[15]

Nasal flaring, another facial sign of respiratory distress, is caused by contraction of the alae nasi, the dilator muscle of the external nares.[10] In adults, nasal flaring reduces nasal resistance by approximately 40% to 50% and total airway resistance by approximately 10% to 30%.[10] Factors regulating alae nasi activity include chemical stimuli that cause hyperpnea (hypoxia and hypercapnia),[10,16,17] inspiratory resistive loading,[17] and local stimuli (negative intraluminal nasal pressure).[16] The proportion of patients in respiratory distress who present with nasal flaring is unknown, as is the level of interobserver agreement in detecting flaring. Ventilator support reduces or eliminates alae nasi activity.[18,19]

Diaphoresis, often best detected on the forehead,[9] accompanies respiratory distress in some patients. Among forty-nine patients admitted to the emergency ward for acute bronchial asthma, Brenner et al[20] found that nine patients had profuse sweating. This subgroup displayed greater abnormalities in peak expiratory flow rate and Pa_{CO_2}. In patients with respiratory distress, diaphoresis may result from increased work of breathing,[21] sympathetic stimulation,[21,22] and hypercapnia-associated cutaneous vasodilation.[21,23] In contrast, diaphoresis in patients with heart failure often is associated with hypoperfusion of the skin, vasoconstriction, and cold extremities.[21]

FIGURE 4-4 Change in the configuration of the mouth in a patient with a tracheostomy who becomes dyspneic. *Left:* The patient is resting during full ventilator support and his mouth is closed. *Middle:* Twelve minutes after disconnection from the ventilator, the patient has developed dyspnea and anxiety and his mouth is open. *Right:* Thirty minutes after reconnection to the ventilator, the patient's respiratory distress has resolved and his mouth is closed.

FIGURE 4-5 Drooping of the eyelids accompanying deterioration of mental status during an episode of respiratory failure. *Left:* A patient developed respiratory compromise secondary to atrial fibrillation and heart failure 2 days after prostate surgery. The patient is drowsy with drooping eyelids, and is moderately dyspneic with an open mouth and groans during exhalation. *Middle:* Despite respiratory compromise, the patient is able to drink. *Right:* After 2 days of medical therapy, the patient's dyspnea has resolved and he is alert, cheerful, and talkative.

Mentation can be evaluated by inspection of the face and by simple questioning. With early respiratory distress, nearly all patients are anxious, and their eyelids are retracted. As distress increases, the level of consciousness often decreases, and the lids tend to fall (Fig. 4-5). Instead of remaining alert to their surroundings, patients gaze vacantly ahead.[9] If respiratory failure is left untreated, apathy leads to drowsiness and then coma. These changes in mentation arise because of the underlying cause of respiratory failure (decreased cardiac output in cases of shock, impaired neurologic function in sepsis), acute hypercapnia,[24] or to a lesser extent, hypoxemia.[24,25] In a classic description, Campbell noted that most (nonhypotensive) patients with an exacerbation of COPD have preserved consciousness on arrival to the emergency room despite Pa_{O_2} being as low as 20 to 40 mm Hg.[25] Although extremely useful in overall patient assessment, facial signs of respiratory distress do not necessarily translate into an automatic decision to intubate a patient (Fig. 4-5).

ACCESSORY AND EXPIRATORY MUSCLE RECRUITMENT

Increased respiratory loads in healthy subjects[26,27] and in ambulatory patients with COPD[28] are met with a proportionately greater use of the rib-cage muscles than of the diaphragm.[26–28] As the load increases, the expiratory muscles are recruited.[26,27,29] In addition to increased activity of rib cage and abdominal muscles, the respiratory centers may increase activity of the accessory muscles, especially the sternomastoids.[30–32] The sternomastoids are activated in patients with respiratory compromise[30] and in healthy subjects breathing with a high level of inspiratory effort. The threshold for sternomastoid activation, however, is lower in patients.[31] In patients with respiratory distress,[5,33] sternomastoid recruitment can be phasic (during inhalation) (Fig. 4-6) or tonic.[29,32] Some patients hold their head off the pillow to enhance sternomastoid action.[9]

TACHYPNEA, PARADOX, TRACHEAL TUG, INTERCOSTAL RECESSIONS

Changes in respiratory rate are one of the most useful signs in evaluating the need for mechanical ventilation. Tachypnea is a near-universal sign accompanying respiratory distress.

Obtaining reliable measurements of respiratory rate and interpreting the values are not straightforward. First, bedside assessment often is inaccurate. In one study, 40% of nurses' estimations of respiratory frequencies deviated by more than 20% from the true value.[34] Agreement as to the presence of tachypnea among physicians, expressed as a κ value (κ of 0 indicates that agreement is no better than chance; κ of 1 indicates complete agreement), was only 0.25.[35] Second, the

FIGURE 4-6 Sternomastoid muscle recruitment and intercostal recession during an episode of respiratory distress.

TABLE 4-1: RESPIRATORY RATES IN HEALTH AND DISEASE

Condition	Number of Subjects	Mean (breaths/min)	SD	Mean + 2 SD
Healthy nonsmoker	65	16.6	2.8	22.2
Healthy smoker	22	18.3	3.0	24.3
Asthma	17	16.6	3.4	23.4
COPD, eucapnia	16	20.4	4.1	28.6
COPD, hypercapnia	12	23.3	3.3	29.9
Restrictive lung disease	14	27.9	7.9	43.7
Pulmonary hypertension	7	25.1	6.4	37.9
Chronic anxiety	13	18.3	2.8	23.9

Abbreviations: COPD, chronic obstructive pulmonary disease; SD, standard deviation.

Source: Data from Tobin et al.[37]

within-day (within an individual) coefficient of variation in respiratory rate among young, healthy adults is 21 ± 12%; in old, healthy adults, it is 29 ± 11%.[36] Thus, accurate quantification of respiratory rate requires counting more breaths than contained in the usual 15-second sample.[36,37] Third, the day-to-day coefficient of variation of respiratory rate is 7 ± 2% in healthy individuals[36]; the value in patients with pulmonary diseases is unknown. Fourth, the typical respiratory rate in patients with different disease states varies from one state to the next[37] (Table 4-1); a rate that is judged high in a previously healthy subject may arouse no concern in a patient with restrictive disease. The upper limit of normal (mean + 2 standard deviations [SD]) in health is 22 breaths/min.[37] The equivalent value for stable patients with COPD is 30 breaths/min, and for patients with restrictive lung disease, 44 breaths/min.[37]

Despite limitations in its measurement, tachypnea is an important clinical sign. In a retrospective case-controlled study of patients discharged from an ICU, the only continuous variables that predicted readmission to the ICU were higher respiratory rate (24 vs. 21 breaths/min) and lower hematocrit.[38] Readmitted patients had a much higher mortality than the control patients, 42% and 7%, respectively, and respiratory problems accounted for more than half the readmissions. Of eighteen patients who were discharged from the ICU with a respiratory rate of more than 30 breaths/min, twelve required readmission. In a study of patients who had experienced a cardiopulmonary arrest, 53% had documented deterioration in respiratory function in the 8 hours preceding the arrest.[39] Of interest, respiratory rate was elevated in most patients (mean: 29 ± 1 [SE (standard error)] breaths/min), whereas other routine laboratory tests showed no consistent abnormalities. That detection of tachypnea did not lead to a change in patient management (in an effort to prevent the arrest) led the authors to surmise that physicians do not fully appreciate its clinical importance.

Shallow respiration (when measured with instrumentation) is common in patients with acute respiratory distress.[40] Judging tidal volume as shallow based on physical examination is very unreliable.[41,42] Clinical skill in this task is not improved by years of experience.[42]

Patients in distress commonly display abnormal chest wall movements.[43,44] Abnormal movements can be separated into three categories. One, asynchrony, consists of a difference in the rate of motion of the rib cage and abdomen (Fig. 4-7). Two, paradox, consists of one compartment moving in the opposite direction to tidal volume (Fig. 4-7). The third abnormality is greater-than-normal breath-to-breath variation in the relative contribution of the rib cage and abdomen to tidal volume; this pattern, termed *respiratory alternans*, represents recruitment and derecruitment of the accessory intercostal muscles and the diaphragm. In the past, it was thought that these three abnormalities of motion represented respiratory muscle fatigue.[45] It is now known that they represent signs of increased load and occur in the absence of fatigue.[46] These abnormalities are seen not only in patients with respiratory distress,[47] but also in some ambulatory patients[37,47] and during sleep (sleep apnea syndrome).[48]

Increased tidal swings in intrathoracic pressure are axiomatic to increases in the work of breathing. The greater downward movement of the diaphragm tends to pull down the trachea (just as a sexton ringing a bell) with each inspiration,[49] producing a sign termed *tracheal tug.* Tracheal tug correlates closely with severity of airway obstruction (Fig. 4-8).[50]

The intercostal spaces normally bulge inward during inhalation and outward during exhalation.[15] Inspiratory retraction of the intercostal space—serving as a window into the pleural space—is increased in patients with respiratory disease (see Fig. 4-6). The suprasternal fossa also moves inward in direct proportion to swings in pleural pressure.[51,52] Focal exaggerated retraction of the intercostal space can occur with a flail chest. Focal expiratory bulging may be seen on the side of a tension pneumothorax or over the area of a flail chest.[15] As with other physical signs, studies often reveal poor agreement among physicians.[35,53] For example, Godfrey et al[53] found agreement among eleven relatively experienced chest physicians in identifying tracheal tug to be midway between chance and maximum possible agreement. Spiteri et al[35] found poor agreement among experienced physicians for detecting reduced chest movements ($\kappa = 0.38$) and cricosternal distance ($\kappa = 0.28$)[35]; they did not address tracheal tug or inspiratory retractions.

The interpretation of data generated by studies that quantify physical signs is hazardous. The entity that researchers are quantifying can be very different from the skill involved in the physician's actions. Physical examination is an art—learned through apprenticeship, not out of a book. Thus, we should bear in mind Braque's caution about art appreciation: "The only thing that matters in art can't be explained." Likewise, the essence of physical examination is its tacit

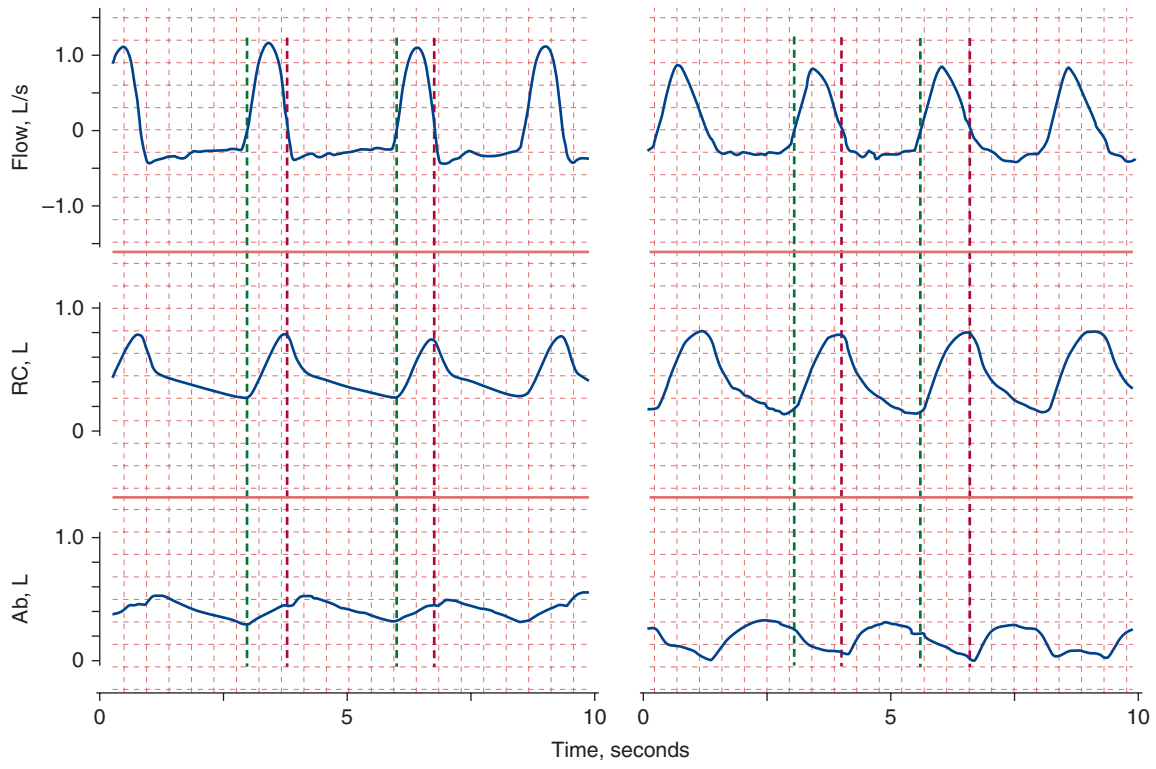

FIGURE 4-7 Recordings of flow (*inspiration upward*), rib cage (*RC*), and abdominal (*Ab*) cross-sectional areas in two patients in respiratory distress. The *green vertical lines* indicate the onset of inspiratory flow and the *red vertical lines* indicate the onset of expiratory flow. On the *left*, expansion of the rib cage is occurring faster than expansion of the abdomen (asynchrony). On the *right*, while the rib cage expands during inspiration, the abdominal cross-sectional area is getting smaller (paradox).

coefficient; the explicit, measurable components may be the least relevant. Another problem with research on physical signs is test-referral bias. For example, the studies of Godfrey et al[53] and Spiteri et al[35] were confined to patients with respiratory diseases; a more appropriate design also would have included healthy subjects and patients with diseases not affecting the lungs. These flaws in the methodology of such studies markedly underestimate the diagnostic power of physical examination.

CARDIOVASCULAR SIGNS OF RESPIRATORY DISTRESS

Respiratory distress frequently is associated with tachycardia and hypertension. Tachycardia and hypertension likely are caused by increased sympathetic discharge.[54] In some patients, such as those with sepsis, cardiac impairment, or severe hypoxemia, respiratory distress is associated with hypotension and not hypertension.

FIGURE 4-8 Tracheal tug in acute respiratory failure. *Left:* During exhalation, the cricoid cartilage is located 2 fingerbreaths above the suprasternal notch (normally, at least 4 fingers). *Right:* During inhalation, the cricoid cartilage is pulled below the suprasternal notch and the thyroid cartilage is 1 fingerbreath above the suprasternal notch, whereas it was 5 fingerbreaths above the notch on exhalation (*left*).

Pulsus paradoxus is defined as an inspiratory fall in systolic pressure of greater than 10 mm Hg.[15] Pulsus paradoxus is very common in patients with an exacerbation of asthma but also in patients with COPD, shock, and pericardial tamponade (see Chapter 36).[15,20]

NONUNIFORM PRESENTATION

Patients with impending respiratory failure do not have a uniform presentation. The spectrum ranges from a patient complaining of dyspnea to a patient with impending respiratory arrest. Several factors are responsible. Patients differ in the balance between work of breathing and the capacity of the respiratory muscles to generate pressure. They also differ in the central processing of neural afferents. For instance, patients with a history of near-fatal asthma have a blunted perception of dyspnea,[55] reduced sensitivity to added inspiratory resistive loads,[56] and a reduced chemosensitivity to hypoxia.[55] Alexithymia, the difficulty in perceiving and expressing emotions and body sensations, occurs more often in patients who experience near-fatal asthma than in less-severely affected patients.[57] In addition, hypoxia, and possibly hypercapnia, can impair sensations of respiratory load.[58]

IMPENDING RESPIRATORY FAILURE

Development of impending respiratory failure is a commonly listed indication for mechanical ventilation.[59] But *impending respiratory failure* has no clear definition. Some clinicians use the term to mean development of severe tachypnea, diaphoresis, and use of accessory muscles of respiration; others use it to mean agonal breathing.

In some circumstances, physicians do not institute mechanical ventilation until they obtain results of diagnostic testing, such as chest radiographs, electrocardiograms, or arterial blood-gas analyses. Even in this situation, clinicians commonly do not change their mind when the test results are different from those expected. In most circumstances, a patient's clinical presentation is so dramatic that mechanical ventilation is instituted without performing arterial blood-gas analysis. If arterial blood-gas results are not available before connecting a patient to a ventilator, they are almost invariably available shortly after. Arterial blood-gas analysis is helpful in choosing the type of support best suited to a patient's needs. Analysis also serves to classify patients into two broad groups: hypoxemic respiratory failure (Table 4-2) and hypercapnic respiratory failure; some patients display features of both.[60]

Hypoxemic Respiratory Failure

PATHOPHYSIOLOGY

The pathophysiologic mechanisms responsible for hypoxemia can be grouped into two broad categories depending on whether there is (or is not) an increased alveolar-arterial oxygen gradient ($A\text{-}aD_{O_2}$).* An increased $A\text{-}aD_{O_2}$ results from either ventilation–perfusion ($\dot{V}_A/\dot{Q}$) abnormalities or excessive right-to-left shunt. (Diffusion impairment, a third cause of increased $A\text{-}aD_{O_2}$, plays only a marginal role in the development of hypoxemia.) Patients with hypoxemic respiratory failure and a normal $A\text{-}aD_{O_2}$ typically have alveolar hypoventilation or inadequate inspiratory partial pressure of oxygen. Hypoxemia results from a low inspired P_{O_2} or when the fractional concentration of inspired oxygen (FI_{O_2}) is less than 0.21, such as at high altitude or when O_2 is consumed from ambient gas secondary to a fire. A low FI_{O_2} also can arise during anesthesia if a low-oxygen gas mixture is administered inadvertently. Hypoxemic respiratory failure also can be caused by the combination of a decreased mixed venous oxygen content and impaired gas exchange, such as in patients with heart failure and concurrent $\dot{V}_A/\dot{Q}$ derangements or increased shunt.

A right-to-left shunt is present when venous blood returning from the tissues passes to the systemic arterial circulation without coming into contact with gas-containing alveoli. The shunt is the major mechanism of abnormal gas exchange in patients with pulmonary edema, ARDS, pneumonia, and atelectasis. In all these instances, the shunt results from the perfusion of alveoli that are unventilated because they are filled with fluid or collapsed.

TABLE 4-2: COMMON CAUSES OF HYPOXEMIC RESPIRATORY FAILURE

Pneumonia
Cardiogenic pulmonary edema
Acute respiratory distress syndrome
Aspiration of gastric contents
Multiple trauma
Immunocompromised host with pulmonary infiltrates
Pulmonary embolism

*$A\text{-}aD_{O_2}$ is calculated as $PA_{O_2} - Pa_{O_2}$, where PA_{O_2} (alveolar O_2 tension) can be estimated according to the simplified alveolar gas equation:

$$PA_{O_2} = FI_{O_2} \times (P_B - PH_2O) - Pa_{CO_2}/R$$

where FI_{O_2} is fractional concentration of inspired O_2 (approximately 0.21 when breathing room air), P_B is barometric pressure (approximately 760 mm Hg at sea level), PH_2O is water vapor pressure (usually taken as 47 mm Hg at 37°C [98.6°F]), and R is respiratory exchange ratio of the whole lung. The respiratory exchange ratio (R) = CO_2 production/O_2 consumption ($\dot{V}_{CO_2}/\dot{V}_{O_2}$) is normally approximately 0.8. In steady state, R is determined by the relative proportions of free fatty acids, protein, and carbohydrate consumed by the tissues. In this equation, it is assumed that alveolar P_{CO_2} and Pa_{CO_2} are the same (usually they nearly are). In healthy young subjects (≤30 years old) breathing air at sea level, $A\text{-}aD_{O_2}$ is usually less than 10 mm Hg, but it increases to as much as 28 mm Hg in some healthy 60-year-old subjects.

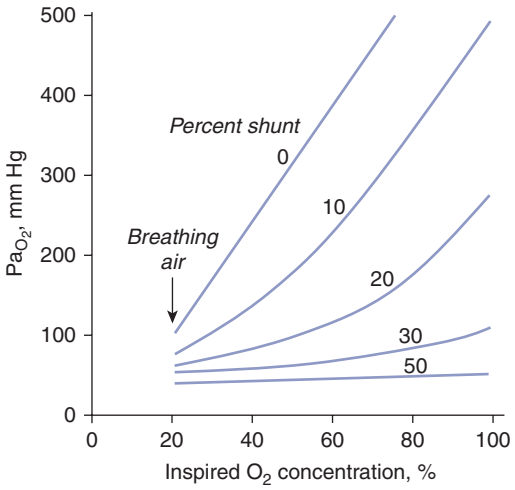

FIGURE 4-9 Relationship between arterial P_{O_2} (Pa_{O_2}) and increases in inhaled oxygen concentrations for different levels of shunt. When the shunt fraction is 30% or more of cardiac output, Pa_{O_2} increases little despite marked increases in inhaled oxygen concentration. The plot is a simplification that ignores factors such as cardiac output and oxygen uptake, which influence the location of the lines. (Modified, with permission, from West.[61])

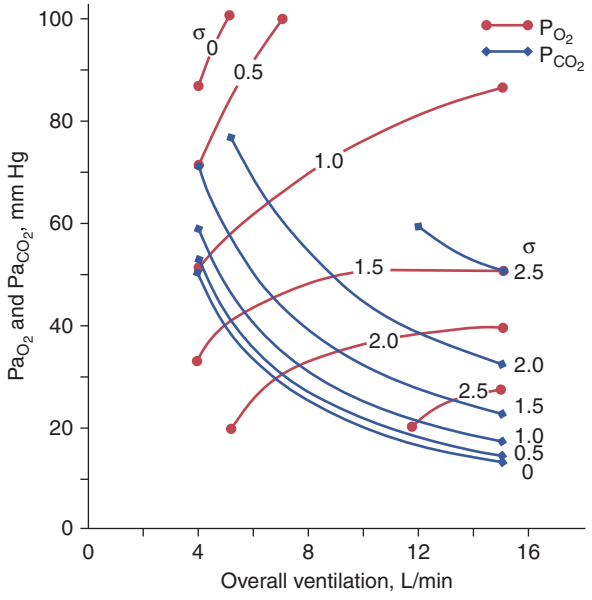

FIGURE 4-10 Effect of increasing overall ventilation on Pa_{O_2} and Pa_{CO_2} (lung model) as a function of different degrees of $\dot{V}_A/\dot{Q}$ mismatching, represented in terms of dispersion or standard deviations (σ) of the log-normal distribution of ventilation and perfusion. (Dispersion of 0.30 to 0.05 = normal $\dot{V}_A/\dot{Q}$ mismatch; 1.0 = moderate $\dot{V}_A/\dot{Q}$ mismatch; 2.0 = severe $\dot{V}_A/\dot{Q}$ mismatch.) Increases in overall ventilation have a powerful effect on Pa_{O_2} and Pa_{CO_2} when $\dot{V}_A/\dot{Q}$ dispersion is small. Abnormal $\dot{V}_A/\dot{Q}$ dispersion does not cause an increase in Pa_{CO_2} as long as patients are able to increase minute ventilation sufficiently. Pa_{O_2} also increases with increases in overall ventilation, although when $\dot{V}_A/\dot{Q}$ dispersions are (very) altered, normal Pa_{O_2} cannot be reached very easily, and further effects on ventilation have little effect on Pa_{O_2}. In the patients who cannot maintain a high rate of ventilation owing to the increased work of breathing and in those whose respiratory motor output increases only slightly when Pa_{CO_2} is high, hypercapnia can ensue. (Modified, with permission, from West.[64])

A characteristics feature of a shunt is the failure of Pa_{O_2} to increase to the expected level when a patient breathes 100% oxygen (Fig. 4-9).[61]

In patients with a large shunt, Pa_{CO_2} may be low because the low Pa_{O_2} stimulates respiratory motor output and minute ventilation ($\dot{V}_E$).[62] A shunt typically produces more severe hypoxemia than does $\dot{V}_A/\dot{Q}$ inequality.

Optimal uptake of oxygen depends on proper matching of ventilation and perfusion within the lung. In semirecumbent young healthy subjects breathing room air, the range (or dispersion) of $\dot{V}_A/\dot{Q}$ ratios is quite small: More than 95% of both ventilation and perfusion is limited between $\dot{V}_A/\dot{Q}$ ratios of 0.3 and 2.1.[63] The dispersion increases with age.[63] With pulmonary disease, the range of $\dot{V}_A/\dot{Q}$ ratios widens,[64] varying from 0 (perfused but unventilated, i.e., shunt) to infinity (ventilated by unperfused, i.e., alveolar dead space). In other words, $\dot{V}_A/\dot{Q}$ inequality does not refer to alterations in the ratio of total ventilation to total perfusion, which constitute global hyperventilation or hypoventilation. (One lung could receive all ventilation and the other all perfusion for an overall $\dot{V}_A/\dot{Q}$ ratio of 1.0).[65] $\dot{V}_A/\dot{Q}$ inequality refers to regional mismatching of ventilation to perfusion. $\dot{V}_A/\dot{Q}$ inequality, no matter what its mechanism, interferes with overall efficiency of the lung for exchanging all gases, including oxygen, CO_2, CO, and anesthetic gases.[62]

$\dot{V}_A/\dot{Q}$ mismatch is the most common cause of hypoxemia. Several compensatory mechanisms tend to minimize the effects of abnormal $\dot{V}_A/\dot{Q}$ ratios. The low PA_{O_2} associated with a low $\dot{V}_A/\dot{Q}$ ratio causes pulmonary vasoconstriction. The low PA_{CO_2} associated with a high $\dot{V}_A/\dot{Q}$ ratio causes hypocapnic bronchoconstriction (e.g., pulmonary embolism).[66] These responses, however, only achieve partial compensation. As $\dot{V}_A/\dot{Q}$ inequality increases in the presence of a constant $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$, there is an immediate and marked fall in Pa_{O_2} and a slower increase in Pa_{CO_2}. The increase in Pa_{CO_2} and, to a lesser extent, the fall in Pa_{O_2} stimulates the chemoreceptors and leads to an increase in $\dot{V}_E$. In patients without a significant reduction in ventilatory capacity, the increase in ventilation is sufficient to bring Pa_{CO_2} back to normal, although it has only a small effect on the fall in Pa_{O_2} (Fig. 4-10). Thus, most patients with $\dot{V}_A/\dot{Q}$ inequalities have a low Pa_{O_2} but normal Pa_{CO_2}.[67] Ventilation in excess of normal alveolar requirement is termed *wasted ventilation*.[62] All normocapnic patients with COPD have increased ventilation of their alveoli, as do most hypercapnic patients.[62]

The different responses of Pa_{O_2} and Pa_{CO_2} to an increase in the level of ventilation is caused by the different shapes of the oxyhemoglobin and CO_2 dissociation curves (Fig. 4-11). The oxyhemoglobin dissociation curve is flat in the normal range. Thus, only units with moderately low $\dot{V}_A/\dot{Q}$ ratios benefit appreciably from the increased ventilation. Lung units that are positioned on the upper portion of the dissociation

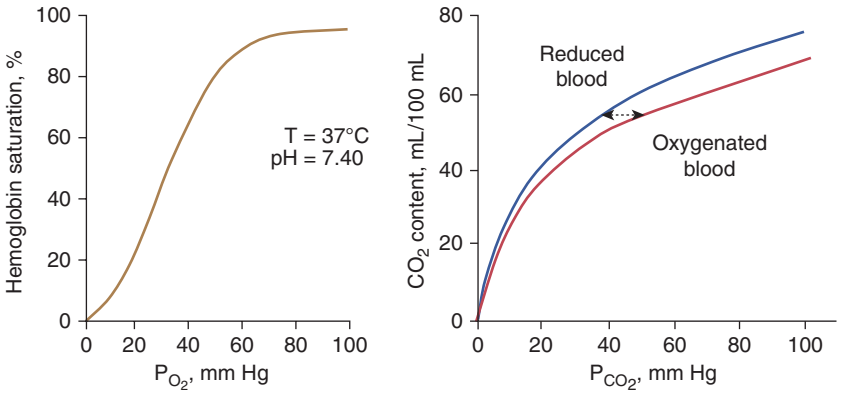

FIGURE 4-11 *Left:* Normal oxyhemoglobin dissociation curve. The curve has a sigmoid shape because when one subunit of the normal tetrameric form of the adult hemoglobin becomes oxygenated, it induces a structural change in the whole complex. Consequently, the three other subunits gain a greater affinity for oxygen until four molecules of oxygen are combined with hemoglobin. *Right:* The CO_2 dissociation curve for oxygenated and reduced blood. The relationship is steeper and more linear than the oxyhemoglobin dissociation curve. Oxygenation of blood causes the curve to shift to the right (Haldane effect), and, for a given CO_2 content, oxygenated blood has a higher P_{CO2} than reduced blood.

curve (high $\dot{V}_A/\dot{Q}$ ratio) develop little increase in the oxygen concentration of their effluent blood. The net result is that with increasing $\dot{V}_E$, the mixed Pa_{O_2} rises only modestly, and some hypoxemia always remains.[62] By contrast, the CO_2 dissociation curve is almost linear in the physiologic range (Fig. 4-11). Thus, an increase in $\dot{V}_E$ raises CO_2 output of lung units with both high and low $\dot{V}_A/\dot{Q}$ ratios.[62] The different shapes of the two dissociation curves are the main reason that patients with parenchymal lung disease have greater hypoxemia relative to hypercapnia. One final compensatory adjustment is possible: increase in cardiac output.[68] Adrenergic stimulation by arterial hypoxemia can raise cardiac output by 50% or more; this improves arterial blood gases by raising mixed venous oxygen and by lowering mixed venous CO_2.[68]

Administration of supplemental oxygen in patients with $\dot{V}_A/\dot{Q}$ inequality will cause arterial hypoxemia to reverse impressively because PA_{O_2} of even poorly ventilated units increases sufficiently to achieve saturation (Fig. 4-12). Unless FI_{O_2} is 1.0, it is impossible to determine the relative contribution of right-to-left shunt versus $\dot{V}_A/\dot{Q}$ inequality to an increase in $A\text{-}aD_{O_2}$.[69] After breathing 100% oxygen for a sufficient time, only units that are totally or almost totally unventilated (shunt, true shunt, or anatomic shunt) will contribute to hypoxemia.[69]

Systemic hypotension and hypertension modulate the ventilatory responses to hypoxemia (and hypercapnia). This so-called ventilatory baroreflex increases the operating point of the ventilatory response to hypoxemia (and hypercapnia) during hypotension and it decreases the operating point of the ventilatory response to hypoxemia (and hypercapnia) during hypertension.[70]

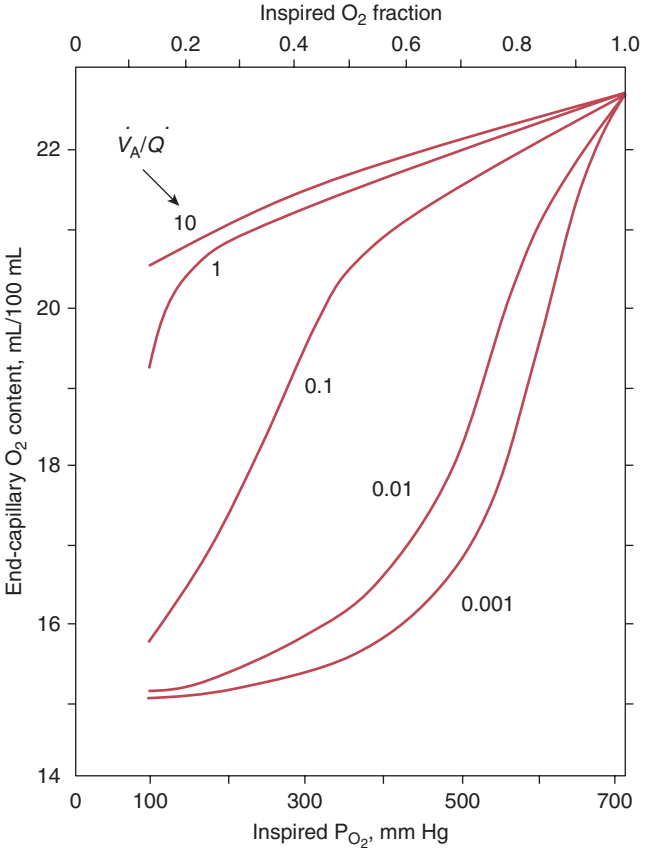

FIGURE 4-12 The effect of alterations in inhaled partial pressure of oxygen (P_{O_2}) on oxygen content of end-capillary blood of a lung unit. Each line depicts a different ventilation–perfusion ratio ($\dot{V}_A/\dot{Q}$). With mild to moderate degrees of $\dot{V}_A/\dot{Q}$ inequality ($\dot{V}_A/\dot{Q}$ down to 0.1), end-capillary oxygen content increases as inhaled oxygen is increased. With severe $\dot{V}_A/\dot{Q}$ inequality ($\dot{V}_A/\dot{Q}$ below 0.1), the increase in end-capillary oxygen content with an increase in inhaled oxygen is much slower; only when inspired P_{O_2} is more than 400 to 500 mm Hg does end-capillary oxygen content of the lung unit reach values equivalent to those seen with mild to moderate degrees of $\dot{V}_A/\dot{Q}$ inequality. (Modified, with permission, from West.[64])

PHYSIOLOGIC EFFECTS OF HYPOXIA

Although the physiologic effects of hypoxia are graded, the damaging effects are sudden.[71] A remarkable degree of

arterial hypoxemia is required to cause tissue hypoxia.[25] In clinical practice, Campbell[25] observed that the lowest Pa_{O_2} compatible with life is 20 mm Hg (equivalent to an arterial oxygen saturation [Sa_{O_2}] of 30% to 40%). Evidence of end-organ damage is difficult to demonstrate in patients with a Pa_{O_2} above 40 mm Hg (equivalent to an Sa_{O_2} of approximately 70%).[25] Obviously, the duration of hypoxemia and the state of circulation (oxygen delivery) play major roles in determining the minimum Pa_{O_2} that does not cause end-organ damage or death.

The threshold Pa_{O_2} commonly used to diagnose hypoxemic respiratory failure is 60 mm Hg, which corresponds to an Sa_{O_2} of 90% (hypoxic hypoxia). Pa_{O_2} values below 60 mm Hg fall on the steep portion of the oxyhemoglobin dissociation curve, and decreases below that value are associated with precipitous falls in Sa_{O_2} (see Fig. 4-11). Although physiologically reasonable, for self-evident ethical reasons, the 60 mm Hg (Pa_{O_2}) threshold cannot be validated experimentally.

The main concern with hypoxemia is impaired tissue oxygenation, especially of the heart and brain. The factors determining oxygen supply to the tissues include hemoglobin concentration, Sa_{O_2}, the affinity of hemoglobin for oxygen (P_{50}), cardiac output, regional oxygen consumption-to-perfusion relationships, and the diffusion of oxygen from the capillary to intracellular sites. The amount of oxygen delivered to the tissues is calculated as

$$O_2 \text{ delivery} = Ca_{O_2} \times \text{cardiac output}$$

where arterial oxygen content (Ca_{O_2}) is calculated as

$$Ca_{O_2} = (Hb \times 1.34 \times Sa_{O_2}/100) + (0.003 \times Pa_{O_2})$$

Even with a satisfactory Pa_{O_2}, tissue hypoxia may arise because of decreased Ca_{O_2} (e.g., decreased hemoglobin concentration or decreased hemoglobin function, such as in carbon monoxide poisoning or anemic hypoxia), decreased oxygen delivery (e.g., cardiogenic shock or stagnant hypoxia), and decreased capacity of the tissues to use oxygen (e.g., sepsis, cyanide intoxication, or histotoxic hypoxia). Otherwise stated, tissue hypoxia can be present despite adequate Pa_{O_2}, or it can be absent despite an abnormally low Pa_{O_2}.[59]

Respiratory Responses. Peripheral chemoreceptors (carotid and aortic bodies) detect changes in arterial oxygen. Within seconds after the onset of hypoxia, they initiate reflexes that are important for maintaining homeostasis.[72–74] The aortic bodies play a minor role in modulating spontaneous respiratory activity, although they have a discernible effect when their gain is increased by hypercapnia.[75]

Hypoxia augments sensory discharge from the peripheral chemoreceptors, which, in turn, send neural impulses to the respiratory centers (inspiratory neurons of the dorsal respiratory group and ventral respiratory group[76]), causing an increase in the $\dot{V}_E$.[72,73,77,78] Hyperpnea, in turn, activates pulmonary afferents, thereby buffering the sympathetic response to hypoxemia.[79]

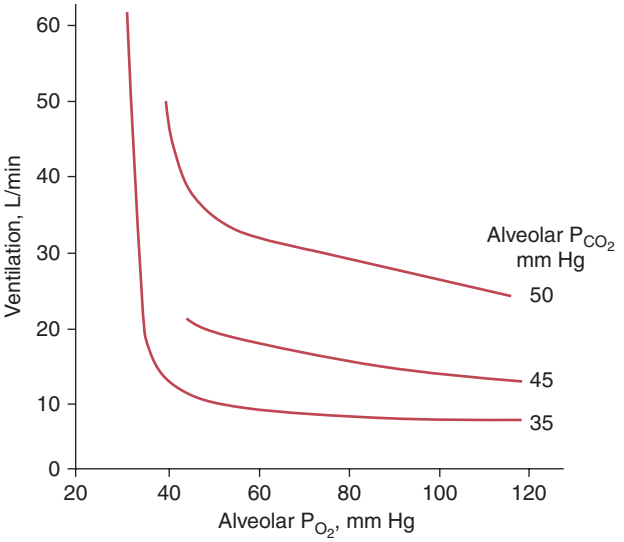

FIGURE 4-13 Relationship between ventilation and alveolar pressure of oxygen (P_{O_2}) at various levels of alveolar carbon dioxide (P_{CO_2}). The ventilatory response increases with the increase in P_{CO_2}. At alveolar P_{CO_2} 35 mm Hg, ventilation exhibits virtually no increase until alveolar P_{O_2} falls below 40 mm Hg and, thereafter, ventilation increases abruptly.

The ventilatory response to progressive hypoxia is hyperbolic[72] and increases in the presence of concurrent hypercapnia[75] (Fig. 4-13). It decreases with age.[80] Chronic hypoxia may induce a reduced ventilatory response to hypoxia in patients with COPD,[75] although the role of airway narrowing in producing this effect cannot be excluded.[75]

The ventilatory response to hypoxemia is attenuated or abolished in patients who have undergone surgical excision of the carotid bodies.[73,74,78,81] The increase in ventilation in response to hypoxemia probably contributes to coronary vasodilation.[82] Stimulation of the carotid bodies with nicotine under normoxic conditions causes an increase in ventilation and coronary vasodilation.[82] Coronary vasodilation does not occur if the increase in ventilation is prevented by general anesthesia.[82]

Cardiovascular Responses. Hypoxic stimulation of chemoreceptors triggers reflex adrenergic vasoconstriction in muscle and coronary vasodilation but does not elicit a reflex response in the cerebral vessels.[74,79,82,83] Hypoxia also causes local vasodilation.[72,79] The net effects are increases in heart rate, cardiac output (resulting from the positive chronotropic effect of hypoxemia, not increased stroke volume[84]), pulmonary artery resistance,[85] and cerebral and coronary blood flow.[74,79,80,82–84] Hypoxemia fails to increase systemic blood pressure[84] or increases it very modestly (<10 mm Hg rise in systolic and diastolic pressures).[77] The increase in blood pressure, but not in heart rate, is absent in patients in whom the carotid bodies are inactivated.[74,77] Persistent tachycardic response to hypoxemia in patients with bilateral carotid body ablation likely is mediated by the effect of hypoxemia on the aortic bodies.[72]

Tachycardia caused by hypoxemia is mediated by multiple factors, including CNS-mediated sympathetic discharge, effect of P_{O_2} on the cardiac pacemaker, and concomitant hyperpnea.[77] These mechanisms presumably override the cardioinhibitory signals (bradycardic effect) from the carotid body.[77] The importance of hyperpnea in overriding the bradycardic effect is supported by the observation that hypoxemia combined with cessation of lung inflation (sleep apnea,[86] breath holding,[87] or neuromuscular blockade during intubation[88]) or diminution of lung inflation (such as when hyperpnea is prevented by controlled ventilation[89,90]) is more apt to produce bradycardia than tachycardia.[72,86] Bradycardia results from the concurrent activation of the carotid bodies by hypoxia and increased cardiac vagal activity induced by apnea.[79,83] The increased vagal activity (induced by apnea) can be so intense as to induce bradycardia in the absence of coexisting hypoxemia; this response has been described in patients with spinal cord injury within seconds of discontinuation from a ventilator.[91] Simultaneously with the increase in cardiac vagal activity, diminution of lung inflation causes marked potentiation of the sympathetic vasoconstrictor response to hypoxemia (secondary to the lack of inhibitory influence of the pulmonary stretch receptors).[83] (This combination of sympathetic vasoconstriction and vagal bradycardia constitutes part of the diving reflex.[83])

Severe hypoxemia is not tolerated by the CNS because it has a high rate of oxygen consumption and lacks alternative energy reserves.[92] Therefore, severe hypoxemia causes cerebral depression.[73] Patients with cerebral hypoxia develop bradycardia, hypotension,[88] and hypoventilation,[93] which further worsens hypoxia and induces a potentially lethal vicious cycle.

CLINICAL PRESENTATION OF HYPOXEMIA

Cyanosis. Physicians commonly view cyanosis as the hallmark of hypoxemia.[72] Cyanosis is recognized as a blueness of the capillary blood visible through the mucous membranes or skin, where capillaries are numerous and close together and the tissues over them are thin and transparent, such as the lips (central cyanosis) and nail beds.[72]

Based on the classic work of Lundsgaard and Van Slyke, it is widely believed that central cyanosis represents the presence of at least 5 g/dL of deoxygenated hemoglobin in the blood of the capillaries.[94] Because the arteries and most of the veins are so far away from the skin, their content cannot influence skin color.[94] Importantly, it is the quantity of reduced hemoglobin per deciliter of capillary blood, not the relative lack oxygenated hemoglobin, that produces the blue coloration of cyanosis.[95] Lundsgaard and Van Slyke demonstrated the crucial effect of hemoglobin on the development of cyanosis.[94] When hemoglobin is 15 g/dL, cyanosis reflects an Sa_{O_2} of 78%. In an anemic patient with a hemoglobin of 9 g/dL, cyanosis will not occur until Sa_{O_2} falls to 65%, whereas in a polycythemic patient, with a hemoglobin of 18 g/dL, cyanosis will occur at a Sa_{O_2} of 83% (Fig. 4-14). In addition to hemoglobin, detection of cyanosis also depends on variables

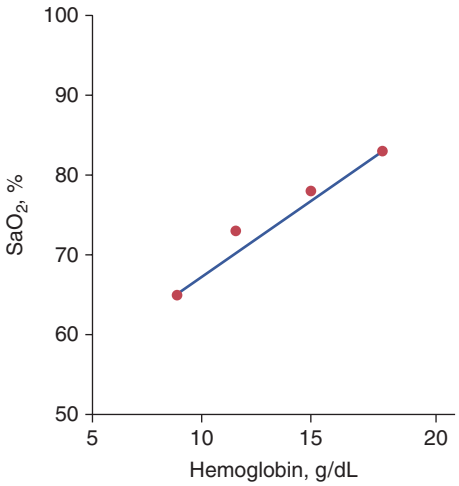

FIGURE 4-14 The dependence of cyanosis—resulting from the presence of 5 g of reduced hemoglobin per deciliter of capillary blood—on prevailing hemoglobin. In anemic patients, cyanosis signifies more severe hypoxemia than in a polycythemic patient. (Based on data from Lundsgaard and Van Slyke.[94])

such as thickness and opacity of the skin and perfusion status, as well as on the visual skills of the observer.[96,97] In seventy-two patients who had Sa_{O_2} values ranging between less than 75% and 100%, agreement among three observers was only 69% when inspecting the tongue, 61% when inspecting the lips, and 53% when inspecting the nail bed.[97] In that study,[97] cyanosis of the tongue and lips was recorded in 40% to 45% of patients with normal Sa_{O_2} values. Rather than a blue or pink color, pallor is seen with both anemia and shock. Thus, severe or fatal tissue hypoxia may occur without cyanosis.[72]

Cardiopulmonary Manifestations. Acute hypoxemia increases respiratory frequency, tidal volume, and $\dot{V}_E$ in almost all subjects.[72] Increases in $\dot{V}_E$, however, are an unreliable guide because the interindividual response is considerable.[96] The standard deviation for the within-subject variability in day-to-day hypoxic ventilatory response is approximately 22%.[98] The respiratory response to mild or moderate hypoxemia may be barely measurable or absent.[72] An increase in heart rate is equally of limited value because many other factors, such as fever, low blood pressure, pain, apprehension, and drugs, can cause it to rise.[72] Moreover, under specific circumstances (see "Cardiovascular Responses" above), hypoxemia causes bradycardia rather than tachycardia. Hypoxemia tends to increase systolic blood pressure in some subjects; the wide variations in response[77] renders arterial pressure of little value in the diagnosis of hypoxemia.[72]

Neurologic Manifestations. The metabolic needs of the brain largely depend on oxidation of glucose to CO_2 and water.[92] The brain cannot store oxygen. It survives only for minutes after the supply is reduced to critical levels.[92] In acute anoxia, consciousness is lost within 15 seconds.

TABLE 4-3: NEUROLOGIC SIGNS AND SYMPTOMS OF HYPOXIA

Pa_{O_2}, mm Hg	Signs and Symptoms of Hypoxia
35 to 50	Loss of critical judgment, confusion, delirium (resembling alcohol intoxication), tremors, asterixis
25 to 35	Somnolence, obtundation, myoclonic jerks, seizures
20 to 25	Loss of consciousness
<20	Death

The electroencephalogram slows with a Pa_{O_2} of less than 35 mm Hg or with blood flow of less than 40% of normal.[92] Loss of the electroencephalogram tracing occurs when cerebral P_{O_2} reaches 20 mm Hg or following 20 seconds of complete anoxia.[92]

In the absence of defects of cerebral blood flow, Pa_{O_2} below 40 mm Hg is required to produce prominent symptoms (Table 4-3).[24,99,100] Confusion and delirium (resembling alcohol intoxication) appear at Pa_{O_2} values of 35 to 50 mm Hg.[65] Tremors and asterixis (flapping tremor elicited by dorsiflexing the wrists with the arms outstretched and caused by a momentary interruption of normal continuous action potentials to both flexor and extensor muscles) are infrequent even when the Pa_{O_2} is less than 40 mm Hg.[24,25] Somnolence and obtundation occur at Pa_{O_2} values of 25 to 35 mm Hg. Some patients develop myoclonic jerks (bursts of excitation to resting muscles) and seizures.[24] At approximately 25 mm Hg, consciousness is lost,[65] and death often ensues.

When considering the neurologic manifestations of hypoxemia, Pa_{O_2} is only a small part of a complex situation. A decrease in Pa_{O_2} may be well tolerated if oxygen delivery is maintained by the combination of increased cardiac output and systemic vasoconstriction.[101] These compensatory mechanisms, however, can be overwhelmed by anemia or carbon monoxide poisoning, which decrease oxygen-carrying capacity (anemic hypoxia), or by atherosclerosis or other causes of vascular occlusion (ischemic hypoxia) in which the increased cardiac output does not suffice to prevent tissue damage.

Hypercapnic Respiratory Failure

PATHOPHYSIOLOGY

Hypercapnic respiratory failure is a state in which ventilation is insufficient to maintain a normal Pa_{CO_2} for the level of metabolic activity (measured by CO_2 production, $\dot{V}_{CO_2}$).[1] Common causes include COPD, severe asthma, conditions where respiratory motor output is decreased (e.g., neoplasm and infections of the CNS, medications, and drugs), neuromuscular-skeletal diseases (e.g., myasthenia gravis, Guillain-Barré syndrome, and trauma), and upper airway obstruction.

Under steady-state conditions, the relationship between Pa_{CO_2}, alveolar ventilation ($\dot{V}_A$), and $\dot{V}_{CO_2}$ is given by the equation

$$Pa_{CO_2} = (\dot{V}_{CO_2}/\dot{V}_A) \cdot K$$

The constant K is usually stated as 0.863; it converts measurements of $\dot{V}_{CO_2}$ from standard conditions to body-temperature conditions. The term $\dot{V}_A$ represents the portion of $\dot{V}_E$ that reaches the terminal gas-exchange units and is calculated as

$$\dot{V}_A = \dot{V}_E - V_D$$

where V_D equals dead space ventilation. A reduction in $\dot{V}_A$ may result from an inadequate $\dot{V}_E$ or an increase in V_D (resulting from an increase in true V_D or a functional increase in V_D secondary to lung regions with high $\dot{V}_A/\dot{Q}$ relationships).

The mechanisms responsible for hypercapnia can be grouped into two categories, depending on whether there is (or is not) an increased A-aD_{O_2}. In pure alveolar hypoventilation (e.g., neuromuscular diseases, drug overdoses, and CNS pathologies), A-aD_{O_2} is usually normal (unless lung abnormalities are present). In disorders associated with $\dot{V}_A/\dot{Q}$ inequality (e.g., COPD and ARDS), A-aD_{O_2} is increased.

Pa_{CO_2} in excess of 90 mm Hg is unlikely in patients breathing room air because the concomitant degree of hypoxia is incompatible with survival.[25] Such Pa_{CO_2} values can occur if a patient is breathing oxygen-enriched air.[102]

PHYSIOLOGIC EFFECTS OF HYPERCAPNIA

Hypercapnia elicits autonomic and ventilatory responses primarily through central chemoreceptors located in the rostral ventrolateral medulla.[74] These respond to changes in hydrogen ion concentration.[74] Hypercapnia, probably via a reduction in intracellular pH, also stimulates peripheral arterial chemoreceptors located in the carotid bodies, aortic bodies, and abdomen.[103,104] Only 15% to 30% of the ventilatory response to hypercapnia results from peripheral chemoreceptor stimulation.[105,106] Not surprisingly, the Pa_{CO_2} of patients with bilateral resection of the carotid bodies is higher (by 4.6 ± 1.3 [SD] mm Hg) than in healthy subjects.[81]

Respiratory Responses. Hypercapnia causes an increase in $\dot{V}_E$; stimulation peaks with an inhaled CO_2 of 10%.[107] In contrast to the hyperbolic response to progressive hypoxemia (see Fig. 4-13), the hypercapnic ventilatory response is linear (Fig. 4-15).[72] The ventilatory response to CO_2 is enhanced in the presence of hypoxia or metabolic acidosis[108] and decreases with age.[80]

Hypercapnia and hypoxia induce different patterns of neuromuscular activation as $\dot{V}_E$ rises—even when the respiratory components of tidal breathing (tidal volume and inspiratory and expiratory times) are similar.[76] First, hypercapnia is a more potent stimulus for expiratory muscle recruitment than is hypoxemia—one-third of subjects do not recruit their expiratory muscles during hypoxemia.[76] Second, activation of the diaphragm is greater during

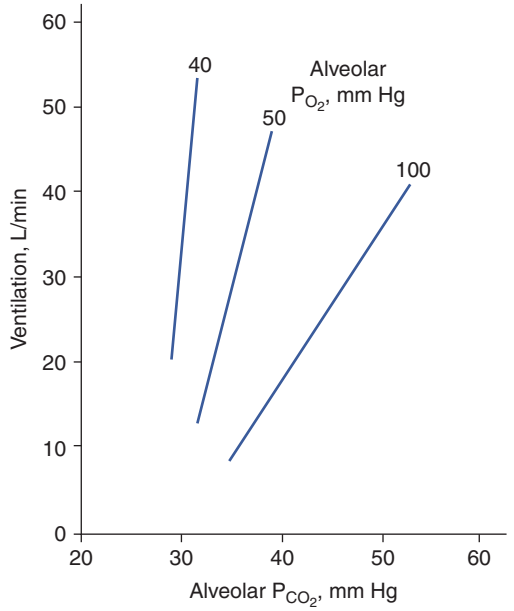

FIGURE 4-15 Ventilatory response to progressive hypercapnia. Ventilation increases linearly with increase in alveolar carbon dioxide (P_{CO_2}). Decreases in alveolar oxygen (P_{O_2}) produce a steeper ventilatory response to progressive hypercapnia.

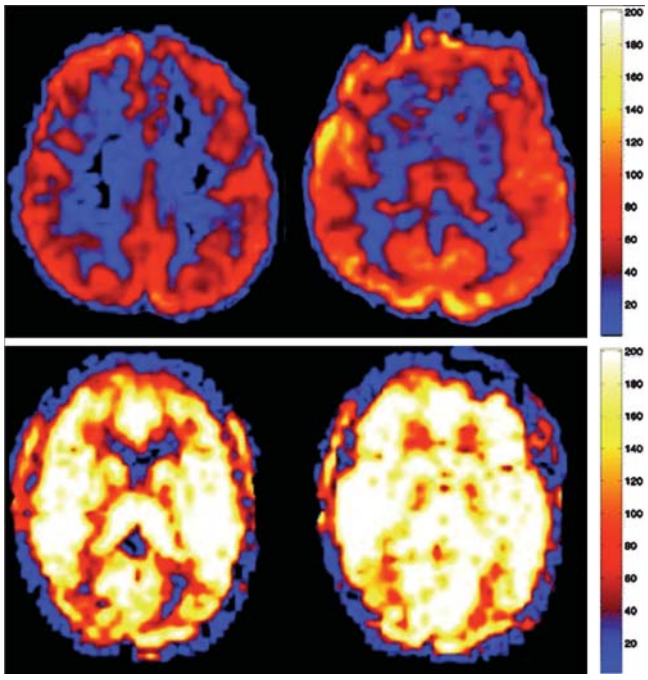

FIGURE 4-16 Arterial spin-labeled magnetic resonance perfusion imaging. *Upper panel:* A patient with normocapnia (Pa_{CO_2} 39 mm Hg), in whom the left image passes through the corona radiata and the right through the thalamus. Cerebral blood flow throughout the gray matter (red discoloration) is normal (mean: 63 mL/100 g tissue/min). *Lower panel:* A patient with emphysema and hypercapnia (Pa_{CO_2} 56 mm Hg), in whom the left image passes through the thalamus and the right through the basal ganglia. Cerebral blood flow is markedly increased (white-yellow discoloration; mean: 175 mL/100 g tissue/min), signifying global hyperperfusion. (Modified, with permission, from Pollock et al.[112])

hypoxemia than during hypercapnia.[76] (The lack of expiratory recruitment during hypoxemia may increase end-expiratory lung volume, which increases oxygen reserves.[76]) The ventilatory response to CO_2 in healthy subjects exhibits a very wide range, 0.47 to 8.16 L/min/mm Hg, although approximately 80% of subjects have a response between 1.5 and 5 L/min/mm Hg.[1]

Cardiovascular Responses. Hypercapnia causes greater increases in sympathetic activity[104,109] and (usually) greater increases in systemic blood pressure (approximately 30 mm Hg rise in systolic pressure and approximately 25 mm Hg rise in diastolic pressure[110]) than does hypoxemia.[104] Acting via baroreflexes, this greater hypertensive response may be partly responsible for the more limited rise in heart rate during hypercapnia than during hypoxemia.[104] The tachycardic response to hypercapnia is blunted in the elderly.[80] Apnea increases the sympathetic nerve activity elicited by hypercapnia.[104] This increase, however, is less than the increase during hypoxemia.[104]

Combined hypoxia and hypercapnia have a synergistic effect on sympathetic nerve activity[104] and hyperpnea. This potentiation may arise because hypercapnia sensitizes the response of peripheral chemoreceptor afferents to hypoxia.[104] Another possibility is that both peripheral and central chemoreceptors synapse on common nuclei in the brainstem.[104]

Hypercapnia not only has a sympathetic vasoconstrictor effect (secondary to chemoreceptor activation) but also has a direct vasodilator effect on systemic arterioles[23,72]; dilation of conjunctival and superficial facial vessels may be noted. The first action, however, is predominant in conscious persons, and blood pressure and heart rate increase. If the vasomotor center cannot respond (e.g., secondary to brain damage, severe ischemia or hypoxia, or deep anesthesia) or is disconnected from peripheral parts of the sympathetic nervous system (e.g., secondary to spinal cord damage or blocking drug or spinal anesthesia), direct vasodilation becomes the sole or dominant effect, and blood pressure falls.[23,72,111]

Hypercapnia causes cerebral hyperperfusion (Fig. 4-16).[112] The increase in blood flow is proportional to the severity of hypercapnia.[112] Cerebrovascular reactivity to CO_2 depends on age (i.e., there is reduced cerebral perfusion reserve in the elderly)[113] and state (i.e., there is a 70% reduction in cerebrovascular reactivity to CO_2 during non–rapid eye movement sleep).[114] Hypercapnic cerebrovascular reactivity also is reduced in patients with preexisting cerebrovascular diseases.[115]

Neurologic Responses. Hypercapnia decreases cerebral metabolic rate for glucose and interferes with cerebral energy

production.[116] The cerebral metabolic rate for oxygen is maintained, or slightly increased, provided that Pa_{CO_2} is less than 90 to 100 mm Hg.[116] For higher values of Pa_{CO_2}, cerebral metabolic rate for oxygen decreases.[116] Hypercapnia has a dual effect on neuron excitability: stimulatory at low concentrations and inhibitory at high concentrations.[72] In humans, very high concentrations (30%) can produce surgical anesthesia, which can be associated with seizures.[72,102,107]

CLINICAL PRESENTATION OF HYPERCAPNIA

The clinical manifestations of hypercapnia result from a complex interaction of several factors, including severity of hypercapnia, comorbidities, and the speed at which the increase in CO_2 has occurred. For example, patients receiving chronic oxygen therapy have been reported to function satisfactorily with Pa_{CO_2} values of greater than 100 mm Hg.[72] Therefore, there is no single threshold of Pa_{CO_2} above which mechanical ventilation is mandatory.

Most signs and symptoms of acute hypercapnic respiratory failure, including hyperpnea, dyspnea, tachycardia and hypertension, and diaphoresis, are similar to those of hypoxemia. Some consider it a waste of effort to try to separate which manifestations are related to hypoxemia and which to hypercapnia.[117]

The major clinical features of hypercapnia are those affecting the CNS. One difference between acute hypoxemic and acute hypercapnic respiratory failure is the greater incidence of neurologic manifestations with the latter. Acute hypercapnia can cause fine tremors (of the outstretched hands, head, or legs), asterixis, myoclonic jerks, sustained myoclonus, and seizures.[24,107] It also can cause cognitive disorders, hostility, irritability, paranoid behavior, somnolence, stupor, and coma.[24] In a study of thirty-two episodes of acute respiratory failure, Kilburn[24] reported that the severity of cognitive disorders, asterixis, and somnolence, and the presence of stupor and coma were closely related to the severity of respiratory acidosis—and not to the severity of hypoxemia.

Some patients with severe hypercapnia have papilledema and elevated cerebrospinal fluid pressure probably because of the increase in blood volume within the near-rigid cranial cavity.[72,118] Under conditions of prolonged hypercapnia (several hours), cortical blood flow may return toward baseline over time.[119] The latter is probably mediated by a buildup of brain extracellular bicarbonate and an increase in pH.[119]

Some patients with combined hypoxemic and hypercapnic respiratory failure become more comatose when treated with oxygen (CO_2 narcosis). The mechanisms responsible for oxygen-induced hypercapnia are complex and probably include reduction in ventilation, increased wasted ventilation (alveolar dead space),[120] and the Haldane effect (Pa_{CO_2} increases because of net release of CO_2 from erythrocytes when Sa_{O_2} is increased)[1] (see Fig. 4-11).

Postoperative Respiratory Failure

Postoperative respiratory failure can be defined as the need for intubation and mechanical ventilation in the 48 hours after surgery.[121] Among more than 180,000 patients who underwent major noncardiac surgery, postoperative respiratory failure occurred in 3%.[121] This exceeds the incidence of cardiac arrest or acute myocardial infarction after noncardiac surgery (1.3%).[122] Among 1055 patients, most of whom underwent lower abdominal/inguinal hernia repair or orthopedic limb surgery, 0.1% required intubation within 7 days of surgery.[123]

Pulmonary complications are estimated to account for nearly 25% of deaths within 6 days of surgery.[124] This figure may be an underestimate; many patients with respiratory failure can be kept alive by ventilator support, only to die from nonrespiratory complications (e.g., sepsis and multiorgan failure).[125] Among patients who undergo major noncardiac surgery, mortality is 27% to 42% for those with postoperative respiratory failure versus 1% to 6% for those without postoperative respiratory failure.[121,126,127] Respiratory failure is the most important determinant of postoperative mortality in 40% to 100% of thoracic surgery patients.[125,128,129]

A common cause of postoperative respiratory failure is the development of atelectasis (Fig. 4-17). Atelectasis is the most frequent pulmonary complication after general surgery (particularly thoracic and upper abdominal surgery) (Table 4-4).[125,128,129] Atelectasis occurs in approximately 90% of patients during anesthesia.[130] During uneventful anesthesia, before any surgery is begun, 15% to 20% of the lung base is collapsed.[131] With thoracic surgery and cardiopulmonary bypass, more than 50% of the lung can be collapsed several hours after surgery.[132] After abdominal surgery, atelectasis can persist for several days,[133] and application of lung recruitment maneuvers and PEEP at the conclusion of the procedure do not improve postoperative oxygenation.[134]

One mechanism for the development of atelectasis during general anesthesia is decreased respiratory muscle tone, which is accompanied by cephalad displacement of the diaphragm, 20% reduction in functional residual capacity (60% reduction in obesity), and compression of lung tissue.[125,135] Two other purported mechanisms are impaired function of surfactant and resorption of gas behind occluded airways (particularly with high FI_{O_2}).[131]

Persistent or new atelectasis after anesthesia can be caused by several mechanisms. First, patients undergoing abdominal or thoracic surgery experience a marked reduction in vital capacity and a smaller but clinically important decrease in functional residual capacity.[135] These changes are ascribed to postoperative pain and diaphragmatic dysfunction.[135,136] Abnormal abdominal mechanics reduce end-expiratory lung volume below (the increased) closing volume, leading to absorption of gas from poorly ventilated lung units.[137] Second, the weakened diaphragm no longer acts as a rigid wall between the thoracic and abdominal space.[136] The positive abdominal pressure transmitted to the thoracic cavity

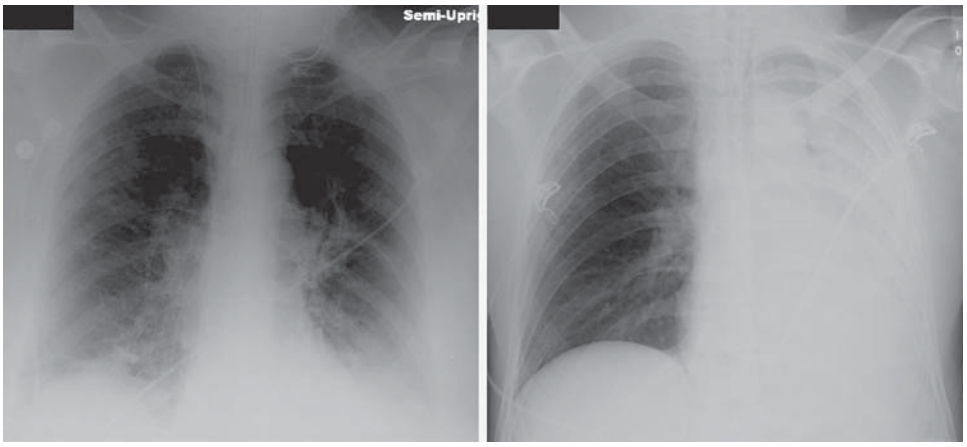

FIGURE 4-17 Postoperative atelectasis. *Left:* Portable anteroposterior chest radiograph showing bibasilar subsegmental atelectasis following hemicolectomy. *Right:* Atelectasis of the entire right lung caused by mucus plugging following drainage of submandibular and pterygomandibular space abscesses.

increases pleural pressure and causes compression atelectasis—particularly in the dependent thorax.[131,138] Third, mucociliary clearance is impaired.[139,140] Fourth, narcotics[141] and pain[142] suppress periodic deep breaths. Lack of intermittent deep breaths favors alveolar collapse by precluding alveolar recruitment and decreasing active forms of alveolar surfactant.[143] Fifth, narcotics[141] and pain[142] also suppress cough and interfere with the ability to clear secretions.[144] In a prospective study of 361 patients undergoing elective lung surgery (including pneumonectomy, lobectomy, wedge and segmental resection, and bullectomy), Bonde et al[144] reported that complications related to retention of secretions (i.e., atelectasis, pneumonia, and respiratory failure) occurred in 30% of patients.[144] On multivariate analysis, being a current smoker, having ischemic heart disease, and the absence of regional analgesia or failure of regional analgesia (thoracic epidural or extrapleural intercostal nerve infusion block) increased the risk of secretion retention.[144] Of twelve in-hospital deaths, ten were considered complications of secretion retention. Sixth, risk of atelectasis is increased with routine use of nasogastric tubes.[123,145,146] Seventh, preexisting pulmonary disease[147] and current smoking[148]—associated with increased postoperative secretions[144]—increase the risk of atelectasis. The end result of atelectasis can be hypoxemic respiratory failure, hypercapnic respiratory failure, or both, and pneumonia and sepsis (Fig. 4-18).[137,149] Development of mucous plugging with lobar or multilobar collapse of the lung is a less-common cause of atelectasis than the development of subsegmental atelectasis (see Fig. 4-17).

Preoperative assessment is useful in identifying patients at increased risk after thoracic and nonthoracic surgery.[123,126,150] In a prospective study of 272 patients undergoing nonthoracic surgery, McAlister et al[150] identified three independent risk factors for postoperative complications: age 65 years or older, smoking of 40 pack-years or more, and maximum laryngeal height of 4 cm or less.

In a subsequent study of 1055 patients undergoing nonthoracic surgery, these investigators reported four independent risk factors for postoperative complications: age 65 years or older, positive cough test (recurrent coughing after asking a patient to cough once), perioperative nasogastric tube, and duration of anesthesia of 2.5 hours or longer.[123] In a prospective study of more than 180,000 patients undergoing major noncardiac surgery, Arozullah et al[126] reported that type of surgery, albumin and blood urea nitrogen levels, functional status, COPD, and age could be used to generate an index to identify patients at risk for postoperative respiratory failure. These results were prospectively validated by the same investigators in a second study comprising more than 180,000 patients undergoing major noncardiac surgery.[121] Solid data on the usefulness of respiratory physiotherapy, including incentive spirometry, inspiratory muscle training, and noninvasive ventilation to *prevent* pulmonary complications, after cardiac or upper abdominal surgery are lacking.[151]

TABLE 4-4: CAUSES OF POSTOPERATIVE RESPIRATORY FAILURE

Intrapulmonary causes
Atelectasis
Aspiration
Pneumonia
Acute respiratory distress syndrome/acute lung injury
Volume overload/congestive heart failure
Pulmonary embolism (thrombus, air, fat)
Bronchoconstriction (asthma/COPD)
Pneumothorax
Extrapulmonary causes
Shock
Sepsis
Decreased respiratory motor output
Phrenic nerve injury
Diaphragmatic dysfunction
Upper airway obstruction
Obstructive sleep apnea

Abbreviation: COPD, chronic obstructive pulmonary disease.

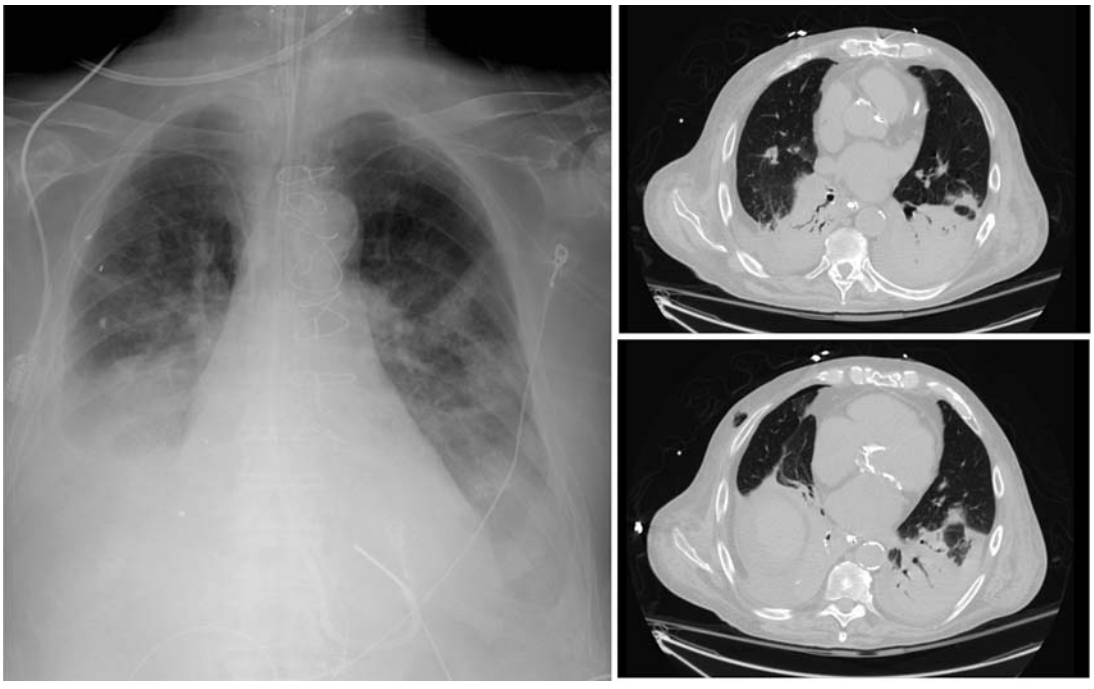

FIGURE 4-18 *Intrapulmonary* and *extrapulmonary* causes of postoperative respiratory failure. Eighty-year-old man with COPD and aortic valve replacement underwent small bowel resection and repair of traumatic diaphragmatic hernia. Six days after surgery he developed respiratory distress caused by atelectasis, atrial fibrillation, volume overload, and aspiration. Following intubation, chest radiograph *(left)* demonstrated discoid atelectasis in the left upper lung zone, pleural effusions, and pulmonary infiltrates. Computed tomography *(right)* revealed air space opacities suggestive of pneumonia and lower-lobe atelectasis.

Patients undergoing cardiac surgery are especially prone to postoperative complications because they are subjected to prolonged anesthesia and, commonly, hypothermia.[152,153] Patients also often require therapy for hypotension or hypertension, as well as fluid resuscitation (including blood transfusions).[152,153] Cardiac surgery can temporarily increase respiratory load.[154–156] At the end of coronary bypass surgery, lung compliance is less and lung resistance greater after chest closure than before surgery.[154] An increase in lung water after cardiopulmonary bypass, especially if the lungs remain collapsed during surgery, contributes to the worsening mechanics. In eight patients undergoing valvular surgery, compliances of the chest wall and lung were less at 4 hours after surgery than before surgery (Fig. 4-19).[155] By 7 hours, chest wall compliance was back to baseline, and lung compliance was higher than before surgery.[155] The investigators speculated that the initial decrease in lung compliance is caused by interstitial fluid secondary to increased vascular permeability.[155] The subsequent increase in lung compliance may result from mobilization of fluid that had accumulated before surgery (as a consequence of valvular disease) and as a result of extracorporeal circulation (increased permeability). Severe restrictive pulmonary defect is the rule,[157,158] and venous admixture (or sum of true shunt and $\dot{V}_A/\dot{Q}$ mismatch) is increased.[158] At the end of surgery, many patients are transferred to the ICU while fully ventilated. Patients then are given the time to rewarm, to metabolize the medications received during anesthesia, and to receive therapy for any hemodynamic derangements that are present.

From the 1960s to 1990s, prolonged controlled mechanical ventilation was the standard of care following cardiac surgery.[159–161] This strategy was justified by the use of high-dose

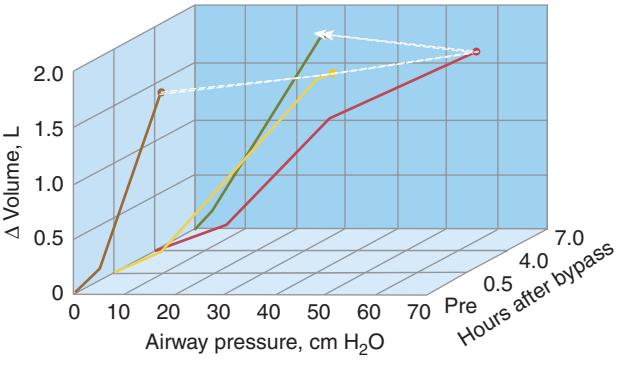

FIGURE 4-19 Cardiopulmonary bypass causes a reversible impairment in respiratory mechanics. Static inflation volume-pressure (V-P) curve of the respiratory system in a patient before cardiopulmonary bypass (*Pre*) and 0.5, 4.0, and 7.0 hours later. Compared with before bypass (*orange curve*), the slope of the V-P curve is less steep 0.5 hours later (*yellow curve*), and less steep again at 4 hours (*red curve*). At 7 hours, the slope of the V-P curve has returned to baseline (*green curve*). An increase in lung water after bypass contributed to the temporary worsening of compliance. *Δ Volume*, changes in lung volume relative to the elastic equilibrium volume of the respiratory system. (Data from Ranieri et al.[155])

narcotic anesthesia and concerns about myocardial ischemia in the early postoperative period.[161–163] Since the early 1990s, under pressure of cost containment and improved resource utilization,[164] early extubation strategies have been implemented successfully in uncomplicated cardiac surgery cases.[152,153,165] Early extubation is achieved by modifying intraoperative anesthetic techniques (e.g., usually a decrease in total opioid administration, use of ultrashort-acting opiates, and use of inhaled techniques[153,166,167]), minimizing sedation during the postoperative ICU stay,[153] and improving postoperative pain control.[168] Recovery to spontaneous respiration and extubation is shorter with rapid tracheal extubation strategies than with conventional strategies—median time of approximately 4 and 7 hours, respectively.[152,153] Approximately 20% to 30% of patients, however, do not tolerate (or are not candidates for) rapid tracheal extubation strategies because of postoperative complications (e.g., bleeding, myocardial ischemia, myocardial infarction, refractory hypoxemia, or neurologic complications).[152,153] Early extubation may improve cardiac output[169] and renal perfusion[162,170] and reduce cardiopulmonary morbidity,[171] as well as decrease hospital stay without adverse outcome.[165,166]

In addition to early extubation (extubation achieved in less than 6 hours after surgery[165]), immediate extubation in the operating room has been reported after coronary bypass grafting with or without valve replacement,[161,167,172,173] single-lung transplantation,[174] and two-stage esophagectomy.[175] Recently, coronary bypass grafting with high thoracic epidural anesthesia in the awake and spontaneously breathing patient has been achieved successfully.[176] This latter strategy remains highly controversial.[177]

Shock

Shock can be defined as a "state in which a profound and widespread reduction of effective tissue perfusion leads to reversible, and, if prolonged, irreversible cellular injury."[178] Based on hemodynamic profile, shock is classified into four categories: cardiogenic, hypovolemic, extracardiac obstructive, and distributive.[178]

PHYSIOLOGIC EFFECTS OF SHOCK

All forms of shock exhibit common cellular metabolic processes that typically lead to cell injury, organ failure, and eventually, death.[178,179] These processes are caused by multiple interrelated factors, including cellular ischemia, circulating or local inflammatory mediators, and free radical injury.[178,179]

Shock elicits at least three respiratory responses: increase in dead space ventilation, respiratory muscle dysfunction, and pulmonary inflammation. The increase in dead space ventilation is an early accompaniment of shock.[180–182] It results from a fall in pulmonary perfusion.[178] (The terminology of dead space is confusing. *Anatomic dead space* is made up of the conducting airways (nose, mouth, pharynx, larynx, trachea, bronchi, and bronchioles). *Alveolar dead space* is made up of alveoli that receive some or no blood flow, which does not match ventilation (units with very high $\dot{V}_A/\dot{Q}$ ratio). *Physiologic dead space* is the sum of anatomic dead space and alveolar dead space.) $\dot{V}_E$ increases to achieve normocapnia.[182,183] $\dot{V}_E$ also may further increase through other mechanisms. First, baroreflex deactivation (secondary to hypotension) amplifies the ventilatory response to stimulation of the peripheral chemoreceptors.[184] Second, direct stimulation of the aortic chemoreceptors occurs as a result of decreased oxygen delivery.[185] (This point, although clearly demonstrated in the cat,[185] remains controversial in humans.[75]) Third, cerebral hypoperfusion causes intracellular hypercapnia and acidosis[72] and, in turn, induces further hyperventilation unless the neurons are depressed (e.g., by hypoxia, lack of substrates, or excessive accumulation of metabolic products).[72] Fourth, increased respiratory drive occurs as a result of peripheral stimulation of pulmonary J receptors.[178] Fifth, increased respiratory drive results from vestibular activation during orthostasis (vestibulorespiratory reflex).[186] Sixth, $\dot{V}_E$ increases to compensate for lactic acidosis,[187] which results in part from the overworked and underperfused respiratory muscles.[182,188,189] The increase in $\dot{V}_E$ accompanying these responses may enhance venous return (through the respiratory pump) and vasoconstriction (through reduced Pa_{CO_2}), helping the cardiovascular system to cope with hypovolemia.[190]

Respiratory muscle dysfunction is one result of the associated cellular dysfunction and injury.[136,191] Many mechanisms contribute to this dysfunction in septic shock, including failure of neuromuscular transmission (because of elevated of muscle membrane potential and failure of excitation–contraction coupling), the cytotoxic effect of nitric oxide and its metabolites, free radicals, ubiquitin-proteasome proteolysis, and, possibly, a decrease in nicotinic acetylcholine receptors.[136,192] Local dysregulation of the circulation and of the Krebs cycle also may contribute.[136] Many pathways purported to be responsible for respiratory muscle dysfunction in sepsis are also activated in cardiogenic and hemorrhagic shock.[193–198]

Laboratory animals with cardiogenic[199] and septic shock[192,200] die of respiratory failure. Death is not caused by pulmonary disease per se but by an inability of the respiratory muscles to maintain adequate ventilation. In dogs with cardiogenic shock, institution of mechanical ventilation decreases the metabolic needs and thus the blood flow to the respiratory muscles (from 21% to 3% of the total cardiac output).[201] A nonrandomized study by Kontoyannis et al[202] in twenty-eight patients with cardiogenic shock provides support for the view that hemodynamic instability is an indication for mechanical ventilation. Compared with nonventilated patients, ventilated patients were weaned from an intraaortic balloon pump more often, and their survival was greater.[202]

The failure to reverse shock and treat the underlying cause promptly predisposes to ARDS (see Chapter 29). Pulmonary vascular resistance increases during shock, including septic shock (in which peripheral vascular resistance is usually decreased).[203]

Hypovolemic, distributive, and extracardiac obstructive shock result in decreased diastolic filling. Low-pressure stretch receptors located in right atrium and pulmonary artery consequently signal the medullary vasomotor centers, triggering sympathetic discharge.[178,204] High-pressure baroreceptors in the aortic arch contribute (negative feedback to the tonic discharge of the medullary vasoconstrictor centers) to the vasomotor response of shock as long as the mean arterial pressure is no lower than 80 to 90 mm Hg.[205] When mean pressure is less than 80 to 90 mm Hg, the aortic baroreceptor response is eliminated (baroreceptor deactivation).[178,205] Likewise, the carotid baroreceptors contribute (negative feedback) to the vasomotor response as long as the mean pressure is no lower than 60 mm Hg.[205] When mean pressure is less than 60 mm Hg, the carotid baroreceptor response is eliminated.[205] When mean pressure is less than 50 to 60 mm Hg, the peripheral chemoreceptors (sensitive to Pa_{O_2}, Pa_{CO_2}, and pH) dominate.[178] The most powerful stimulus to sympathetic tone during severe shock, however, is the ischemic response of the CNS.[205] When mean pressure falls below 50 to 60 mm Hg, the medullary chemoreceptors become active.[205] Maximal sympathetic stimulation is induced by these receptors when mean pressure is 15 to 20 mm Hg, resulting in maximal cardiovascular stimulation.[205] The Cushing response to increased intracranial pressure is an example of this reflex operating in a different setting.[178] Increased sympathetic outflow from the CNS is aimed at supporting oxygen delivery to vital organs. Other compensatory responses include releases of adrenocorticotropic hormone, antidiuretic hormone, and aldosterone, which contribute to sodium retention and maintenance of cardiovascular catecholamine responsiveness.[178,179,206]

CLINICAL PRESENTATION OF SHOCK

Patients in shock or in the process of developing it may report dyspnea. Patients are usually tachypneic and tachycardic; they have primary respiratory alkalosis or a metabolic acidosis with some degree of respiratory compensation. Tachypnea, combined with low tidal volume, worsens dead space ventilation. The skin of patients in septic shock is initially warm and dry. It is typically cold and clammy when cardiac output is low. Livedo reticularis is sometimes seen in patients who have profound hypotension, necessitating the use of high-dose pressors (Fig. 4-20). Shock is usually not an all-or-none phenomenon that occurs abruptly after injury or infection. Instead, homeostatic compensatory mechanisms are engaged.[178,179] Early in the course, subtle signs of

FIGURE 4-20 Livedo reticularis in shock. A 69-year-old woman developed severe gallstone pancreatitis *(left upper panel)* complicated by acute respiratory distress syndrome (ARDS) *(left lower panel)* and shock resistant to high-dose vasopressors. *Right:* A few hours after institution of mechanical ventilation the patient developed diffuse livedo reticularis of the skin, which is characterized by pale, ischemic, hypoperfused areas interspersed with erythematous areas of increased perfusion.

hemodynamic stress include tachycardia and decreased urine output. During early shock, assessment based on vital signs, central venous pressure, and urinary output may fail to detect global tissue hypoxia.[207] If the precipitating insult is too great or progresses quickly, compensatory mechanisms fail, and overt shock follows.[178]

Compensatory mechanisms tend to protect the CNS from the ill effects of decreased cerebral perfusion. In the absence of cerebrovascular compromise, ischemic injury is unusual if mean arterial pressure is 50 to 60 mm Hg or higher.[178] Before ischemic injury, consciousness may become altered, depending on perfusion deficit. Contributory factors include electrolyte disturbances, hypoxemia, and hypercapnia.[178] Sepsis-related encephalopathy can occur at higher arterial pressures (secondary to inflammatory mediators); it is associated with increased mortality.[208] Altered consciousness by itself may be an indication for intubation.

Intubation versus Mechanical Ventilation

In some instances, patients require endotracheal intubation to maintain airway patency because of upper airway obstruction, an inability to protect the airway from aspiration, or to manage secretions. Not all intubated patients necessarily require ventilator support.

UPPER AIRWAY OBSTRUCTION

Upper airway obstruction is one of the most urgent and potentially lethal medical emergencies. Complete airway obstruction lasting for as little as 4 to 6 minutes can cause irreversible brain damage.[209] The upper airway, which encompasses the passage between the nares and carina,[210] can be obstructed for functional or anatomic reasons. Among the first are vocal cord paralysis and laryngospasm.[210–213] Among the second are trauma, burn, infections, foreign bodies, and tumors.[209,210] Functional and anatomic obstruction can occur postoperatively in patients with redundant pharyngeal soft tissue (sleep apnea) and loss of muscle tone related to postanesthetic state.[210–212]

The first warning of airway obstruction in an unconscious patient may be failure of a jaw-thrust maneuver to open the airway or an inability to ventilate with a bag valve.[209] In a conscious patient, respiratory distress, stridor, altered voice (aphonia or dysphonia), snoring, dysphagia, odynophagia, prominence of neck veins, and neck and facial swelling all may indicate impending airway obstruction.[209,210] Patients may bring their hands to their neck, a sign of choking.[210] Other signs include suprasternal and intercostal indrawing and reduced or absent air movement on auscultation. Wheezing may be present (or absent). Thoracoabdominal paradox may be prominent. Sympathetic discharge is high. Patients are diaphoretic, tachycardic, and hypertensive. As asphyxia progresses, bradycardia, hypotension, and death ensue.[210]

Upper airway obstruction can be complicated by pulmonary edema (Fig. 4-21)[210,211]—incidence of 11% in one adult series[214]—or pulmonary hemorrhage.[212] Increased venous return (more negative intrathoracic pressure and catecholamine-induced venoconstriction) contributes to pulmonary edema, but it cannot be the sole mechanism;[215] as intrathoracic pressure becomes more negative, venous return to the right ventricle becomes flow-limited.[216] Other factors contributing to pulmonary edema include decreased left-ventricular preload (leftward shift of interventricular septum), increased left-ventricular afterload (increased negative intrathoracic pressure and catecholamine-induced elevation of systemic vascular resistance), pulmonary vasoconstriction (hypoxemia and acidosis), and possibly, stress failure of the alveolar-capillary membrane.[212,217]

Whether pulmonary edema develops during (or after) relief of upper airway obstruction may depend on whether the obstruction is fixed or variable.[211] Fixed upper airway obstruction results in vigorous inspiratory efforts (Mueller maneuver) followed by vigorous expiratory efforts (Valsalva

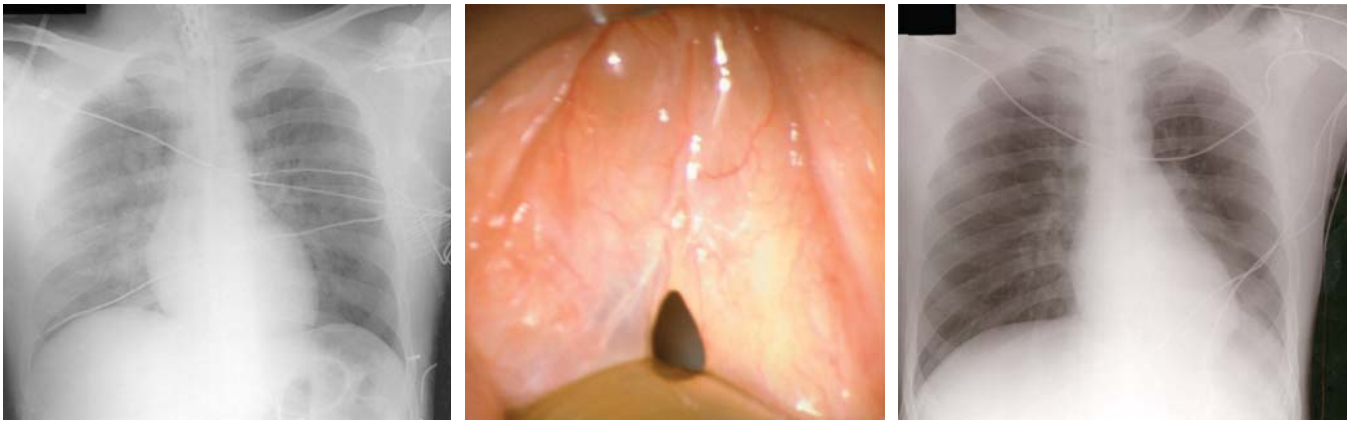

FIGURE 4-21 Pulmonary edema caused by upper airway obstruction. *Left:* Portable anteroposterior chest radiograph of a 35-year-old man who developed pulmonary edema secondary to laryngeal edema. *Middle:* Laryngeal edema demonstrated by direct laryngoscopy. *Right:* Radiograph following resolution of pulmonary edema. (Central panel used, with permission, from Wittekamp et al.[213])

maneuver).[211,214] Exhalation against an obstructed airway raises intrathoracic and alveolar pressures. The positive expiratory pressure decreases pulmonary vascular filling and opposes the hydrostatic forces that favor transudation of fluid into the alveoli during inhalation.[214] With a sudden relief of obstruction, positive expiratory pressure is lost; consequently, there is a massive transudation of fluid from the pulmonary interstitium into the alveoli (pulmonary edema) over minutes to hours. In contrast to fixed obstruction, variable extrathoracic upper airway obstruction hinders inhalation. Exhalation usually is unaffected. In this situation, the hydrostatic forces, which favor transudation of fluid into the alveoli during inhalation, are unopposed, leading to edema before relief of the obstruction.[211]

Upper airway obstruction may worsen suddenly because resistance varies with the fourth power of the radius. A slight change in airway anatomy may increase resistive load dramatically.[210] For example, manipulation of the upper airway by an inexperienced clinician may induce edema, which can increase airway resistance markedly and induce asphyxia.

An initial assessment is undertaken to determine severity of airway compromise. If compromise is judged severe, the airway should be secured immediately. If ventilation is adequate, more detailed assessment is wise.[209] Arterial blood gases are not particularly helpful because they are not specific to airway patency.[209] They may show little change until a patient is in extremis.[209]

Steps to relieve airway obstruction include use of pharyngeal airways, endotracheal intubation, cricothyrotomy, tracheotomy, endoscopy, intubation over a fiber-optic bronchoscope, and medications (e.g., epinephrine, norepinephrine, antihistamines, steroids, and antibiotics).[218] In general, pharmacotherapy cannot reverse mechanical obstruction. Use of helium-oxygen mixtures should not engender a false sense of security.[218]

The nature of respiratory noises helps to localize lesions.[209] Stridor is an inspiratory sound typically caused by a lesion above the thoracic inlet (usually glottic or supraglottic). Wheezing is generated below this level.[209] Snoring, a feature of obstructive sleep apnea, can be life-threatening. A patient with an obstructed airway should not be sedated until the airway has been secured; minimal sedation may precipitate acute respiratory failure.

Cricothyrotomy and tracheotomy can be performed at the bedside or in the operating room. If time permits and the patient is conscious and moving sufficient air to speak, it may be best to transport the patient to the operating room.[218] Although percutaneous tracheotomy is gaining in popularity, it is best performed in an already intubated patient and not as an emergency procedure.[218]

INABILITY TO PROTECT THE AIRWAY FROM ASPIRATION

Patients with severe bulbar weakness or decreased consciousness may be unable to protect the airway against aspiration.[219,220] The lack of a gag reflex or cough on suctioning suggests impaired protective reflexes.[221] If the cervical spine is stable, the head should be flexed while checking for airway obstruction. Inability to maintain a patent airway is an indication for elective intubation.[221]

Patients who require an oral airway or special appliances may require prophylactic intubation; such patients are unstable and can asphyxiate or vomit and aspirate suddenly.[221] Ideally, patients with depressed consciousness should be assessed while asleep, a time during which they are at greatest risk of obstruction.[221]

Severe head injury is a condition requiring intubation for airway protection. In the past, controlled hyperventilation (Pa_{CO_2} of 25 to 35 mm Hg) was delivered in these patients with the goal of reducing intracranial pressure. Such a strategy, however, has proven harmful and is no longer recommended.[222] It is unknown whether the use of short periods of hyperventilation to suddenly lower intracranial pressure are harmful or not.

SECRETIONS

Occasionally, endotracheal intubation or tracheostomy may be required to manage a large amount of secretions or to remove secretions in severely debilitated patients who themselves cannot clear them.[59,144]

Many patients with the preceding conditions are capable of maintaining adequate gas exchange following endotracheal intubation. Yet most intensivists still connect such patients to a ventilator. This decision commonly is taken independently of any consideration about the work of breathing imposed by an endotracheal tube.[223]

GOALS OF MECHANICAL VENTILATION

The fundamental goal of mechanical ventilation is to keep a patient alive and free from iatrogenic complications so that the catastrophic precipitating event(s) may resolve. Attention should be directed to the primary disorder.

Reversal of Apnea

The goal of mechanical ventilation in the apneic patient is to restore ventilation.

Reversal of Respiratory Distress

For obvious ethical reasons, no human studies have addressed the natural course of acute respiratory failure in the presence of increased work of breathing or, for that matter, with any other type of respiratory failure. Animal data indicate that increased loads can cause respiratory muscle damage, CO_2 retention, and as a terminal event respiratory muscle fatigue.[136] Increased load may be responsible for

respiratory muscle damage in patients with COPD[224] and in patients dying while supported by mechanical ventilation.[225] In sepsis, increased respiratory efforts are particularly damaging to the respiratory muscles.[226]

Despite intense research, the role of contractile fatigue in the development of respiratory failure in patients is unknown.[136] Diaphragmatic contractility has been quantified objectively (phrenic nerve stimulation) in only one study where patients developed acute respiratory distress (during weaning from mechanical ventilation).[5] No change in diaphragmatic contractility was documented.[5] It is not known if the latter observation applies to patients in respiratory distress who have yet to undergo mechanical ventilation.

It seems self-evident that connecting a patient to a ventilator and providing ventilator assistance should unload the respiratory muscles and, possibly, reduce muscle stress. To date, however, we do not know the desirable level of unloading (and for how long) for a specific patient. Insufficient unloading can be dangerous to the respiratory muscles, as can excessive unloading (see Chapter 43).[227]

Although most patients in acute respiratory failure have increased work of breathing, this may not be the sole problem. Most patients also have abnormal gas exchange, impaired muscle perfusion, and sepsis-induced muscle dysfunction.[6,228,229] In patients with increased work of breathing, unloading by the ventilator may appreciably reduce $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$.[8,54] These reductions, in turn, may improve concurrent hypoxemia and hypercapnia.

Reversal of Severe Hypoxemia

Mechanical ventilation is commonly commenced with 100% oxygen. The response helps to define the underlying pathophysiology and thus aids in differential diagnosis and therapy (see Figs. 4-9 and 4-12). For example, if 100% oxygen fails to increase Pa_{O_2} in a patient with an exacerbation of COPD, the underlying problem is not pure $\dot{V}_A/\dot{Q}$ mismatch (as is typical with acute bronchitis); instead, the patient has coexisting shunt. Common causes of shunt include pneumonia, congestive heart failure, atelectasis, and pulmonary embolism. (For a discussion of oxygen toxicity, see Chapter 45.)

Patients with increased shunt commonly exhibit considerable improvement in oxygenation with application of PEEP. The improvement results from a decrease in shunt[230] secondary to recruitment of previously atelectatic areas and redistribution of extravascular lung water from alveoli to peribronchial and perivascular spaces.[231] If cardiac output decreases (with PEEP), this can contribute to the decrease in shunt.[230,232]

PEEP causes an increase in dead space through several mechanisms. First, an increase in lung volume exerts radial traction on the airways, increasing their volume with a consequent increase in *anatomic dead space*. Second, increased airway pressure tends to divert blood flow from ventilated lung units by compressing capillaries. The consequent development of areas of high $\dot{V}_A/\dot{Q}$ ratio (or even unperfused areas) produces an increase in *alveolar dead space*. Such dead space is especially common in the uppermost lung units, where pulmonary artery pressure is relatively low because of the hydrostatic effect.[61,233] If the capillary pressure falls below airway pressure, the capillaries may collapse completely and the lung units become unperfused (Fig. 4-22).[233] Two factors encourage collapse: very high airway pressure and low venous return.

Dantzker et al[230] showed that increasing levels of PEEP can induce two distinct patterns of $\dot{V}_A/\dot{Q}$ distribution. Some patients experienced no change in the pattern of $\dot{V}_A/\dot{Q}$ relationships (Fig. 4-23). Other patients experienced broadening of the ventilation dispersion—increases of areas with

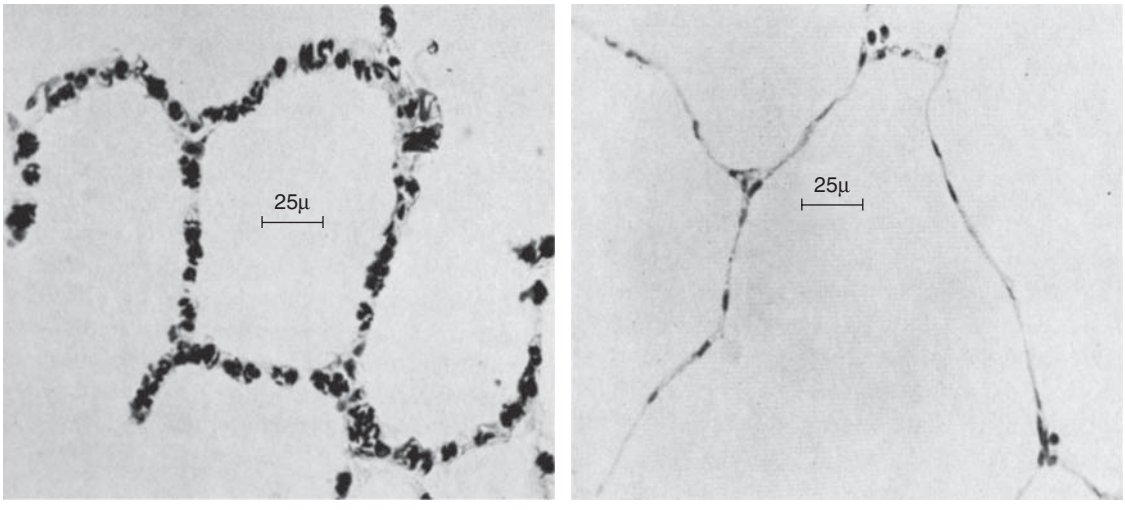

FIGURE 4-22 Effect of an elevated airway pressure on the structure of pulmonary capillaries. *Left:* Normal appearance. *Right:* An increase in alveolar pressure above capillary pressure produces capillary collapse. (Used, with permission, from Glazier et al.[233])

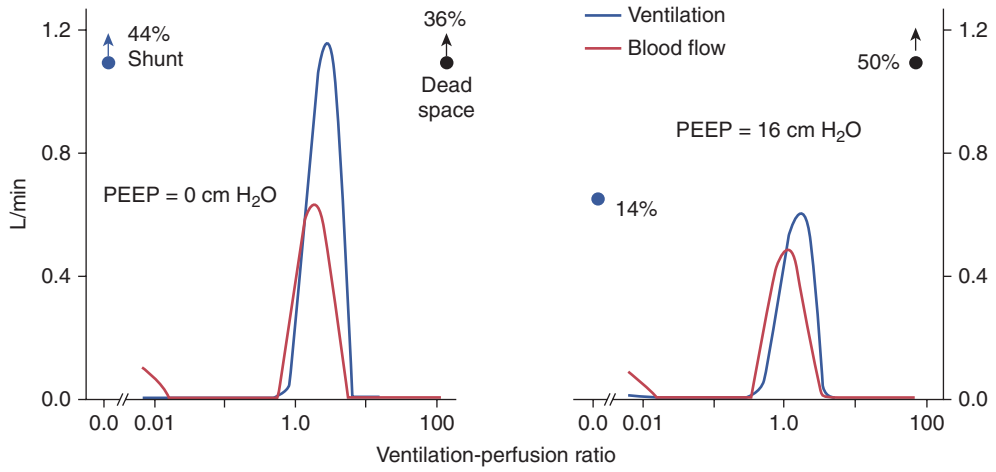

FIGURE 4-23 Effect of positive end-expiratory pressure (PEEP) on shunt and dead space in a patient with acute respiratory distress syndrome. A progressive increase in PEEP from 0 to 16 cm H_2O caused a decrease in shunt from 44% to 14% of the cardiac output and an increase in dead space from 36% to 50% of the tidal volume. The shape of the distribution of ventilation and perfusion did not change. (Modified, with permission, from Dantzker et al.[230])

high $\dot{V}_A/\dot{Q}$ ratios and alveolar dead space (Fig. 4-24). The improvement in gas exchange with PEEP is even greater when pressors are used to prevent the expected decrease in cardiac output during PEEP.[234]

In some patients, PEEP causes no improvement or even a decrease in Pa_{O_2}. This effect is the result of increased dead space ventilation, diversion of blood flow from well-ventilated to unventilated regions, and decreased cardiac output (especially if circulating blood volume is depleted).[61] Lack of improvement in oxygenation with PEEP also may result from a patent foramen ovale because PEEP can increases the right-to-left shunt.[235]

Because PEEP can decrease cardiac output,[230,236] its net effect should be judged in terms of oxygen delivery. Mixed venous P_{O_2}[207,236] has been used as a surrogate for oxygen delivery. Other potential hazards of PEEP include reduced splanchnic and renal blood flow, barotrauma, and ventilator-induced lung injury (see Chapter 10).

In addition to mechanical ventilation, patients with hypoxemic respiratory failure may require other therapies, such as antibiotics (pneumonia), diuretics, and inotropic support (heart failure). Ancillary strategies to reverse hypoxemia include exogenous surfactant, nitric oxide supplementation and prone position.[237] These strategies can increase oxygenation in patients with ARDS, but none has improved patient outcome.

Theoretically, patients with hypoxemia secondary to $\dot{V}_A/\dot{Q}$ mismatch can be managed by increasing FI_{O_2}

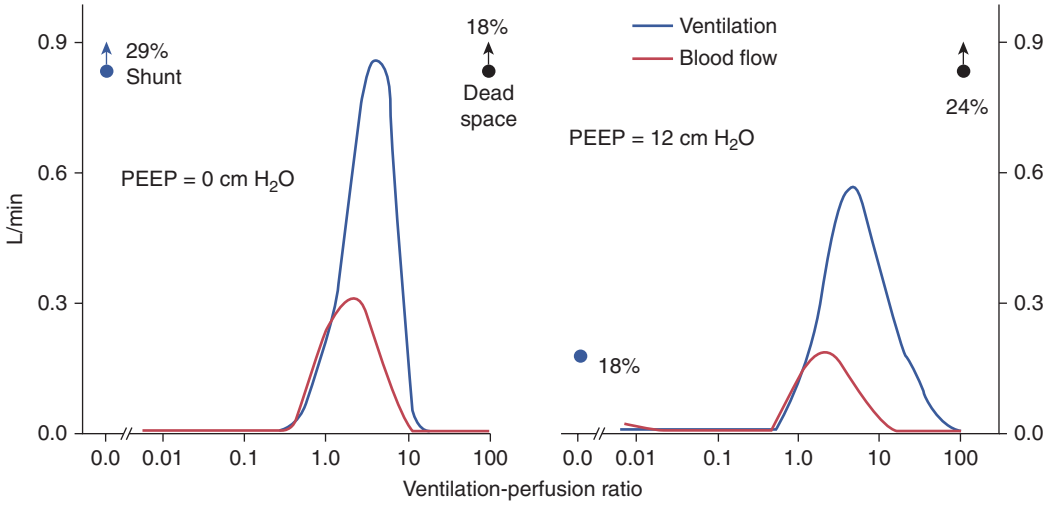

FIGURE 4-24 Effect of positive end-expiratory pressure (PEEP) on shunt and dead space in a patient with acute respiratory distress syndrome. An increase in PEEP from 0 to 12 cm H_2O produced a decrease in shunt (from 29% to 18%) and increase in dead space (from 18% to 24%). Also apparent is a widening of the dispersion in ventilation with the development of units with very high $\dot{V}_A/\dot{Q}$; these may have resulted from diversion of blood flow or increased ventilation of these areas of the lung. (Modified, with permission, from Dantzker et al.[230])

without mechanical ventilation (see Fig. 4-12). In reality, such patients always have increased ventilatory requirements (see Fig. 4-10), which may demand ventilator support. Many patients with $\dot{V}_A/\dot{Q}$ inequality requiring mechanical ventilation are hyperinflated (e.g., COPD or status asthmaticus). Hyperinflation decreases the efficiency of the respiratory muscles in generating pressure, which contributes to the respiratory distress.[136]

In a study of seven patients with exacerbations of COPD, mechanical ventilation improved $\dot{V}_A/\dot{Q}$ mismatch by redistributing blood flow away from low $\dot{V}_A/\dot{Q}$ areas.[238] Dispersion of the distribution of ventilation also improved. Dead space or ventilation of high $\dot{V}_A/\dot{Q}$ units did not change.[238] Patients with increased $\dot{V}_A/\dot{Q}$ mismatch associated with COPD or ARDS may benefit from careful application of PEEP (see Chapter 10). Use of PEEP in patients with status asthmaticus is fraught with danger (see Chapter 30).

Reversal of Severe Hypercapnia

Severe hypercapnia depresses the CNS and decreases respiratory motor output.[239] A viscous cycle can arise: Hypercapnia depresses motor output leading to more hypercapnia.[240,241] Hypercapnia can decrease diaphragmatic contractility, although not consistently.[136] Acidosis may be more important than hypercapnia in depressing respiratory muscle contractility.[136]

The goal of mechanical ventilation in patients with hypercapnic respiratory failure is to improve $\dot{V}_A$. Ventilator strategies need to be tailored to the specific setting. In hypercapnic patients with status asthmaticus or COPD, the prolonged respiratory time constant poses a significant challenge. If the ventilator is set to deliver small tidal volumes at high respiratory frequencies, the prolonged time constant may interfere with lung emptying, and hyperinflation may ensue. Moreover, small tidal volumes may not achieve adequate alveolar ventilation because physiologic dead space is increased. Larger tidal volumes may achieve adequate alveolar ventilation but require longer expiratory times than do smaller tidal volumes. A common strategy to ensure sufficient time for exhalation is to increase inspiratory flow. The increase in flow decreases the time of mechanical inflation and, if respiratory rate remains constant, prolongs time available for exhalation. An increase in inspiratory flow, however, is commonly associated with an increase in respiratory rate.[242,243] Yet, despite the reduction in the respiratory cycle, the decrease in inspiratory time is accompanied by an increase in time available for exhalation—and a decrease in inspiratory effort.[243]

Neuromuscular disorders, such as Guillain-Barré syndrome, myasthenia gravis, and spinal cord injury, can cause hypercapnic respiratory failure.[136] These patients usually have normal lung mechanics, unlike patients with COPD or asthma. The normal time constant allows for greater flexibility in the setting of the ventilator.

Overzealous ventilation can cause serious complications, including life-threatening alkalosis, decreased cerebral perfusion, and cardiovascular instability. Patients previously hypercapnic are especially vulnerable to these complications. When severe, alkalosis is occasionally associated with coronary artery spasm,[244] confusion, myoclonus, asterixis, and seizures.[245]

Respiratory alkalosis reduces ionized calcium. For each 0.1-unit rise in pH, ionized calcium falls by 0.05 mmoL/L.[246] These changes are too modest and inconsistent[247] to account for the increased central and peripheral excitability associated with alkalosis. Paresthesias, carpal-pedal spasm, and tetany, seen in acute hyperventilation, are caused by the direct effects of respiratory alkalosis on neurons.[248] Other effects of alkalosis include increase in hemoglobin affinity for oxygen and, in the presence of increased shunt, a possible worsening of $\dot{V}_A/\dot{Q}$ relationship (secondary to a decrease in hypoxic pulmonary vasoconstriction).[249] Precipitous decrease in Pa_{CO_2} reduces blood flow to the CNS,[250] which may contribute to confusion and loss of consciousness in patients with hyperventilation.[245]

The most common hemodynamic instability associated with overzealous ventilator management of the hypercapnic patient (prolonged time constant) is hypotension. Hypotension often results from an increase in intrinsic PEEP after intubation—although a decrease in sympathetic tone caused by the decrease in Pa_{CO_2} and administration of sedation may be contributory factors. In this setting, the circulation usually is restored promptly by stopping ventilation for 30 seconds (or more) and then resuming less vigorous ventilation.

In the 1940s and 1950s, it was reported that rapid CO_2 washout after hypercapnia could cause hypotension (removal of cyclopropane anesthesia in humans)[251,252] and life-threatening ventricular arrhythmias (dog experiments).[253,254] Hyperkalemia appeared to be involved.[253,254] More recent series in patients, however, have not substantiated the earlier studies.[102,255] For example, Prys-Roberts et al[102,255] reported no electrocardiographic alterations when Pa_{CO_2} was reduced from approximately 80 mm Hg to less than 20 mm Hg over 5 minutes in anesthetized patients. Some practitioners suggest that supraventricular and ventricular arrhythmias associated with alkalemia[256] may occur only in patients with ischemic heart disease.[257] Whether reductions in ionized magnesium could contribute to cardiac irritability remains unclear.[247]

Excessive ventilation, over time, causes bicarbonate wasting by the kidney. In patients who retain CO_2 when clinically stable, this renal wasting (of bicarbonate) will increase ventilatory demands during weaning.

Goals of Mechanical Ventilation in Postoperative Respiratory Failure and Trauma

Patients developing postoperative hypoxemia usually are treated with supplemental oxygen and chest physical therapy (including incentive spirometry).[258–260] In approximately

10% of patients undergoing major elective abdominal surgery, supplemental oxygen and chest physical therapy do not prevent respiratory failure.[258] Squadrone et al[258] undertook a randomized study in more than 200 patients who had undergone major elective abdominal surgery and who developed hypoxemia within 1 hour of the operation. They compared the incidence of intubation in patients receiving standard treatment (50% oxygen and chest physical therapy) and patients who also received 7.5 cm H_2O CPAP (delivered noninvasively with a helmet). Compared with the control group, patients receiving CPAP had lower rates of intubation (1% vs. 10%) and complications (e.g., pneumonia, infection, and sepsis). The CPAP group spent fewer days in the ICU. Exclusion criteria included history of COPD, asthma, sleep apnea, heart failure, hypercapnia, and respiratory acidosis. Thus, these results[258] may not apply to those patients who are at greatest risk of postoperative atelectasis.

Bonde et al[149] undertook a prospective, randomized study in 102 patients undergoing elective lung surgery who were considered at high risk for retention of secretions.[144] Minitracheotomy (4-mm percutaneous cricothyroidotomy device) was performed at the conclusion of surgery in one group. Sputum retention was 30% in a conventionally treated group and 2% in the minitracheotomy group ($p < 0.005$).[149] Atelectasis was less common in the minitracheotomy group. Incidences of pneumonia, respiratory failure, myocardial infarction, and death were not affected by minitracheotomy.[149] Significant complications of minitracheotomy have been reported, however.[261,262] Therefore, its routine use, even in patients at risk of secretion retention, needs to be considered on a case-by-case basis.

Some patients with multiple trauma present with a flail chest. Many such patients may have respiratory failure secondary to underlying lung damage or other pathophysiology and may require mechanical ventilation. Flail chest on its own, however, is not an indication for mechanical ventilation.[263] In one randomized study of patients with flail chest who were hypoxemic and in respiratory distress, noninvasive CPAP decreased mortality and nosocomial infection as compared with patients who underwent endotracheal intubation and ventilation.[264]

Goals of Mechanical Ventilation in Shock

In hemodynamically unstable patients, tissue perfusion, including that of the CNS, is compromised.[179,207] Two main goals are to establish an adequate airway and reduce $\dot{V}_{O_2}$.[178] By resting the respiratory muscles and allowing for sedation, mechanical ventilation can reduce $\dot{V}_{O_2}$[265,266] and decrease sympathetic tone.[54] These effects may improve tissue perfusion,[201,267] which may explain why ventilator support improves outcome in animals[199] and patients in shock.[202] It is important to achieve good patient–ventilator synchronization;[268,269] otherwise, work of breathing increases, which diverts blood to the respiratory muscles and away from other vulnerable tissue beds.

DELIVERY OF MECHANICAL VENTILATION: INVASIVE VERSUS NONINVASIVE MECHANICAL VENTILATION

Solid experimental data support the use of noninvasive ventilation in patients with acute respiratory failure caused by severe exacerbations of COPD (limited to patients deemed not to require immediate intubation).[270] Noninvasive ventilation is probably superior to invasive ventilation in patients with cardiogenic pulmonary edema complicated with hypercapnia[271] and in immunocompromised patients with early hypoxemic respiratory failure.[270]

Sinuff et al[272] studied the use of a practice guideline for noninvasive ventilation in patients admitted to hospital for an exacerbation of COPD or congestive heart failure. The developers of the guideline pointed out that data from randomized trials do not support use of noninvasive ventilation in other disease states. Before introduction of the guideline, 65% of patients with diseases other than COPD or cardiogenic pulmonary edema were managed without endotracheal intubation. After introduction of the guideline, 100% of these patients were intubated; mortality also tended to increase (from 20.5% to 34.3%). This study raises the possibility that introduction of a practice guideline may cause an increase in morbidity and mortality.[272,273] A practice guideline could discourage physicians from the use of noninvasive ventilation in subgroups of patients who are likely to benefit from its use simply because benefit has not yet been demonstrated in a randomized trial and thus has not been incorporated into the practice guideline. In an accompanying editorial, Hill[273] commented: "The concern is that by classifying a sizable category of patients as 'not meeting noninvasive positive pressure ventilation criteria,' the authors could have unintentionally encouraged endotracheal intubation in this subgroup, possibly contributing to morbidity and mortality."

Chapters 18 and 34 provide detailed discussion of noninvasive ventilation.

INDICATIONS FOR MECHANICAL VENTILATION AND NOSOLOGY

Indications: True versus Stated

In publications on mechanical ventilation, listed indications commonly include acute respiratory failure, exacerbation of chronic respiratory failure (secondary to infection, bronchoconstriction, heart failure), coma, and neuromuscular disease. Many patients, however, have these same conditions but do not require ventilator assistance. Consider COPD, one of the most common indications for mechanical ventilation. At any point in time, much, much less than 1% of patients with COPD are receiving mechanical ventilation. This small

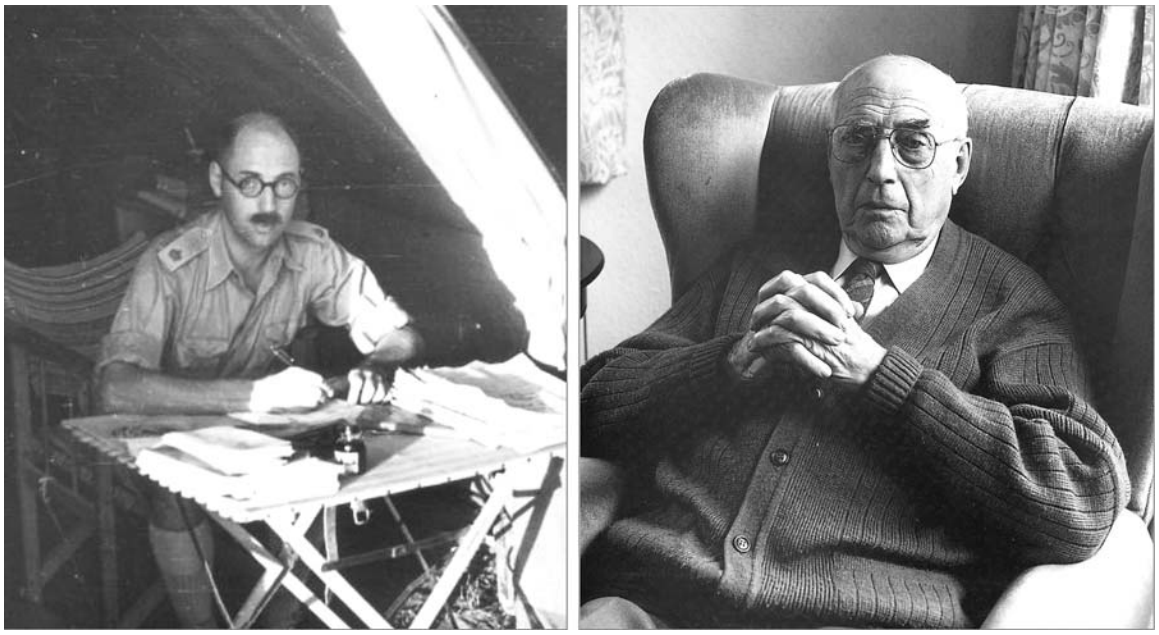

FIGURE 4-25 Guy Scadding was one of the founders of the British Thoracic Society and first editor of *Thorax*. He served in the Royal Army Medical Corps during World War II *(left)*, and is sometimes credited with changing the outcome of the war through his successful treatment of the pneumonia that Winston Churchill developed in Tunisia in December 1943.[274] Scadding wrote extensively on use of medical semantics and nosology. (Used, with permission, from Scadding[275] and Sinclair et al.[276])

subset is commonly identified as those with acute respiratory failure. But the definition of acute respiratory failure is vague and the criteria loose. The usual defining criterion is a Pa_{O_2} of less than 60 mm Hg (sometimes combined with a Pa_{CO_2} of >50 mm Hg). It is patently absurd to suggest, however, that all patients with a Pa_{O_2} of 59 mm Hg (or lower) need ventilator assistance and that all patients with a Pa_{O_2} of 61 mm Hg (or higher) can be managed without it.

As such, the usually stated indications for mechanical ventilation are elastic, lacking meaningful boundaries. What, then, is the real reason to institute it? We believe that the most honest description of a physician's judgment at this juncture is: "The patient looks like he (or she) needs to be placed on the ventilator." That is, a physician institutes mechanical ventilation based on his or her gestalt of disease severity as opposed to slotting a patient into a particular diagnostic pigeonhole.

At first blush, this admission makes the undertaking of mechanical ventilation appear less scientific than other areas of medicine. Students of medicine are taught to make a diagnosis before initiating treatment. The usual teaching is that an accurate diagnosis will make the appropriate treatment relatively obvious. But this medical model is plausible only for diseases where the precise etiology is known (such as a microbial agent). The medical model is also more ideal than real. To understand the limitations of this model—and the apparent lack of science concerning ventilator indications—the reader needs to grapple with nosology, the discipline that names and classifies diseases. Guy Scadding (1907–1999)[274–276] wrote more lucidly on nosology than most; he made explicit the factual implications of medical usage of disease names. The account in this chapter borrows extensively from his writings (Fig. 4-25).

Nosology

The first attempt to introduce a systematic and consistent nomenclature for diagnostic terms was made in the mid-nineteenth century.[277] Diseases were no longer viewed in terms of a galenic humoral disequilibrium. Instead, they were regarded as discrete entities—real things. This ontologic model grew out of the increasing use of autopsy, which was seen to uncover the true reasons for the corporeal changes induced by disease.[278] Ideally, each disease category would be identified through elicitation of pathognomonic signs on physical examination and the finding of a defining lesion on autopsy. This thinking is conveyed in the quip circulated by nineteenth-century physicians: If you were suffering from some mysterious illness, the best thing to do was go to Vienna (then the Mecca of medical science)[279] and be diagnosed by Skoda and autopsied by Rokitansky.

Disease Definition and Characteristics

How is disease defined? A *disease* is "the sum of abnormal phenomena displayed by a group of patients in association with a specified common characteristic (or set of characteristics) by which these patients differ from the norm (of healthy people) in such a way as to place them at a biological disadvantage."[280]

There are four main classes of characteristics by which diseases can be defined:

1. *Syndrome.* Historically, diseases are defined initially by way of a description of symptoms and signs; when these constitute a recognizable pattern, they are referred to as a *syndrome* (e.g., ARDS).
2. *Disorders of structure (morbid anatomy).* When a specifiable disorder is found to be associated constantly with a morbid-anatomic change, it tends to be named in these terms (e.g., the switch from jaundice to hepatitis).
3. *Disorders of function (pathophysiology).* When a disorder is found to be associated constantly with a specific abnormality of function, the abnormality may be used to name the disorder (e.g., hypothyroidism).
4. *Causation (etiology).* When the cause of a disease is discovered, the disease generally is redefined in causal terms (Legionnaire disease). Scadding[280] refers to another category, "clinical entity," that always needs an ad hoc explanation; he says, "It often seems to be the refuge of one who has not succeeded in clarifying his or her thoughts, but is nevertheless determined to put them into words."

In general, the direction of scientific advance follows the preceding sequence, although many conditions are never described in etiologic terms. The primary purpose of applying a name to a disorder is to provide a brief statement of the medical understanding of its nature (from syndrome to etiologic mechanism) and to serve as a verbal device for ease of communication. The American-European consensus definition of ARDS,[281] for example, has served as the basis of patient recruitment for most of the recent trials of mechanical ventilation in ARDS. Yet, as discussed in detail by Marini (see Chapter 31), this definition lacks scientific rigor. Nevertheless, in everyday practice, the term *ARDS* helps a clinician to predict prognosis and prescribe treatment. Moreover, in emergency settings (such as the ICU), problems are discussed and major decisions often are made without making any explicit diagnosis. Indeed, this is the rule rather than the exception when instituting mechanical ventilation. An experienced critical care physician can identify a patient who will die if left untreated but who might live if managed by mechanical ventilation—even though the physician is unable to identify the etiology of that patient's illness. Nevertheless, in such situations where physicians cannot put forward a defensible diagnosis, they still apply descriptors (at Scadding's level of "clinical entity"), such as "the patient is tiring out," to justify their judgment that mechanical ventilation is indicated.

Definitions: Essentialist and Nominalist

What are the factual implications of the naming of a disease? Diseases are defined in essentialist or nominalist terms. An *essentialist definition* tries to describe the true essence of an entity: the essential quality (invariable and fixed properties) that makes a given entity the type of thing it is—the "whatness" of an entity. (The study of the essence of things is called *ontology.*[282]) Essentialist ideas about diseases are implicit in everyday speech.[283] For example, a patient presents with a cough and mucoid sputum. The doctor makes a diagnosis of chronic bronchitis. The patient then thinks that chronic bronchitis is causing his or her cough. Given that chronic bronchitis is defined as a productive cough, the patient's reasoning is circular.

Such usage lays a linguistic trap: Many laypeople and some doctors think that the names of diseases refer to active agents that cause the illness. To talk of diseases as if they existed as real entities is plausible (at first sight) only in relation to diseases that are defined in etiologic terms.[284] Even then we must not confuse an etiologic agent with the disease itself. The disease is the effect on the affected person; diseases have no existence apart from patients. We treat patients, not diseases. When we speak of treatment of a disease, we are employing an ellipsis for treatment of patients with that disease.[280] All this brings to mind Osler's admonition: "It is much more important to know what sort of patient has the disease than to know what sort of disease the patient has."[278]

A *nominalist definition* recognizes that the task of revealing the essence of the *definiendum* is impossible.[285,286] Instead, it simply uses words to state the set of characteristics that are used to identify a member of a class (make a diagnosis). Such a definition makes it possible to determine whether a particular example (clinical picture) falls into a category to which a name (a disease) is applied.[287] A nominalist definition avoids the essentialist fallacy of regarding diseases as causes of illness; instead, it is simply naming a class of entities or events.

The nominalist–essentialist distinction becomes clearer if we consider the definition of acute respiratory failure. Karl Popper, who condemned essentialist definitions, observed that a good definition in science should be read from right to left, not left to right.[288] Consider the sentence, "Acute respiratory failure is the presence of a Pa_{O_2} of less than 60 mm Hg, with or without a Pa_{CO_2} of greater than 50 mm Hg, together with physical findings indicative of increased work of breathing." Reading from right to left, the sentence provides a "nominalist" answer to the clinician's question, "What shall we call the presence of a Pa_{O_2} of less than 60 mm Hg, with or without a Pa_{CO_2} of greater than 50 mm Hg, together with physical findings indicative of increased work of breathing?" rather than providing an "essentialist" answer to the question, "What is acute respiratory failure?" That is, the term *acute respiratory failure* is handy shorthand for the longer, more cumbersome description. Nothing more. The term *acute respiratory failure* contains no information about medicine, and nothing is to be gained from analyzing it.

Diagnostic Process, Treatment, and Value Judgment

The process of making a diagnosis goes through two broad steps. First, the physician undertakes an initial review of the clinical features, looking for a pattern that suggests one or

more diseases. For example, a clinician notes eyelid retraction, tracheal tug, sternomastoid contraction, tachypnea, and monosyllabic speech. The physician concludes that the patient is in acute respiratory distress (an "entity" rather than a disease). Second, the physician undertakes a directed search for the defining characteristics (pathognomonic findings) of each of a number of suspected diseases.[289] Let us consider a patient who exhibits all the above-listed features of acute respiratory distress. On learning that the patient had been extubated a half hour previously, the physician suspects laryngeal edema and carefully listens for stridor. In a second patient, a physician's initial assessment again may reveal the general features of acute respiratory distress. On learning that this patient also has fever, chills, and rust-colored sputum, the physician suspects pneumonic consolidation. The physician then undertakes careful palpation (for tactile vocal fremitus), percussion (for dullness), and auscultation (for whispering pectoriloquy, egophony, and bronchial breathing).

The clinical diagnostic criteria are the descriptive features that best discriminate between one disease and other diseases with which it might be confused. In the best-case scenario, the clinical diagnostic criteria are made up largely of defining characteristics. None of the features is conclusive, but together they produce a degree of probability that justifies a diagnosis on which practical management may be based.[287] It is possible to state defining characteristics in objective, demonstrable terms when a disease is defined etiologically or as a disorder of structure or function.[280] The same is also possible for a disease defined syndromically if the description of the syndrome includes objectively demonstrable elements. For example, as entry criteria for a research study, respiratory distress might be defined (arbitrarily) as meeting three of the following four elements: respiratory rate greater than 33 breaths/min, a Pa_{O_2}/FI_{O_2} ratio of less than 300, phasic sternomastoid contraction, and nasal flaring. That is, in the context of this study, respiratory distress can be defined without making subjective value judgments.

When making decisions about the treatment of an individual patient, however, it is not possible to avoid subjective value judgments (things being assessed on a scale of goodness or badness). Ultimately, the decision of whether to institute mechanical ventilation (or not) boils down to a value judgment by the patient's physician. In some instances this decision will be preceded by a physician's making of a diagnosis. In many cases, however, physicians institute mechanical ventilation without having formulated a precise diagnosis. Along the same lines, Gross[290] has argued that it is unlikely that management of asthma would be improved were it possible to articulate a more widely accepted definition of this disease.

Factual Implications of Disease Terminology

Nosology is rarely discussed at medical conferences.[277] Questions on terminology are regarded as recondite and pedantic, eliciting yawns from the audience. When a speaker is asked to define the clinical entity about which he or she is speaking, the speaker may appear puzzled—believing that everyone surely knows what the term means. The audience becomes restless, seeing the question as a philosophical diversion that distracts from the hard scientific facts that the speaker is trying to discuss. Yet it makes little sense for a speaker to present detailed data analysis on a condition that the speaker cannot define. Likewise, readers should treat with a jaundiced eye statistics in surveys that list precise diagnoses for which mechanical ventilation was used. The ghost of such unrealistic (and unattainable) precision also hovers over lists of reasons for why patients were intubated in reports on controlled trials of noninvasive ventilation versus conventional therapy.

The application of precise mathematical methods to vague and ill-defined concepts gives them a false air of respectability that cloaks ignorance and perpetuates confusion.[284] It is unfortunate that the more fundamental the concept to which a word refers, the less careful we tend to be about the use of a clear definition.[291]

CONTRAINDICATIONS TO MECHANICAL VENTILATION

Complications associated with mechanical ventilation can be lethal (see Chapters 43 to 47). Thus, mechanical ventilation should be used only when it is clearly needed. Intubation is not the first approach for most patients with an exacerbation of COPD; instead, noninvasive ventilation is the first choice. The same sequence probably holds for selected patients with congestive heart failure or immunocompromise. Mechanical ventilation should not be instituted when a mentally competent patient or a surrogate designated to make decisions on behalf of a noncompetent patient refuses it. If time permits, the patient and family should be instructed about the likely impact of mechanical ventilation on prognosis. For instance, hospital mortality of patients with idiopathic pulmonary fibrosis requiring mechanical ventilation is 68%[292] to 100%,[293] and 92% of the survivors are dead within 2 months of hospital discharge.[292]

CONCLUSION

When we started to write this chapter, we expected to end it by formulating a set of concrete recommendations as to when mechanical ventilation should be instituted. Readers willingly wade their way through complex pathophysiologic concepts if they believe the material enhances their understanding of a clinical topic. At the end, however, they expect to see the complexity reduced to a set of concrete recommendations, preferably conveyed as a list of entities with numerical values attached. That final step is not possible with this chapter. More than is the case for any other chapter in this book, it is not possible to articulate the indications for mechanical ventilation in the form of a list of items.

If it is not possible to formulate a list, then what? When you, dear reader, are in severe respiratory distress and a physician is standing at your bedside deciding whether or not to ventilate (and possibly intubate) you, what type of physician are you hoping will make this decision? We can speak only for ourselves. The physician we want is a person deeply versed in pathophysiologic concepts, skilled in the art of physical examination, with extensive experience of cases similar to our own illness, and blessed with good clinical judgment. We expect that physician to base the decision (on which our life depends) on his or her clinical gestalt. And we recognize that the physician may not be able to articulate the precise reasons behind this decision in the form of words.

Why can't our ideal physician express these thoughts in explicit terms? A wise physician standing at a patient's bedside senses a great deal of worthwhile information—much more than can be expressed in words. In short, there is a very large tacit coefficient to clinical knowledge—physicians *know* much more than they can communicate verbally.[294] There is an enormous difference between the assessment made by an experienced physician standing at a bedside and the assessment the same physician makes on hearing information (about the same patient) relayed over the telephone by a junior resident. An experienced and wise physician employs intuition rather than explicit rules in deciding what is best for a particular patient in a particular setting. A physician who regards such intuition as unscientific betrays a fundamental misunderstanding of the epistemology of science.[286]

Our failure to formulate a list of indications does not mean that we advocate a laissez-faire approach to instituting mechanical ventilation. Earlier we mentioned the absurdity of saying that mechanical ventilation is always indicated for acute respiratory failure, defined as a Pa_{O_2} of less than 60 mm Hg. This does not mean that we consider Pa_{O_2} unimportant. On learning that a patient has a sustained Pa_{O_2} of 40 mm Hg, a physician will take immediate steps to institute assisted ventilation. But it is not possible to pick a Pa_{O_2} breakpoint (between 40 and 60 mm Hg) below which the benefits of mechanical ventilation decidedly outweigh its hazards. It is futile to imagine that decision making about instituting mechanical ventilation can be condensed into an algorithm with numbers at each nodal point. In sum, an algorithm cannot replace the presence of a physician well skilled in the art of clinical evaluation who has a deep understanding of pathophysiologic principles.

CONVENTIONAL METHODS OF VENTILATORY SUPPORT

This page intentionally left blank

SETTING THE VENTILATOR

5

Steven R. Holets
Rolf D. Hubmayr

The choice of ventilator settings should be guided by clearly defined therapeutic end points. In most instances, the primary goal of mechanical ventilation is to correct abnormalities in arterial blood-gas tensions. In most patients, this is accomplished easily by adjusting the minute volume to correct hypercapnia and by treating hypoxemia with oxygen (O_2) supplementation. Because the volume, frequency, and timing of gas delivered to the lungs have important disease-specific effects on cardiovascular and respiratory systems functions, the physician must avoid simply managing the blood-gas tensions of the ventilator-dependent patient. After a brief review of the capabilities of modern ventilators, this chapter discusses the mechanical determinants of patient–ventilator interactions and defines therapeutic end points in common respiratory failure syndromes. These sections provide background for the major thrust of the chapter, which is to detail the physiologic consequences of positive-pressure ventilation and to develop recommendations for ventilator settings in various disease states based on this knowledge.

CAPABILITIES OF MODERN VENTILATORS

The incorporation of microprocessors into ventilator technology has made it possible to program ventilators to deliver gas with virtually any pressure or flow profile. Significant advances have been made in producing machines that are more responsive to changes in patient ventilatory demands, and most full-service mechanical ventilators display diagnostic information contained in airway pressure (Paw), volume (V), and flow ($\dot{V}$) waveforms. Because of these added capabilities, the practitioner is being challenged with a staggering array of descriptive acronyms for so-called new modes of ventilation. To avoid unnecessary confusion, it is useful not to focus on specific modes for the moment but rather to consider three general aspects of ventilator management: (a) the choice of inspired-gas composition, (b) the means to ensure the machine's sensing of the patient's demand, and (c) the definition of the machine's mechanical output.

Choice of Inspired-Gas Composition

Practically speaking, decisions regarding the composition of inspired gas concern only the O_2 concentration (see "Acute Lung Injury and Hypoxic Respiratory Failure" below). Although there may be occasions when the care provider considers supplementing the inspired gas with nitric oxide, the efficacy of nitric oxide therapy for most forms of hypoxic respiratory failure remains to be established.[1] There has been growing interest in the biologic effects of hypercapnia on gas exchange, vascular barrier properties, and innate immunity.[2–7] Therapeutic hypercapnia, that is, the deliberate supplementation of inspired gas with carbon dioxide (CO_2), however, cannot be recommended at this point in time. On extremely rare occasions, it may be appropriate to use a helium-oxygen mixture in an attempt to lower the flow resistance across a lesion in the distal trachea or mainstem bronchi, and there has been some interest in the use of helium in asthma.[8] Currently, these approaches must be considered experimental.

Machine's Sensing of Patient's Demand (Ventilator Triggering)

Ideally, a mechanical ventilator should adjust not only its rate but also its instantaneous mechanical output in response to changing patient demands. Conventional modes of ventilation cannot do so; instead, such modes execute a predefined pressure or flow program after an effort has been sensed.

Volume preset controlled mechanical ventilation (CMV) refers to a mode during which rate, tidal volume (V_T), inspiratory-to-expiratory timing (I:E ratio), and inspiratory flow profile are determined entirely by machine settings and cannot be altered by either the rate nor the amplitude of the patient's effort. Occasionally, investigators refer to ventilation as "controlled" when spontaneous respiratory muscle activity has been abolished by mechanical hyperventilation or by pharmacologic means (e.g., sedation and neuromuscular blockade).

Assist-control ventilation (ACV) gives the patient the option of initiating additional machine breaths when the rate, set by the physician, is insufficient to meet the patient's rate demand. ACV differs from intermittent mandatory ventilation (IMV) in that all delivered breaths execute the same pressure or flow program, depending on the choice of primary mode. The ACV feature has lured many providers into the erroneous assumption that the primary machine rate setting is unimportant (see "Acute Lung Injury and Hypoxic Respiratory Failure: Respiratory Rate" below).

Traditionally, machine algorithms for detecting patient effort have keyed on the airway pressure signal.[9] Because the inspiratory port of ventilators is closed during machine expiration, any inspiratory effort that is initiated near relaxation volume (Vrel) causes a fall in Paw. When Paw reaches a predefined trigger threshold (usually set 1 to 2 cm H_2O below the end-expiratory pressure setting), the machine switches from expiration to inspiration. In the presence of dynamic hyperinflation, the inspiratory muscles must generate considerably more pressure than the set airway trigger pressure before a machine breath is delivered[10] (see "Obstructive Lung Diseases" below).

Particularly in older ventilator models and in less-sophisticated portable machines intended for home use, it used to be common to find delays of up to 0.5 second between the onset of inspiratory muscle activity and machine response. In most ventilators used today, such delays are less than 100 milliseconds.[11] Sensing delays are common when the Paw is monitored in the machine rather than near the patient–ventilator interphase. In the former case, the ventilator tubing acts as a capacitor, delaying the transmission of pressure from the intrathoracic airway to the pressure transducer. Additional delays can be attributed to dynamic hyperinflation and physical constraints on the opening and closing of demands valves. Considering that most ventilator-dependent patients generate between 4 and 8 cm H_2O pressure in 100 milliseconds,[10,12] delays can cause significant effort expenditure and discomfort. More importantly, patients may terminate seemingly ineffective inspiratory efforts prematurely only to initiate another effort of greater amplitude shortly thereafter. This leads to discrepancies between patient and machine rate.[13,14] Discrepancies are seen often in weak or heavily sedated patients with severe hyperinflation and high intrinsic respiratory rates.[13,15]

Flow-triggering algorithms are alternatives or adjuncts to Paw-based triggering. During "flow triggering," a base flow of gas is being delivered to the patient during the expiratory as well as the inspiratory phases of the machine cycle.[9] Unless the patient makes an inspiratory effort, gas bypasses the endotracheal tube and is discarded through the expiratory machine port. In the absence of patient effort, expiratory flow is equal to inspiratory base flow. In the presence of an inspiratory effort, gas enters the patient's lungs and is thereby diverted from the expiratory machine port. A discrepancy between inspiratory and expiratory base flow is sensed, and the ventilator switches phase. Because "flow triggering" alleviates the need to rarefy gas against an occluded demand valve, initially it was considered superior to pressure-based trigger algorithms.[9,16] Because most new-generation ventilators have combined pressure and flow-sensing capabilities, these distinctions no longer apply.

Options for Defining the Machine's Mechanical Output

The mode of mechanical ventilation often refers to the shape of the inspiratory pressure or flow profile and determines whether a patient can augment V_T or rate through his or her own efforts.

Volume-Preset Mode

In conventional volume-preset mode, each machine breath is delivered with the same predefined inspiratory flow-time profile. Because the area under a flow-time curve defines volume, V_T remains fixed and is uninfluenced by the patient's effort. Volume-preset ventilation with constant (square wave) or decelerating inspiratory flow is the most widely used breath-delivery mode. Breath delivery with flows that decrease with increasing lung volume are effective in reducing peak Paw. It is not clear, however, whether they protect the lungs from overdistension injury any more than square wave flow profiles.

The mechanical output of a ventilator operating in the volume-preset mode is uniquely defined by four settings: (a) the shape of the inspiratory flow profile, (b) V_T, (c) machine rate, and (d) a timing variable in the form of either the I:E ratio, the duty cycle (T_I/T_{TOT} [inspiratory time/total respiratory time]), or the T_I. In some ventilators, timing is set indirectly through the choice of peak or mean inspiratory flow (V_T/T_I). Figure 5-1 illustrates the relationships among these and other breathing-pattern parameters of significance.

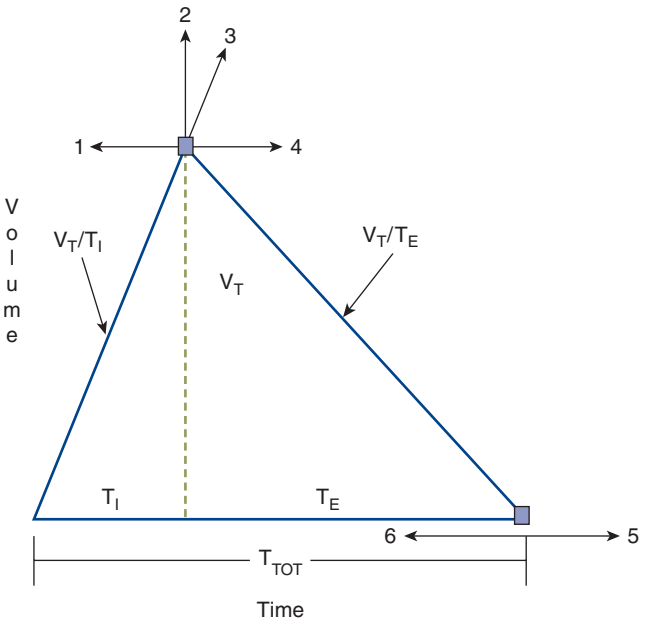

FIGURE 5-1 Idealized spirogram of a breath delivered during volume-preset mechanical ventilation. Examples 1 through 6 indicate specific changes in ventilator settings and illustrate the consequences on flow and timing variable. (For abbreviations, see Table 5-1.) (1) Increasing mean inspiratory flow (V_T/T_I) at a constant machine rate setting results in a reduced I:E ratio and vice versa. T_I, T_I/T_{TOT}, and mean expiratory flow (V_T/T_E) decline. (2) Increasing V_T at constant T_I/T_{TOT} or I:E setting increases mean inspiratory flow and requires an increase in mean expiratory flow. Remember that mean inspiratory flow equals peak inspiratory flow when delivery modes with constant square wave flow profiles are used. (3) Increasing V_T at a constant mean inspiratory flow setting increases T_I, T_I/T_{TOT}, I:E ratio, and mean expiratory flow. (4) Decreasing mean inspiratory flow at a constant machine rate setting results in an increase in the I:E ratio and vice versa. T_I, T_I/T_{TOT} and mean expiratory flow rise. (5) Reducing the machine backup rate (f_M) at a fixed I:E ratio or T_I/T_{TOT} setting always prolongs T_I and lowers mean inspiratory flow. The timing effects of reducing f_M at a fixed inspiratory-flow setting cannot be predicted without knowledge of the patient's actual trigger rate. (6) Increasing f_M at a fixed I:E ratio or T_I/T_{TOT} setting always raises inspiratory flow. The timing effects of increasing f_M at a fixed inspiratory-flow setting cannot be predicted without knowledge of the patient's actual trigger rate.

Pressure-Preset Mode

During pressure-preset ventilation, the ventilator applies a predefined target pressure to the endotracheal tube during inspiration. The resulting V_T and inspiratory flow profile varies with the impedance of the respiratory system and with the strength and duration of the patient's inspiratory efforts. Therefore, when the lungs or chest wall become stiff, airway resistance increases, the patient's own inspiratory efforts decline, or T_I decreases, V_T decreases. An increase in respiratory system impedance can lead to a dangerous fall in minute ventilation ($\dot{V}_E$), hypoxemia, and CO_2 retention, but in contrast to volume-preset modes, it does not predispose the patient to an increased risk of barotrauma. On the other hand, pressure-preset modes are no safeguard against ventilator-induced lung injury because large fluctuations in respiratory impedance or patient effort would result in large V_T fluctuations directly undermining the primary objective of lung-protective mechanical ventilation (see section on Acute Lung Injury and Hypoxic Respiratory Failure).

Pressure-support ventilation (PSV), pressure-controlled ventilation (PCV) and airway pressure release ventilation (APRV) are the most widely used forms of pressure-preset ventilation. In contrast to PCV, PSV requires the patient's effort before a machine breath is delivered. Consequently, PSV is not suitable for the management of patients with central apneas. During PCV, the physician sets the machine rate, the T_I, and thus the I:E ratio. In PSV, phase switching is linked to inspiratory flow, which, in turn, depends on the impedance of the respiratory system, as well as on the timing and magnitude of inspiratory muscle pressure output.[11,14] APRV is akin to PCV with a long duty cycle, but with one important distinction: patients are able to take spontaneous breaths throughout all phases of the machine cycle.

PSV remains a popular weaning mode for adults. Its popularity is based on the premise that weaning from mechanical ventilation should be a gradual process and that the work of unassisted breathing through an endotracheal tube is unreasonably high and could lead to respiratory muscle failure in susceptible patients. Actual measurements of pulmonary resistance and work of breathing before and after extubation do not support this reasoning,[17,18] and several large clinical trials have established equivalence between PSV and T-piece weaning (unassisted breathing from a bias-flow circuit).[19–21] In the PSV mode, a target pressure is applied to the endotracheal tube, which

TABLE 5-1: LIST OF ABBREVIATIONS

τ	Time constant
AC	Assist-control mode
ARDS	Adult respiratory distress syndrome
CMV	Controlled mechanical ventilation
CPAP	Continuous positive airway pressure
Ers	Elastance of the respiratory system
Edi	Electromyographic tracing of the diaphragm
F	Force
f_A	Actual breathing rate
FEF_{25-75}	Forced expiratory flow in the mid vital capacity range
FI_{O_2}	Fractional inspired oxygen concentration
f_M	Machine backup rate
I:E ratio	Inspiratory-to-expiratory time ratio
IMV	Intermittent mandatory ventilation
Pa_{CO_2}	Arterial CO_2 tension
Pa_{O_2}	Arterial O_2 tension
Paw	Airway pressure
PCV	Pressure-controlled ventilation
PEEP	Positive end-expiratory pressure
$PEEP_E$	Extrinsic positive end-expiratory pressure
PEEPi	Intrinsic positive end-expiratory pressure
Pel	Elastic recoil pressure
P_{tp}	Transpulmonary pressure
Pmus	Inflation pressure exerted by inspiratory muscles
Pres	Resistive pressure
Prs	Recoil of respiratory system
PSV	Pressure support ventilation
SIMV	Synchronized intermittent mandatory ventilation
T_E	Expiratory time
T_I	Inspiratory time
T_I/T_{TOT}	Duty cycle
T_{TOT}	Total cycle time
TLC	Total lung capacity
$\dot{V}$	Flow
$\dot{V}/\dot{Q}$	Ventilation-perfusion ratio
$\dot{V}_{CO_2}$	Volume of CO_2 produced in liters per minute
$\dot{V}_E$	Minute ventilation
$\dot{V}_I$	Mean inspiratory flow
V(t)	Instantaneous lung volume
$\dot{V}_E/V_T$	Dead-space-to-tidal-volume ratio
Vee	Volume of lungs at end expiration
Vrel	Relaxation volume
V_T/T_E	Mean expiratory flow
V_T/T_I	Mean inspiratory flow
V_T	Tidal volume
Vtrapped	Volume of gas remaining in the elastic element at the beginning of a new machine inflation
Wel	Elastic work

augments the inflation pressure exerted by the inspiratory muscles (Pmus) on the respiratory system. When inspiratory muscles cease to contract and Pmus falls, inspiratory flow (a ventilator-sensed variable) declines, and the machine switches to expiration. Early PSV modules were designed to generate pressure ramps (square wave inflation pressure) and had relatively rigid flow-based, off-switch criteria. Most recent versions of PSV afford control over the rate of rise in inspiratory pressure and the flow threshold at which inspiration is terminated.[11,14,22]

Synchronized Intermittent Mandatory Ventilation

During synchronized intermittent mandatory ventilation, a specified number of usually volume-preset breaths are delivered every minute. In addition, the patient is free to breathe spontaneously between machine breaths from a reservoir or to take breaths augmented with PSV. Most ventilators allow the operator to choose between volume- and pressure-preset mandatory breaths. Unless the patient fails to breathe spontaneously, machine breaths are delivered only after the ventilator has recognized the patient's effort; that is, ventilator and respiratory muscle activities are "synchronized." Because nowadays all IMV circuits are synchronized, the terms *IMV* and *synchronized intermittent mandatory ventilation* are used interchangeably. Although synchronized intermittent mandatory ventilation remains a viable and popular mode of mechanical ventilation, compared with the alternatives, PSV and T piece, it has clearly proven inferior as a weaning modality.[19,20,23,24] Moreover, the care provider needs to be aware of certain pitfalls when using IMV. Even a small number of volume-preset IMV breaths per minute may make the blood-gas tensions look acceptable in patients who otherwise meet criteria for respiratory failure. One should suspect this in patients with small spontaneous V_T (≤3 mL/kg of body weight), in those with thirty or more inspiratory efforts per minute regardless of whether they trigger a machine breath, and when dyspnea and thoracoabdominal paradox indicate a heightened respiratory effort. One reason that IMV remains popular is because it silences apnea alarms by masking PSV-induced respiratory dysrhythmias, which are common in sleeping and obtunded patients.[25–27]

Dual-Control and Advanced Closed-Loop Modes

Many new-generation mechanical ventilators feature modes with closed-loop feedback control of both pressure and volume.[28,29] While a detailed description of the operating principles of every new mode is beyond the scope of this chapter, it is important to understand the rationale behind dual-control modes and some of their general operating characteristics. The idea behind most dual-control modes is the meeting of a ventilation target while maintaining low inflation pressures. To this end, ventilator output is adjusted based on volume, flow, and pressure feedback. This may occur within each machine cycle or gradually from one cycle to the next. Modes that adjust output within each cycle execute a predetermined pressure-time program as long as the desired V_T is reached. When the V_T target is not reached, inspiration continues at a preselected inspiratory flow rate (volume-limited) until the target volume is attained. *Volume-assured pressure support* and *pressure augmentation* are examples of such modes.[30] Breath-to-breath dual-control modes are pressure-limited and time-cycled or flow-cycled. Ventilator

output is derived from the pressure–volume relationship of the preceding breath and is adjusted within predefined pressure limits to maintain the target V_T. *Adaptive support ventilation, pressure-regulated volume control*, *volume control+*, *autoflow*, *adaptive pressure ventilation*, *volume support*, and *variable pressure support* are examples of breath-to-breath control modes. There is no evidence that the use of dual-control modes improves patient outcomes.[31,32] Moreover, there is a conceptual problem insofar as less complex modes already safeguard against hypoventilation, whereas dual-control modes do little to protect the patient from a potentially harmful increase in the regulated variable, that is, large V_T-mediated lung injury.[33,34]

Neurally adjusted ventilatory assistance (NAVA) and *proportional-assist ventilation* (PAV)[35–37] are the most complex, and arguably the most promising, closed-loop ventilation modes. During NAVA, the diaphragm's electrical activity is recorded with an esophageal probe, and the signal is conditioned and transposed into a positive airway pressure output. During PAV, the ventilator derives its mechanical output from continuously monitored Paw, V, and $\dot{V}$ information, which, in turn, reflects Pmus. The operating principles of PAV will be easier to understand after a review of patient–ventilator interactions (see "The Mechanical Determinants of Patient-Ventilator Interactions" below). Compared to conventional modes of mechanical ventilation, both NAVA and PAV preserve the biologic variability in breathing rate and V_T, which is generally considered lung protective.[38] Moreover, the maintenance of intrinsic respiratory control mechanisms is likely to reduce the probability of exposing the lungs to injurious deformations. Although there is ample literature on the effects of closed-loop modes on patient–ventilator interactions and physiologic end points, there is insufficient clinical experience to judge efficacy of these modes compared to conventional approaches. This is particularly true for NAVA, which was only recently introduced to the world market, but holds particular promise as platform for delivering noninvasive mechanical ventilation and as a support mode for neonates and small infants. Be this as it may, the full-scale migration of closed-loop modes from expert hands into general practice will likely depend on the willingness of providers to acquire the physiologic insights and skills necessary for managing patients who are ventilated with "unconventional" modes.

THE MECHANICAL DETERMINANTS OF PATIENT–VENTILATOR INTERACTIONS

Inspiratory Mechanics

It is useful to think of patient–ventilator interactions in terms of a mechanical or electrical analog system consisting of a resistive element (resistor) and an elastic element (capacitor) in series. The forcing function is defined by the pressure or flow "program" that is executed by the mechanical ventilator.

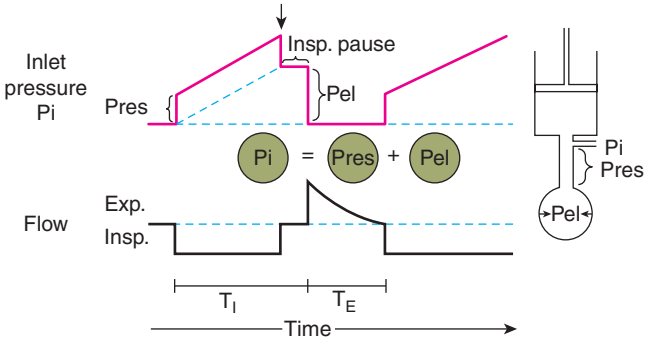

FIGURE 5-2 Components of inlet pressure. The model of the respiratory system at right consists of a resistive element (straight tube) and an elastic element (balloon) connected to a ventilator (piston). During inflation of the model with constant flow *(lower panel)*, there is a stepwise increase inlet pressure (Pi) that equals the loss of pressure across the resistive element (Pres) (*upper panel*). Thereafter, Pi increases linearly and reflects the mechanical properties of the elastic element (Pel). Pi is the sum of Pres and Pel. At end inspiration, when flow has ceased (Insp. Pause), Pi decreases by an amount equal to Pres; Pi equals Pel during Insp. Pause. T_I, inspiratory time; T_E, expiratory time. (Used, with permission, from Hubmayr, et al. Physiologic approach to mechanical ventilation. *Crit Care Med.* 1990;18:103–113.)

In Figure 5-2, a piston pump (the mechanical ventilator) is attached to a rigid tube (the resistive element) and a balloon (the elastic element). An in-series mechanical arrangement means that at any time *t*, the pressure that is applied to the tube inlet $Pi(t)$ (near the attachment to the ventilator) is equal to the sum of two pressures, an elastic pressure $Pel(t)$ and a resistive pressure $Pres(t)$:

$$Pi(t) = Pel(t) + Pres(t) \quad (1)$$

The tube outlet pressure at the junction with the balloon is equal to the pressure inside the balloon, that is, Pel. Pres is the difference in pressure between the tube inlet and the tube outlet. Assuming linear-system behavior, the inlet pressure-time profile can be computed for any piston stroke volume (Vstroke) and flow ($\dot{V}$) setting, provided the resistive properties of the tube (R) and the elastic properties of the balloon (E) are known:

$$Pi(t) = EV(t) + R\dot{V}(t) \quad (2)$$

The elastance (E) is a measure of balloon stiffness and is equal to the Pel-to-V stroke ratio (assuming 0 volume and pressure at the beginning of balloon inflation). Therefore, $Pel(t)$ in Eq. (1) can be replaced with $EV(t)$ in Eq. (2). Because the Ohm law states that the tube resistance (R) is equal to the Pres-to-$\dot{V}$ ratio, $Pres(t)$ in Eq. (1) can be replaced with the product $R\dot{V}(t)$ in Eq. (2).

Equations (1) and (2) are based on the equation of motion, which describes the force (F) that must be applied to a mass (M) in order to move it a certain distance (d) at a rate dd/dt against a spring (elastic) load:

$$F(t) = kd(t) + k'(dd/dt)(t) + k''[d(dd/dt)](t) \quad (3)$$

where k = stiffness of the spring (analogous to E); k' = frictional resistance between mass and supporting surface

(analogous to R); and k'' = inertance, which is proportional to mass.

The first and second derivatives of d (analogous to volume) represent the velocity (dd/dt, analogous to flow) and the acceleration [$d(dd/dt)/dt$] of the mass at time t, respectively. As long as the mass of the moving parts in the model of Figure 5-2 is small, any inertive-pressure component that is dissipated during the acceleration of gas at the beginning of the pump instroke can be ignored. Therefore, the respiratory analog of the equation of motion [Eqs. (1) and (2)] considers only elastic and resistive pressures.

Consider the Pi-time profile of a tube-balloon system with resistance of 10 cm $H_2O \times L/s$ and an elastance of 10 cm H_2O when the piston pump is programmed to deliver a volume of 0.5 L with a constant (square wave) flow of 0.5 L/s. Because flow and R remain constant throughout inflation, Pres is constant at 5 cm H_2O and accounts for the initial step change in inlet pressure at the beginning of inflation. As gas enters the balloon, Pi increases further and reaches a value of 10 cm H_2O at end inflation. At that instant, the tube is occluded (end-inflation hold), causing Pi to drop by an amount equal to Pres (as flow returns to 0). The end-inflation hold pressure is equal to Pel at that volume. Its value of 5 cm H_2O is equal to the product of piston stroke volume (0.5 L) and elastance (10 cm H_2O/L), as follows from Eqs. (1) and (2). Subtracting Pres from Pi(t) yields the Pel per time course during inflation. Pel increases linearly with time and volume. Its rate of rise (dPel/dt) parallels that of Pi and is determined by E and the flow setting of the piston:[39]

$$E \times \dot{V} = (dp/dV) \times (dV/dt) = dP/dt \quad (4)$$

Although changes in inspiratory flow result in proportional changes in dPel/dt, flow has no effect on peak Pel, provided that Vstroke, and thus peak lung volume, is held constant. This is in contrast to peak Pi, which reflects flow-dependent changes in Pres, as well as change in Pel, at end inflation. The relevance of this important property of linear single-compartment systems will become apparent later when the relationships between ventilator settings and barotrauma (balloon yield stress) are discussed (see "Acute Lung Injury and Hypoxic Respiratory Failure" below).

Expiratory Mechanics

In mechanically ventilated subjects, expiration is usually a passive process that is driven by the elastic recoil (Pel) of the respiratory system. Assuming linear pressure-volume and pressure-flow relationships, the instantaneous expiratory flow [$\dot{V}exp(t)$] is given by

$$\dot{V}exp(t) = Pel(t)/R \quad (5)$$

Because $Pel(t)$ is a function of E and of the instantaneous lung volume [$V(t)$], Eq. (5) can be rewritten as

$$\dot{V}exp(t) = E \times V(t)/R = V(t)/R \times C \quad (6)$$

where C (the compliance of the respiratory system) is simply the inverse of the elastance (E). The product of R and C characterizes the time constant (τ) of single-compartment linear systems. The time constant defines the time at which approximately two-thirds of the volume above $Vrel$ has emptied passively. From this it should be clear that patients with increased respiratory system resistances and compliances (e.g., patients with emphysema) are prone to dynamic hyperinflation even if one ignores nonlinear system behavior, such as flow limitation, for the moment.

The volume of gas remaining in the elastic element at the beginning of a new machine inflation ($Vtrapped$) can be calculated as follows:

$$Vtrapped = V_T/(e^{TE/\tau} - 1) \quad (7)$$

In other words, the degree of dynamic hyperinflation is determined by the choice of ventilator settings, specifically mean expiratory flow (V_T/V_E) and the time constant of the respiratory system, which reflects its mechanical constants R and C.[40] These important concepts are expanded on under "Obstructive Lung Diseases" below.

Limitations of Linear Single-Compartment Models

Before linear model principles are applied to the ventilator management of patients, one must be cognizant of the model's limitations. The limitations fall into two general categories: those related to nonlinear respiratory system characteristics and those related to respiratory muscle activation during mechanical ventilation. Sources of nonlinear system behavior include inhomogeneities within the numerous bronchoalveolar compartments (particularly when the lungs are diseased),[41] respiratory system hysteresis from recruitment of alveolar units and time-dependent surface tension phenomena,[42] and phenomena related to dynamic airway collapse and expiratory flow limitation.[43] Coactivation of the respiratory muscles during mechanical ventilation invalidates Eqs. (1) through (7) insofar as they alter the impedance of the respiratory system and change the driving pressure for expiratory flow. If one assumes that the respiratory muscles and the ventilator are arranged in series, then the monitoring of pressure, volume, and flow at the airway opening offers the opportunity to define the magnitude, rate, and duration of respiratory muscle output in mechanically ventilated subjects.[44,45]

DEFINING THERAPEUTIC END POINTS IN COMMON RESPIRATORY FAILURE SYNDROMES

Numerous diseases of cardiopulmonary systems can cause respiratory failure. From a ventilator management perspective, it is useful to group them into those that cause lung failure and those that cause ventilatory pump failure.

The hallmark of lung failure is hypoxemia, which is usually the result of severe ventilation-perfusion mismatch. The hallmark of ventilatory pump failure is hypercapnia. Ventilatory pump failure may be caused by disorders of the central nervous system, peripheral nerves, or respiratory muscles. It also may accompany diseases of the lungs, such as emphysema, once the ventilatory pump fails to compensate for inefficiencies in pulmonary CO_2 elimination. Two classic examples of hypoxic and hypercapnic ventilatory failure that require fundamentally different approaches to mechanical ventilation are the acute respiratory distress syndrome (ARDS) and chronic airflow obstruction. The therapeutic goal in ARDS is to protect the lung from mechanical injury while raising lung volume in an attempt to reduce shunt by reexpanding collapsed and flooded alveoli. In contrast, the therapeutic goal in a patient with hypercapnic ventilatory failure from exacerbation of airways obstruction is to reduce dynamic hyperinflation and to protect the respiratory muscles from overuse.

ACUTE LUNG INJURY AND HYPOXIC RESPIRATORY FAILURE

Acute lung injury (ALI) is a syndrome associated with bilateral pulmonary infiltrates and a gas-exchange impairment severe enough to lower the arterial oxygen tension-to-fractional inspired oxygen concentration ratio (Pa_{O_2}/FI_{O_2}) below 300.[46] Heart failure and moderate to severe preexisting chronic lung disease must be absent. ALI and its more severe form, ARDS, are often complications of systemic illnesses such as sepsis.[47] The impairment on pulmonary gas exchange therefore is accompanied frequently by microcirculatory failure. The general management goal in these disorders is to augment systemic oxygen delivery until the metabolic demands of the organism can be met. This goal requires an integrated approach between cardiovascular and ventilator support.[48]

Ventilator support is often difficult because exceedingly high ventilatory requirements challenge the performance capacity of mechanical ventilators; render patients at risk for barotrauma, ventilator-induced lung injury, and cardiovascular collapse; and often are accompanied by excessive respiratory muscle activity ("fighting the ventilator"). All these conditions on occasion can necessitate heavy sedation and neuromuscular blockade.

Fractional Inspired Oxygen Concentration

The two principal means by which the physician can increase Pa_{O_2} in ARDS are to raise the FI_{O_2} and to elevate the volume about which the lungs are being ventilated. The danger inherent in raising $FI_{O_2}$is oxygen toxicity,[49] whereas manipulating lung and/or V_T may result in ventilator-induced lung injury[34,50] and/or barotrauma.[51] Presented with the choice between two different kinds of adverse reactions, physicians currently tend to be more fearful of mechanical lung injury than of oxygen toxicity. Unfortunately, there are no clinical outcome studies that shed light on the interactions between these two iatrogenic insults. It is common practice to initiate ventilator support with an FI_{O_2} of 1.0 and to ignore the potential for oxygen toxicity during the first few hours of ventilator management. Although, generally speaking, the relative and combined risks of oxygen toxicity and overdistension injury of the lungs remain poorly defined, there are instances in which it seems wise to minimize FI_{O_2}, namely, in patients who have received drugs such as bleomycin or amiodarone, which make the lungs particularly susceptible to reactive O_2 species-mediated injury.[52]

FIGURE 5-3 Computed tomographic (CT) scan of a patient with acute respiratory failure in the supine position. Note the patchy, nonuniform distribution of alveolar edema. (Used, with permission, from Gattinoni L, et al. Body position changes redistribute lung computed-tomographic density in patients with acute respiratory failure. *Anesthesiology.* 1991;74:15–23.)

Manipulating End-Expiratory Lung Volume

The insults to the lungs of patients with hypoxic respiratory failure are often patchy and result in flooding and closure of dependent airspaces (Fig. 5-3).[53,54] Paraspinal regions of the lung appear most susceptible to atelectasis (lack of aeration) because, in the supine posture, they normally empty close to their residual volume and they receive most of the pulmonary blood flow.[55] Therefore, insults to their capillary integrity are most likely to promote alveolar flooding, closure of airspaces by liquid plugs, surfactant inactivation, and gas-absorption atelectasis.[56] The accumulation of airway liquid and foam also generates interfacial forces that are large enough to abrade the epithelial lining of small airways during breathing, causing further injury.[57–61] Ventilator management therefore must be directed toward preventing the repeated opening and closing of unstable lung units, which means reestablishing aeration and ventilation of the flooded lung (Fig. 5-4).[62]

There are several ways to achieve this objective: (a) by raising overall lung volume through the judicious use of extrinsic positive end-expiratory pressure (PEEP), (b) by raising lung volume dynamically through "intentional gas trapping," (c) by increasing V_T, and (d) by taking advantage of the local

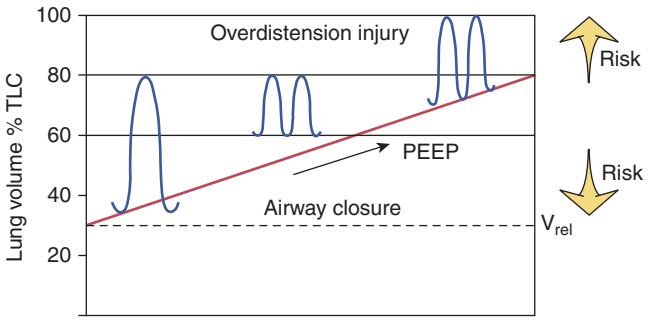

FIGURE 5-4 Schematic of the therapeutic end points of ventilator management in ARDS. Raising peak lung volume toward total lung capacity (TLC) increases the risk of barotrauma. Keeping the minimal volume near relaxation volume (Vrel) raises the likelihood of alveolar derecruitment at end expiration and the need to apply large opening pressures so as to recruit collapsed and flooded lung regions during the subsequent breath.

distending forces generated by an actively contracting diaphragm. Any one of these approaches may be combined with so-called recruitment maneuvers, which consist of sustained (up to 40 seconds) inflations of the lungs to high volumes and pressures.[63–65] The preferred and time-tested approach is the judicious use of extrinsic PEEP. All the other means of raising lung volume are comparatively untested, and in the case of V_T, manipulations can be outright harmful.[33,34] Although there is a strong physiologic rationale to condition (i.e., "open") the lungs with recruitment maneuvers before a PEEP adjustment, most experimental and clinical data indicate that conditioning effects are relatively short-lived.[66–69] Because it is common for patients with ALI to have an increased respiratory rate, a component of dynamic hyperinflation is often present.[70] Despite the short time constant for lung emptying, the use of extrinsic PEEP valves, which in older-generation ventilators represent resistive as well as threshold loads, and ventilator settings that require large mean expiratory flows (V_T/T_E; see "Mean Expiratory Flow: The Hidden Variable" below) contribute to dynamic hyperinflation.

Although the experimental evidence in support of PEEP therapy in injured lungs is overwhelming, its specific application to clinical practice remains controversial. There is general agreement among experts that patients with injured lungs should be ventilated with PEEP settings greater than 5 cm H_2O. The risk, however, of overinflating and thereby damaging well-aerated, generally nondependent lung units and adverse hemodynamic effects set limits to an aggressive recruitment strategy.[71,72] Uncertainty about the topographic distribution of lung parenchymal stress and related stress injury thresholds are partly the reason why there is no consensus as to whether PEEP should be set arbitrarily to 10, 15, or 20 cm H_2O, whether it should be targeted to specific physiologic end points, and, if so, what those end points and their specific target thresholds should be. Several large randomized clinical trials have failed to resolve the controversy about "best PEEP."[73–75] Although none of these trials established superiority of one specific PEEP strategy over another, proponents of aggressive lung recruitment argue that PEEP was not targeted to the appropriate surrogate end points. Specifically, lung recruitment, chest wall recoil, and parenchymal stress were not measured or considered in the choice of PEEP settings.

Tools for assessing recruitment responses include (a) measures of regional lung aeration with computed tomography or electrical impedance imaging of the chest,[76–78] (b) measurement of lung and/or respiratory system pressure–volume relationships,[79–82] and (c) assessment of within-breath oscillations in arterial O_2 tension with indwelling arterial O_2 sensors with fast response times.[83,84] At the bedside, the most readily available PEEP management guides are airway inflation pressure amplitude, ΔP (in case of volume preset ventilation) or V_T (in case of pressure preset ventilation). As long as raising PEEP causes recruitment of previously "closed" lung units without overdistending already open ones, ΔP will decrease, reflecting the corresponding increase in compliance. In relaxed patients who are being ventilated with a pressure preset mode, the PEEP-related effect on lung compliance can be inferred from corresponding V_T changes. Adjusting PEEP until ΔP reaches a minimum, or conversely in the case of pressure preset ventilation until V_T reaches a maximum, is in line with the stress-index hypothesis.[81] The latter states that inflating lungs over the linear range of the respiratory system pressure–volume curve is most lung protective.

Patients who are likely to recruit in response to PEEP and who indeed may benefit from raising PEEP above 10 cm H_2O at the outset are patients with an increased end-expiratory chest-wall recoil pressure, which may or may not be associated with a reduced chest-wall/abdominal compliance[85–87] and patients whose airway and alveolar edema can be redistributed easily.[88,89] In critically ill patients, the most common conditions associated with increased chest-wall recoil are obesity, ileus, and ascites.[84,90] The ability to influence the distribution of edema within and between lung regions is greatest in the early stages of inflammation. In the later stages of ARDS, when the inflammatory exudate turns from liquid to a gel, it becomes much harder to "open" a closed airspace. The likelihood of high PEEP causing recruitment is even less once organizing pneumonia, alveolar remodeling, and fibrosis dominate the pathology.[91,92]

One attempt to identify groups of patients who are more or less likely to respond to PEEP has been to classify their insults as indirect versus direct.[89] Indirect insults such as abdominal sepsis are more likely associated with a favorable PEEP response (possibly because their chest-wall recoil is high and their alveolar exudate is liquid), whereas a direct insult, from a microbial lung infection, for example, tends to be more PEEP resistant (airway secretions tend to be viscous, and the alveolar exudate has the consistency of a gel). There is, however, enough variability in lung and chest-wall mechanics within and across these two patient populations to warrant a case-by-case assessment of pulmonary and hemodynamic responses to PEEP or recruitment maneuvers. Although most clinicians choose PEEP levels according to indices of arterial oxygenation,[75] there is

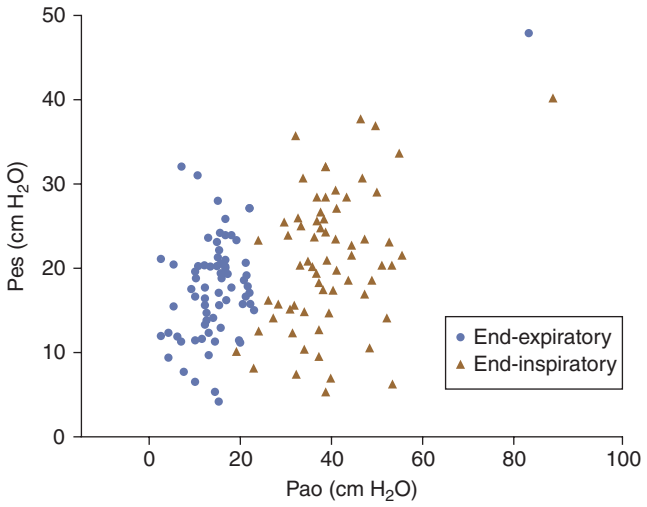

FIGURE 5-5 Relationship between airway pressure (*x axis*) and esophageal pressure (*y axis*) at end-expiration (*solid circles*) and end-inspiration (*open triangles*) in mechanically ventilated patients with ALI. As a group, most patients were managed at PEEP settings ≥10 cm H_2O, yet the corresponding esophageal pressure exceeded PEEP in 50% of instances. This suggests that the lungs were compressed by the chest wall and not sufficiently recruited at end-expiration. (Used, with permission, from Talmor, et al. Esophageal and transpulmonary pressures in acute respiratory failure. *Crit Care Med.* 2006;34:1389.)

preliminary evidence that favors PEEP adjustments guided by esophageal manometry.[93] Notwithstanding uncertainty about "mediastinal artifacts" in recumbent patients with pleural effusions and "heavy lungs,"[94,95] the pressure in the mid to lower esophagus represents an estimate of local, if not global, lung surface (or pleural, Ppl) pressure. As such, when referenced to airway pressure (Pao, a surrogate of alveolar pressure in the absence of flow) the esophageal pressure (Pes) informs about lung stress (i.e., transpulmonary pressure, Ptp). Remarkably, several reports indicate that up to 50% of patients with injured lungs have a negative Ptp at end expiration (Pes >Pao) despite PEEP settings as high as 20 cm H_2O (Fig. 5-5).[82,93] It would be easy to dismiss these findings as artifact, were it not for a small prospective randomized clinical trial that hinted at a survival benefit in patients in whom PEEP therapy was targeted to an end-expiratory Ptp of +5 cm H_2O.[93] It suggests that in the recumbent posture the injured lung is mass loaded by the chest wall and resists emptying on account of interfascial forces from alveolar or airway fluid and foam.[56] It may also mean that the risks of overinflating nondependent lung units, which are undoubtedly stressed by the more aggressive PEEP approach, is not as great as generally thought.

For those who rely on acute changes in Pa_{O_2} as surrogate end points of PEEP management, certain caveats are in order. In critically ill patients with injured lungs, Pa_{O_2} is sensitive to changes in metabolic rate and cardiac output.[96,97] Because patients with injured lungs have $\dot{V}/\dot{Q}$ mismatch as well as shunt, changes in mixed venous oxygen tension, which result from changes in metabolic rate and cardiac output, must influence arterial P_{O_2}. Therefore, the P_{O_2} response to step changes in PEEP (and/or recruitment maneuvers) is determined by a net balance between positive and negative effects. Positive effects include (a) reductions in the number of lung units with low $\dot{V}/\dot{Q}$ and shunt as a result of their recruitment, (b) increases in cardiac output driven by the sympathomimetic effects of CO_2 retention (the latter invariably accompanies recruitment maneuvers), and (c) a fall in oxygen uptake associated with respiratory acidosis.[98,99] Negative effects include (a) increases in low $\dot{V}/\dot{Q}$ and shunt in patients who are PEEP-resistant and in whom the increased alveolar pressure diverts blood away from normal lung toward diseased lung,[100] (b) a fall in cardiac output resulting from volume- and pressure-mediated decreases in venous return,[101] (c) a fall in cardiac output resulting from volume-mediated and pressure-mediated increases in pulmonary artery pressure and right-ventricular afterload,[102] and (d) increases in systemic oxygen consumption as a behavioral response to increased lung expansion and CO_2 retention. The cardiovascular and metabolic confounders of the recruitment response may be deduced from pulse and blood-pressure responses. Alternatively, lung recruitment ought to result in a change in respiratory system mechanics. The clinician, however, should be under no illusion that such change will be large and easy to discern from peak and plateau pressure measurements.[79] This is so because comparisons between states require careful attention to muscle relaxation and the matching of volume and time histories.[103] Finally, because clinicians generally must rely on pulse oximetry as opposed to online P_{O_2} measurements, they must consider the time delays secondary to circulation time and signal processing when assessing the recruitment response.[104]

Choosing the Appropriate Tidal Volume

The choice of V_T is arguably the most important decision a care provider makes when initiating mechanical ventilation. For many years, physicians have chosen ventilator V_T between 10 and 15 mL/kg of actual body weight. This recommendation can be traced back to the early days of positive-pressure ventilation, when this therapy was reserved for patients with neuromuscular diseases, such as poliomyelitis. Patients with near-normal lungs feel more comfortable when they are ventilated with two to three times normal V_T. In patients with injured lungs, however, a V_T of as little as 10 mL/kg of actual body weight can have devastating effects on lung structure, function, and, ultimately, outcome.[33,34,50,105]

To fully appreciate the importance of V_T settings, it is useful to consider distinct physical lung-injury mechanisms: (a) regional overinflation, caused by the application of a local stress or pressure that forces cells and tissues to assume shapes and dimensions that exceed those experienced during even the most strenuous exercise,[106,107] (b) so-called low-volume injury associated with the repeated opening

and closure of unstable lung units,[57–59] (c) inactivation of surfactant, on account of large alveolar surface-area oscillations,[108,109] and (d) interdependence mechanisms that raise cell and tissue shear stress between neighboring structures with differing mechanical properties.[110]

The injured lung is particularly susceptible to physical damage because its inspiratory capacity is reduced and its dorsal units tend to get obstructed with liquid plugs.[111,112] As a result, the greater the V_T, the greater is the likelihood that the lung will be damaged by both high-volume and low-volume injury mechanisms. One approach that requires no judgment whatsoever is simply to adopt in all patients with injured lungs the settings of the low V_T arm of the ARDS Network clinical trial,[34] which established the efficacy of lung-protective mechanical ventilation. Patients randomized to the low V_T arm received a V_T of 6 mL/kg of predicted body weight. If their end-inflation pause pressure exceeded 30 cm H_2O, then V_T was reduced further to as little as 4 mL/kg of predicted body weight. In patients in whom 6 mL/kg of predicted body weight resulted in breath stacking, effectively doubling their V_T, and in whom stacking could not be abolished with sedation, V_T was increased up to 8 mL/kg of predicted body weight. This approach was associated with a 23% reduction in all-cause mortality compared with a high-V_T strategy.[34]

The uniform adoption of the ARDS Network recommendation to set V_T to 6 mL/kg predicted body weight in all patients with injured lungs has been challenged.[85,113] Epidemiologic studies have established height and gender as opposed to actual body weight as the best predictors of absolute lung volume, including total lung capacity (TLC).[114,115] The ARDS Network investigators predicted ideal body weight from an equation based on height and gender. A graphic comparison of the two predictive equations (Fig. 5-6) shows that 1 mL/kg of predicted body weight corresponds to 1% predicted TLC. Therefore, the recommendation to restrict V_T of patients with injured lungs to 6 mL/kg of predicted body weight amounts to restricting V_T during mechanical ventilation to no more than 6% of preinjury TLC. The right-hand side of the figure shows that there is no correlation between predicted TLC and actual body weight in a population of patients who were ventilated at the Mayo Clinic in 2001.[105] Although these observations underscore the fallacy of scaling V_T to actual body weight, one may reasonably argue that scaling V_T to predicted body weight also misses the mark. To the extent to which the treatment objective of lung-protective mechanical ventilation is to minimize lung stretch, one would want to scale V_T to the capacity of the injured lung and not that of the lung before it was injured. It is well established that the injured lung has fewer recruitable lung units than a normal lung, hence the analogy to "baby lung," a term coined by Gattinoni.[112] Given the variability in lung impairment and hence lung capacity between patients with ALI, it is not surprising that a seemingly uniform V_T setting of 6 mL/kg predicted body weight produces very different parenchymal deformations in a population with lung disease.[85,113]

Lung tissue deformation can be quantified as strain. A strain is a normalized measure of deformation representing the displacement between particles in the body relative to a reference length. A recent report suggests that in normal anesthetized and mechanically ventilated pigs, lung damage occurs only when a strain greater than 1.5 to 2.0 is reached or overcome, implying that normal lungs are quite resistant to ventilator-induced injury.[116] Strain was defined as the fractional volume change between functional residual capacity and the thoracic gas volume at end-inflation. Because none of the animals were ventilated with PEEP, strain equaled V_T/functional residual capacity. Although these data are reassuring for anesthesia practice, it is important to remember that the threshold for strain injury of 2.0 may not hold in instances in which the provider increases end-expiratory

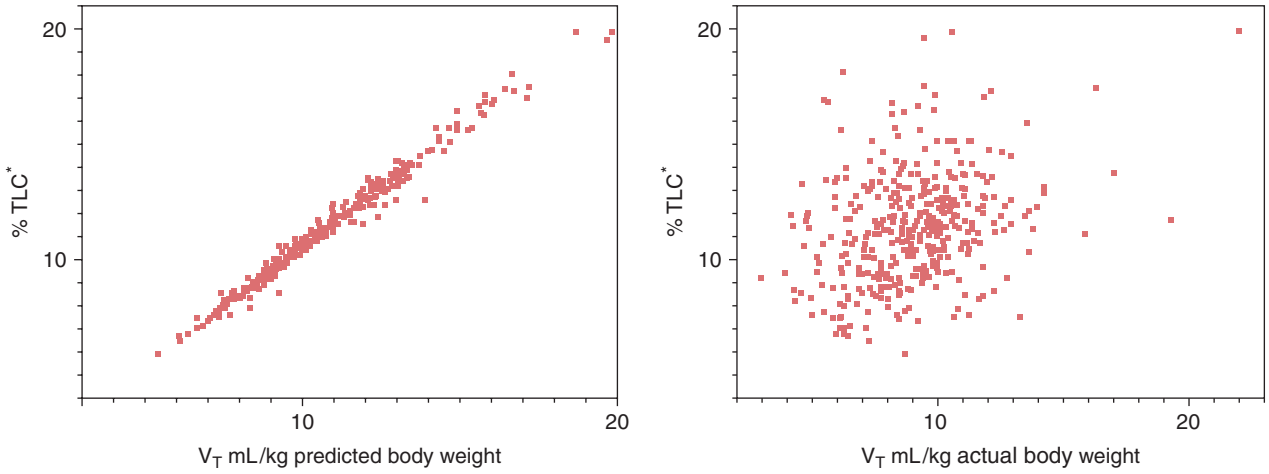

FIGURE 5-6 Predicted or ideal (*left panel*) and actual body weights (*right panel*) of 332 mechanically ventilated patients plotted against their predicted normal total lung capacity (%TLC). The predictive equations for ideal body weight and TLC are based on height and gender. Not surprisingly, the correlation between predicted body weight and predicted TLC is excellent. Note, however, that the correlation between actual body weight and percent TLC is extremely poor. The source data are from patients included in a report by Gajic et al.[105]

lung volume through the use of PEEP. Be this as it may, it must be understood that strain is critically dependent on the choice of reference volume.

Even though there is a powerful rationale for scaling V_T to the capacity of the injured lung, lung capacity or the number of recruitable lung units is rarely measured in current practice. The recommendation to limit airway inflation pressure to ≤30 cm H_2O reflects concerns about overstretching the lung,[117] but ignores the highly variable influence of the chest wall on lung volume and respiratory system mechanics in ALI.[118] Lung capacity, that is, the size of the "baby lung," can be inferred from measurements of thoracic gas volume at a defined airway pressure using either gas-dilution methods or computed tomography.[113,119] Alternatively, the inspiratory capacity can be inferred from the volume of gas that enters the lung during an inflation from 5 to 40 cm H_2O.[84] Although this approach is certainly feasible, there is currently no consensus as to what fraction of capacity V_T may safely occupy.

The results of the low-volume ventilation ARDS Network trial generated a heated debate as to whether outcome differences reflected the obsolete management of the high V_T group or improved management of the low V_T group.[120] Be this as it may, the debate produced some important questions: (a) Is the choice of V_T also important in patients who are ventilated with what generally are considered "safe" inflation pressures? (b) Are ventilator modes in which diaphragmatic activity is preserved superior to the low V_T approach used in the ARDS Network trial? (c) Should one care about V_T restrictions in patients with lung diseases other than ALI?

1. *Is the choice of V_T also important in patients who are ventilated with what generally are considered "safe" inflation pressures?* Inflating the lungs beyond TLC greatly increases the risk for barotrauma. Barotrauma is characterized by extraalveolar air and is an entity distinct from ventilator-induced lung injury.[50,51] In upright man, the transpulmonary and alveolar pressures at TLC approximate 25 and 35 cm H_2O, respectively.[121] The lungs of recumbent patients with ALI, however, are frequently not fully inflated at these pressures.[122] There is an ongoing debate as to whether mechanical ventilation with plateau pressures of less than 30 cm H_2O is safe irrespective of the choice of V_T. None of the available clinical and experimental studies is sufficiently convincing to base general management recommendations on. In the absence of convincing data, one should exercise extreme caution when departing from low V_T guidelines in patients with ALI. Indeed, circumstantial evidence and reasoning favor strict adherence to low V_T guidelines in patients with ALI because (a) spontaneous hyperventilation, which by definition never exceeds TLC, has been implicated as a cause of surfactant dysfunction and noncardiogenic pulmonary edema,[123] (b) repeated inflations of the respiratory system to pressures and volumes below TLC but above the upper inflection point of the inflation P-V curve are associated with lung injury,[81,116] and (c) a post hoc analysis of ARDS Network data suggested that patients in all plateau pressure quartiles derived benefit from V_T reductions.[124]
2. *Are ventilator modes in which diaphragmatic activity is preserved superior to the low V_T approach used in the ARDS Network trial?* Patient-assisted breathing modes, such as PSV, bilevel pressure ventilation, and APRV or NAVA, have been touted as modes of choice in the management of patients with ALI.[125,126] The evidence in support of this recommendation is not as strong as that in support of the low V_T strategy employed in the ARDS Network trial.[34] The rationale for partial support centers on the increased regional ventilation and reduced incidence of atelectasis in dorsal lung regions when diaphragmatic activity is preserved.[127,128] Whether this observation has bearing on patient survival, however, is currently unclear. It should be noted that, on general principles, V_T-related effects on lung structure and function, including injury mechanisms, are not specific to ventilator mode. Until proven otherwise it should be assumed that a V_T of 12 mL/kg predicted body weight is potentially injurious to the lungs regardless whether the patient breathes spontaneously, is mechanically ventilated in a low-pressure preset support mode, or is paralyzed and fully supported in a volume-controlled mode.
3. *Should V_T be restricted in patients with respiratory failure from conditions other than ALI?* To the extent to which lung strain and alveolar overdistension are the prevailing injury mechanisms, lungs with relatively preserved inspiratory capacity are much less susceptible to deformation injury.[116] To date, several prospective clinical trials in search of associations between intraoperative ventilator settings and biomarkers of lung stress have either uncovered no significant association or favor a low V_T strategy.[129,130] A retrospective cohort study, however, of patients who were mechanically ventilated for more than 48 hours and who did not have ALI from the outset, identified V_T as a major risk factor for the subsequent development of noncardiogenic pulmonary edema.[105] This association was recently confirmed in a prospective clinical trial.[131] Because there is no compelling reason why any patient with normal or near-normal lungs would benefit from or need a V_T of greater than 10 mL/kg of predicted body weight, V_T settings above this threshold should be used with caution.

Respiratory Rate

Having settled on a V_T and an end-expiratory volume, adjustments in the machine backup rate (f_M) should be made considering: (a) the patient's actual rate demand, (b) the patient's anticipated ventilatory requirement, and (c) the impact of the rate setting on breath timing (see Fig. 5-1). Virtually all patients with hypoxic respiratory failure are tachypneic and usually require f_M settings of between 20 and 30 breaths per minute. Unless the patient has been paralyzed

or has been so heavily sedated that spontaneous inspiratory triggering efforts are not sensed, f_M settings of 20 breaths per minute or lower are poorly tolerated because: (a) neurohumoral feedback from lung edema and inflammation induces rapid shallow breathing independent of chemoreceptive and mechanoreceptive effects on central pattern generation, (b) in the presence of a severe gas-exchange impairment, low rates and minute volumes would cause CO_2 retention, which, in turn, elicits its own disease state–independent effects on respiratory rate and drive, and (c) discrepancies between actual (triggered) and set machine (backup) rate promote breathing patterns with inverse inspiratory-to-expiratory timing ratios and double triggering. Inverse breathing-pattern ratios are not compatible with normal phase-switching mechanisms in the presence of respiratory distress. Conventional ventilator modes are not capable of varying T_I or inspiratory flow with the actual machine rate. For example, at an f_M setting of 10 breaths per minute, the T_{TOT} is 6 seconds. If the I:E ratio is set at 1:2, or if V_T and flow have been set to 0.5 and 0.25 L/s, respectively, then T_I is fixed at 2 seconds, and expiratory time (T_E) will be 4 seconds. If the patient actually triggers at 20 breaths per minute, then T_{TOT} declines to 3 seconds. T_I remains fixed at 2 seconds because it is determined by the preset machine (backup) rate, the I:E ratio, or the inspiratory-flow setting. T_E now must decrease from 4 seconds to 1 second, and the actual I:E ratio will increase from 1:2 to 2:1. At a rate of 30 breaths per minute (T_{TOT} = 2 seconds), T_E becomes 0, and "fighting the ventilator" must result. For these reasons, the f_M always should be set close to the patient's actual rate. If the actual rate is so high that effective ventilation cannot be achieved, then the patient needs additional sedation and possibly neuromuscular blockade. However, it should be emphasized that some patients, while ventilated in closed-loop modes, such as PAV or NAVA, chose rates in the high 30s and 40s, but maintain adequate gas exchange and sustainable workloads. Under these conditions, tachypnea need not imply discomfort or inadequate ventilator support!

Timing Variables

I:E RATIO

The setting of timing variables in conjunction with V_T and extrinsic PEEP determines the volume range over which lungs are cycled during ventilation. A long T_I, a high T_I/T_{TOT}, and a low mean inspiratory flow all promote ventilation with an inverse I:E ratio. Despite the considerable number of endorsements of inverse-ratio ventilation in ARDS, the beneficial effects of increasing I:E beyond 1:1 on pulmonary gas exchange tends to be marginal, provided that V_T and end-expiratory volumes are held constant.[132] All ventilators provide the option of maintaining lung volume at end inflation through the use of an inspiratory-hold time or pause time that usually is expressed as a percentage of the total cycle time (%T_{TOT}). For the purpose of defining the I:E ratio, the pause time is considered part of the inspiratory machine cycle. Long pause times favor the recruitment of previously collapsed or flooded alveoli and offer a means of shortening expiration independent of rate and mean inspiratory flow ($\dot{V}_I$). Although alveolar recruitment is a desired therapeutic end point in the treatment of patients with edematous lungs, one should at least consider that keeping the lungs expanded at high volumes (and pressures) for some time may damage relatively normal units and may cause adverse hemodynamic effects.

INSPIRATORY FLOW

Most ventilators require that mean $\dot{V}_I$ and its profile be specified. Mean $\dot{V}_I$ is equal to the ratio of V_T to T_I. Therefore, one cannot change flow without affecting at least one of the other timing variables (see Fig. 5-1). It is also important to consider that changing the flow profile from a square wave to a decelerating or sine-wave pattern prolongs T_I in ventilators that require a peak-flow setting. This is so because non–square-wave profiles have a higher peak-to-mean flow ratio; that is, it takes longer to deliver the predefined V_T than in square-wave flow delivery modes. Unless the patient is struggling, mean $\dot{V}_I$ usually is set to no more than 1 L/s during volume-preset ventilation. In patients in whom lung recruitment and oxygenation are the primary therapeutic end points, setting flow (and rate) so that the T_I/T_{TOT}) approximates 0.5 (I:E = 1) tends to achieve the goal. Increasing flow always will raise peak airway pressure, but this need not be of concern if most of the added pressure is dissipated across the endotracheal tube. On the other hand, there is experimental evidence that the rate of lung expansion is a V_T-independent risk factor for lung deformation injury. Although $\dot{V}_I$ is one of the factors that determine the regional distribution of inspired gas,[41] the lung volume–independent effects of flow on pulmonary gas exchange are too unpredictable to warrant general guidelines. Much more important is the realization that the combined effects of flow, volume, and time settings influence the functional residual capacity and the degree of dynamic hyperinflation.[40,133,134]

MEAN EXPIRATORY FLOW: THE HIDDEN VARIABLE

Mean expiratory flow is defined by the ratio of V_T to T_E. $T_E = T_{TOT} - T_I$. $T_{TOT} = 60/f$ (per minute). Because the f_M and the actual f may differ from each other in the assist-control mode (AC), the assumed and the actual T_{TOT} also may differ. Recall from the discussion on rate and timing that T_I is defined by both the set f_M and the set I:E ratio and that T_I remains constant irrespective of the actual rate. In contrast, T_E is affected by the actual breathing rate (f_A): $T_E = 60/f_A - T_I$. Therefore, the choice of volume and timing settings, together with the patient's trigger rate, determine mean expiratory flow. V_T/T_E is the principal ventilator setting-related determinant of dynamic hyperinflation. A patient with airway obstruction and a maximal forced expiratory flow (FEF) of

0.2 L/s in the mid–vital capacity range, and obviously cannot accommodate a V_T/T_E of 0.5 L/s without an increase in end-expiratory lung volume (see "Obstructive Lung Diseases" below).

Minute Ventilation

In general, minute ventilation ($\dot{V}_E$) is not a variable that is set directly by the operator, but it is the consequence of the V_T and rate settings. $\dot{V}_E$ is an important determinant of the body's CO_2 stores and consequently of the arterial CO_2 tension (Pa_{CO_2}):

$$Pa_{CO_2} = \frac{\dot{V}_{CO_2} \times k}{\dot{V}_E(1 - V_D/V_T)} \quad (8)$$

where $\dot{V}_{CO_2}$ = volume of CO_2 produced in liters per minute; V_D/V_T = dead-space-to-tidal-volume ratio, a variable with which the efficiency of the lung as a CO_2 eliminator can be approximated; and $k = 0.863$ and is a constant that scales $\dot{V}_{CO_2}$ and $\dot{V}_E$ to the same temperature and humidity.

If the main goal of mechanical ventilation were to normalize Pa_{CO_2}, then $\dot{V}_E$ would be the most important machine setting. Although a "normal" Pa_{CO_2} is one of the therapeutic end points of mechanical ventilation, at times, normocapnia can be achieved only with high lung inflation volumes and pressures. This is particularly true in patients with ALI because they are often hypermetabolic (high $\dot{V}_{CO_2}$) and in addition suffer from $\dot{V}/\dot{Q}$ mismatch (high V_D/V_T).[135] For these reasons, it is not unusual to encounter patients with ALI whose $\dot{V}_E$ requirements exceed 20 L. In the past, concerns about acid–base status dominated the choice of ventilator settings. In recent years, however, the focus on mechanical lung injury has resulted in a reappraisal of therapeutic priorities that now places the prevention of lung injury above the goal to normalize CO_2 tensions and acid–base status. The corresponding ventilation strategy has been termed *permissive hypercapnia*.[136,137] Permissive hypercapnia means that the physician accepts a Pa_{CO_2} outside the expected or "normal" range in order to minimize the potential for ventilator-induced lung injury. Because such a ventilation strategy runs contrary to the limits set by the chemoresponses of neural ventilatory control mechanisms, permissive hypercapnia usually requires heavy sedation, and sometimes paralysis of the patient. Until recently, most providers considered neuromuscular blockade as an intervention of last resort; several clinical trials, however, by the same team suggest a survival benefit associated with early, time-limited neuromuscular blockade in patients with severe ARDS.[138]

There is a great deal of interest in the consequences of hypercapnia on pulmonary vascular barrier function, signaling mediated by reactive oxygen and nitrogen species, innate immunity, and ultimately, patient survival.[2–7,139–141] The science is fascinating, but it is not sufficiently advanced to derive clinical management decisions. That said, most experts probably would agree that (a) there is no universal pH or P_{CO_2} threshold that mandates a corrective action, (b) the use of bicarbonate buffers to correct respiratory acidemia is unproven, and (c) tracheal gas insufflation generally is effective in reducing Pa_{CO_2} by 10 mm Hg or less.[142,143] Renewed interest in extracorporeal membrane oxygenation as an adjunct to lung-protective mechanical ventilation may well alter the current approach to permissive hypercapnia in years to come.[144] Except for several extracorporeal membrane oxygenation centers with high patient volumes, however, this intervention should be considered experimental at this point in time.[145]

OBSTRUCTIVE LUNG DISEASES

In patients with obstructive lung diseases, there is a reduced capacity for generating expiratory flow. When obstruction is severe enough to cause ventilatory failure, dynamic airway collapse is virtually always present during the expiratory phase of the ventilatory cycle.[10,146] This means that the passive elastic recoil forces of the relaxed respiratory system are large enough to produce maximal expiratory flows in the tidal breathing range. Such patients are prone to dynamic hyperinflation, which may adversely affect circulation,[147] may increase the risk of barotrauma,[148] and can place the diaphragm and inspiratory muscles at a mechanical disadvantage.[149–151] Consequently, the primary therapeutic goal of mechanical ventilation in obstructive lung disease is to minimize the thoracic volume about which the lungs are ventilated. Additional goals vary with the context in which airflow obstruction is observed. Patients with long-standing obstruction from emphysema or chronic bronchitis (unless they are "fighting the ventilator") usually are easy to ventilate and simply may need respiratory muscle rest and a resetting of the CO_2-response threshold to more normal values. These secondary therapeutic objectives are highly controversial. In contrast, patients with acute severe asthma often "fight the ventilator" and therefore often require sedation, neuromuscular blockade, and ventilation with permissive hypercapnia.[136,148] Such patients are prone to neuromuscular insults from glucocorticoids and paralytic agents and may require prolonged mechanical ventilation for weakness long after lung mechanics normalize.[152]

Minimizing Dynamic Hyperinflation

The ventilator management of patients who are prone to dynamic hyperinflation is best understood after a review of the expiratory mechanics of the relaxed respiratory system (see "The Mechanical Determinants of Patient–Ventilator Interactions" above). The key determinants of end-expiratory lung volume in a ventilated patient are the time constant of the respiratory system ($R \times C$) and the V_T/T_E that has been imposed by the ventilator settings.[40] Figure 5-6 underscores these concepts, which are fundamental to formulating a meaningful management plan. If it is assumed that a mechanical inflation of 1 L is initiated from Vrel at a rate of 20 breaths per minute and an I:E ratio of 1:2, the patient

has 2 seconds to exhale. In the example in Figure 5-6, the maximal mean passive expiratory flow that can be achieved in this volume range (between Vrel and Vrel + 1 L) is given by the expiratory flow-volume curve. In this example, the maximal mean flow is only 0.25 L/s. Hence, in the 2 seconds available for expiration, the patient can exhale only half the inspired volume (0.5 L) before the next inflation is initiated by the machine. Thus, the second breath is begun at a lung volume of Vrel + 0.5 L. Maximal mean expiratory flow over the new volume range (Vrel + 0.5 L and Vrel + 1.5 L) is 0.3 L/s. This flow is still insufficient for adequate lung emptying. A new steady state will be achieved only when the increase in lung volume results in a maximal mean expiratory flow of 0.5 L/s, which is equal to the obligatory mean expiratory flow imposed by the ventilator settings.

Dynamic hyperinflation is associated with an increase in alveolar pressure at end expiration. This pressure, also called *intrinsic positive end-expiratory pressure* (PEEPi), is the pressure of the respiratory system at end expiration plus any pressure generated by respiratory muscles.[10,153] In the absence of muscle activity, the degree of dynamic hyperinflation can be inferred from the end-expiratory airway occlusion pressure (PEEPi) and the elastance of the relaxed respiratory system (Ers):

$$\text{Vee} - \text{Vrel} = \text{Ers}/\text{PEEPi} \qquad (9)$$

where Vee is the volume of the lungs at end expiration.

In the presence of muscle activity from active expiration or inspiratory triggering efforts, PEEPi is a meaningless measurement. This limitation also applies to some extent to esophageal pressure-derived estimates of PEEPi. In some ventilators, PEEPi can be estimated at the "press of a button"—by pressing an end-expiratory hold button and waiting until airway opening pressure reaches a steady value. In ventilators in which the timing of end-expiratory occlusions is not automated, the measurement of PEEPi is considerably more difficult.

As illustrated in Figure 5-7, ventilator adjustments designed to minimize dynamic hyperinflation should be geared toward lowering mean expiratory flow (V_T/T_E). In a paralyzed patient with asthma, V_T can be reduced to as little as about 4 mL/kg of predicted body weight, whereas TE is prolonged through increases in mean inspiratory flow (1 to 1.5 L/s), adjustments in the I:E ratio (1:4 to 1:5), and reductions in f_M (approximately 10 breaths per minute). As discussed earlier, such a strategy is likely to produce hypercapnia, but even severe acidemia is usually well tolerated in paralyzed subjects.[154] High inspiratory-flow settings, which are required to prolong T_E, are bound to increase peak Paw and may raise concerns about barotrauma. It must be emphasized, however, that much of this added "resistive pressure" is dissipated along the endotracheal tube and proximal airways and that, on balance, increasing the rate of lung inflation seems less damaging than ventilating asthmatic lungs near TLC. Consistent with this hypothesis, the incidence of barotrauma can be reduced significantly in patients with status asthmaticus when ventilator settings are chosen to maintain peak lung volume within 1.4 L of Vrel.[148,155,156]

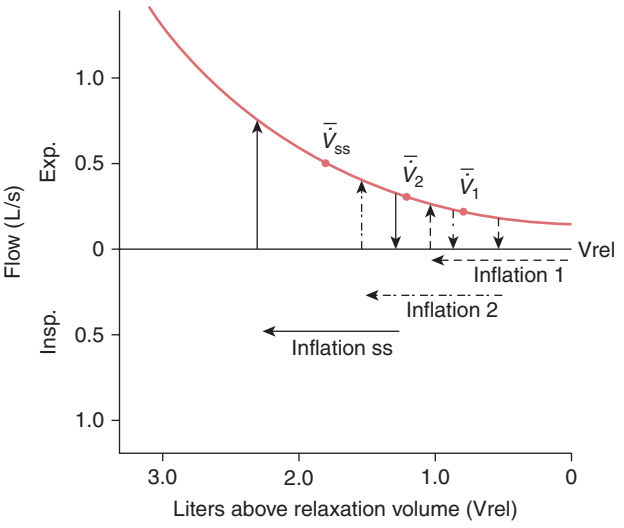

FIGURE 5-7 Diagrammatic demonstration of how insufficient expiratory flow produces dynamic hyperinflation. The *broken horizontal arrow* shows the first breath of 1 L initiated from relaxation volume (Vrel) at a rate of 20 breaths per minute and a T_I/T_{TOT}) of 0.33 (*inflation 1*). The *solid curved line* shows the maximal expiratory flow that can be produced during passive exhalation by the elastic recoil pressure of the system. In the 2 seconds available from expiration, the maximum mean expiratory flow of the first breath ($\dot{\bar{V}}_1$) is only 0.25 L/s. Therefore, only 0.5 L can be exhaled in the 2 seconds before the next inhalation of 1 L is initiated (*inflation 2*). According to the flow–volume relationship, a maximal mean expiratory flow of 0.3 L/s ($\dot{\bar{V}}_1$) can be achieved over this volume range. A steady state, during which inspiratory and expiratory volumes are matched, will be reached only when the maximal mean expiratory flow ($\dot{\bar{V}}_{ss}$) equals 0.5 L/s. (Used, with permission, from Hubmayr, et al. Physiologic approach to mechanical ventilation. *Crit Care Med.* 1990;18:103–113.)

Permissive hypercapnia and neuromuscular blockade are rarely required in patients with ventilatory failure from exacerbations of chronic obstructive lung diseases. Nevertheless, many such patients have respiratory rates in the high teens and low twenties, making it difficult to prolong T_E beyond approximately 2 seconds. This makes it virtually impossible to ventilate these patients near Vrel. Recall that patients with end-stage obstruction may have maximal expiratory flows of 0.2 L/s or less up to volumes near TLC.[146] In the nonparalyzed patient, hypercapnia sets limits to the reductions in V_T; consequently, attempts must be made to reduce the patient's respiratory rate. Sometimes the only way to minimize hyperinflation without having to resort to neuromuscular blockade is through the judicious use of sedatives with the intent of reducing inspiratory efforts until they fail to initiate a machine breath (see "Asynchrony Between the Patient's Effort and Machine-Delivered Breaths" below).

Use of Continuous Positive Airway Pressure

In patients with hypoxic respiratory failure, continuous positive airway pressure (CPAP) is used to raise lung volume to recruit closed and flooded alveoli and to improve oxygenation.

In contrast, the goal of CPAP therapy in patients with obstruction is to minimize inspiratory work.[157] Figure 5-8A shows the potential mechanisms of action of CPAP in obstructed patients schematically. The figure shows the pressure–volume relationships of the relaxed respiratory system and depicts the elastic work (Wel) needed to raise lung volume from end expiration to end inspiration (shaded area) in the presence of dynamic hyperinflation. Wel has two components: (a) work required to halt expiratory flow by counterbalancing respiratory system recoil at end expiration (W related to PEEPi) and (b) work expended during inflation of the lungs and thorax. In theory, the inspiratory work related to PEEPi (darker shaded area) can be provided externally with CPAP equal to PEEPi. As CPAP approaches PEEPi, however, additional hyperinflation may occur.[158] To guard against CPAP-induced worsening of hyperinflation, the physician can monitor peak or end-inflation hold pressure as an indicator of peak lung volume.

Figure 5-8B shows an alternative mechanism by which CPAP may reduce inspiratory Wel. CPAP may result in exhalation below the new Vrel through the recruitment of expiratory muscles.[153,159] Subsequent relaxation of the expiratory muscle inflates the lungs passively back to the new Vrel. Inspiratory muscles are unloaded because the expiratory muscles do part of the inspiratory work. This is depicted by the lighter-shaded area in Figure 5-7B. This mechanism is of limited value in patients with severe obstruction, however, because low maximal flows prevent significant reductions in lung volume below Vrel.

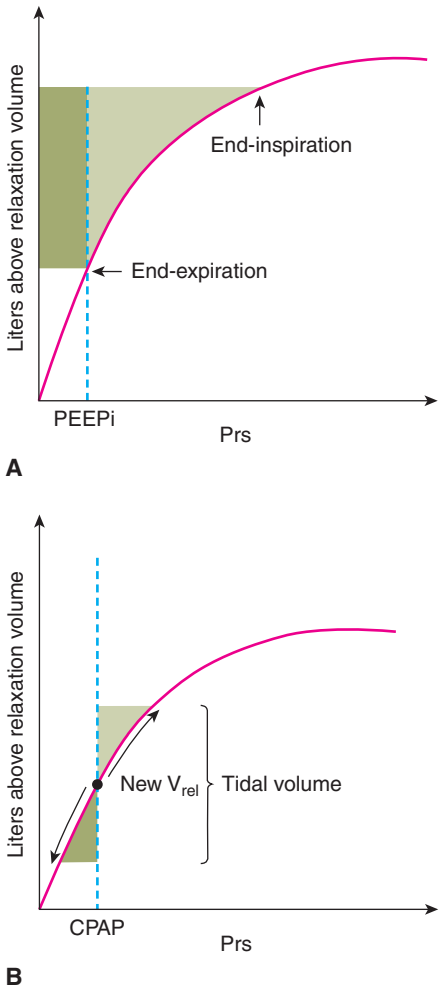

FIGURE 5-8 **A.** Effect of dynamic hyperinflation of elastic inspiratory work. The *solid curve* shows the relationship between the volume above Vrel and the recoil of the respiratory system (Prs). Dynamic hyperinflation exists. Inspiration is now initiated from a volume above Vrel. The increase in lung volume necessitates an increase in the elastic inspiratory work, which may be considered to have two components: work to halt expiratory flow (*darker-shaded area*) and work required to inflate the respiratory system (*lighter-shaded area*). **B.** Effect of CPAP on respiratory work. The *solid curve* is the pressure–volume curve of the respiratory system. With CPAP, a new Vrel is achieved. To conserve inspiratory elastic work, the patient recruits expiratory muscles and exhales below the new Vrel. The elastic work performed by the expiratory muscles is represented by the *darker-shaded area*. Relaxation of the expiratory muscles inflates the lungs back to the new Vrel without inspiratory effort. The inspiratory muscles then increase lung volume further, performing elastic inspiratory work *(lighter-shaded area)*. Hence CPAP reduced the work of the inspiratory muscles by letting the expiratory muscles do part of the inspiratory work. (Used, with permission, from Hubmayr, et al. Physiologic approach to mechanical ventilation. *Crit Care Med.* 1990;18:103–113.)

Ventilatory Pump Failure and Chronic CO_2 Retention

RESTING THE RESPIRATORY MUSCLES

In the 1970s and 1980s, much emphasis was placed on respiratory muscle fatigue as a common cause of ventilatory failure.[160] Experimental evidence that this truly occurs in a clinical setting remains elusive.[161] Without addressing all the pros and cons of minimizing the patient's contribution to inspiratory work, evidence is mounting that mechanical ventilation inhibits respiratory motor output primarily through mechanoreceptive pathways. Studies on volunteers and patients have shown that depending on state and ventilator settings, spontaneous respiratory muscle activity can be abolished, reduced, or entrained to the ventilator.[162–164] Two respiratory control aspects of patient–ventilator interactions deserve particular emphasis. First, volume-preset mechanical ventilation at settings that normalize blood-gas tensions provides no safeguard against excessive respiratory work.[44] This means that ventilating patients in a volume-preset assist-control mode offers no universal guarantee for sufficient respiratory muscle rest. Second, sleeping and obtunded patients are susceptible to PSV setting-induced central apneas.[26–29] This can lead to problems if a clinician feels compelled to increase ventilator support without a mandatory backup in order to reduce the work of breathing at night. If this is done through low IMV backup rates, then apneas may trigger ventilator alarms and cause arousal and sleep fragmentation.[25]

RESETTING THE CHEMOSTAT

It remains controversial whether patients with chronic hypercapnia and complicating acute ventilatory pump failure should be "mechanically" hyperventilated to normocapnia in an attempt to restore normal chemoresponsiveness. Proponents of such a ventilator strategy may argue that CO_2 has negative inotropic effects on respiratory muscles[165] and that experience with nocturnal ventilator assistance suggests that resetting CO_2 responsiveness is feasible in some instances.[166] Opponents argue that maintenance of normocapnia in the presence of lung disease requires a high minute volume, which could represent a fatiguing load on the respiratory muscles. As a general rule, at the time weaning is contemplated, sustainable CO_2 tensions should range between 40 and 50 mm Hg. Patients who are being weaned with CO_2 tensions in the sixties tend not to do well and are severely limited.

APPROACHES TO COMMON POTENTIALLY ADVERSE PATIENT–VENTILATOR INTERACTIONS

Respiratory Alkalosis

In spontaneously breathing normal subjects, $\dot{V}_E$ is closely coupled to Pa_{CO_2} and reflects both rate and V_T responses of the ventilatory control system. In mechanically ventilated subjects, V_T is often preset, thereby uncoupling ventilation from respiratory drive and confining the influence of neural control on the regulation of breathing to machine trigger rate. Consequently, ventilated patients with high intrinsic respiratory rates can have CO_2 tensions significantly below normal. Because associated alkalemia may contribute to arrhythmias and cardiovascular instability,[167] patients often are sedated, and the ventilator settings are adjusted with the goal of raising Pa_{CO_2}. In most instances of ventilator-induced hypocapnia, tachypnea is unrelated to hypoxemia or increased CO_2 drive per se. The causes of tachypnea may be behavioral in origin, as with pain and anxiety syndromes, or neurohumoral in origin, as with circulatory failure or in conjunction with lung and airway inflammation. Because tachypnea and increased ventilatory drive rarely are caused by CO_2 itself, any means of reducing ventilator-delivered volumes is effective in raising Pa_{CO_2}.

Asynchrony Between the Patient's Effort and Machine-Delivered Breaths

Asynchrony between vigorous spontaneous efforts and machine-delivered breaths is often referred to as "fighting the ventilator." Because inspiratory efforts often are followed by active expiration in patients with increased drive, discrepancies between machine and patient T_I cause peak Paw to exceed the alarm (safety) limit (usually set to 45 cm H_2O), resulting in premature termination of inspiratory flow and insufficient ventilation. Although the initial management should be to raise the f_M and increase inspiratory flow up to 1.5 L/s, many patients with asynchrony require sedation and, on rare occasions, neuromuscular blockade. It is of note that the mechanisms of action by which sedatives facilitate mechanical ventilation have not been fully detailed. When "fighting the ventilator" reflects pain and anxiety, their mode of action is easily understood. Not all manifestations of respiratory distress, however, are behavioral in origin. It is not known to what extent various sedatives reduce the magnitude of inspiratory efforts (drive), slow respiratory rate, or facilitate the entrainment of medullary inspiratory pattern generation to the ventilator.

Asynchrony between patient and machine breaths is very common. This is particularly true for patients with high intrinsic respiratory rates, for patients with reduced inspiratory pressure output from low drive or respiratory muscle weakness, for patients with airways obstruction, and when ventilator support results in greater than normal V_T.[13,14,16,153] For example, Figure 5-9 shows pressure and flow tracings of a patient with airways obstruction and hypercapnic ventilatory failure during PSV of 10 and 5 cm H_2O. Arterial O_2 and CO_2 tensions were normal at both settings, and the patient did not appear to be in distress. The small deflections in expiratory flow marked by arrows represent inspiratory efforts (I) during the expiratory phase of the machine cycle. In the presence of dynamic hyperinflation, Pmus must counterbalance the expiratory recoil forces (Pel) before a new machine breath can be triggered. If ΔPmus is less than Pel minus the machine trigger sensitivity, then the inspiratory effort is wasted and does not result in a machine breath. At the PSV setting of 10 cm H_2O in this example, only every third inspiratory effort results in a machine breath (3:1 coupling). The low ΔPmus, the persistence of machine inflation after the cessation of inspiratory effort, and the presence of airways obstruction, with its propensity for dynamic hyperinflation, all contribute to machine trigger failure. Note that the reduction in PSV from 10 cm H_2O to 5 cm H_2O and the lower peak volume account for the reduced number of wasted inspiratory efforts. An awareness of this problem is important because the physician otherwise may attribute an increase in machine rate following reductions in PSV to impending failure or a fatiguing load response.

Because asynchrony between the patient and machine is common, its diagnostic and prognostic significance remains uncertain. When asynchrony impairs ventilator assistance or causes patient discomfort, treatment is required in the form of sedation and adjustments in CPAP, rate, flow, or trigger mode. When "wasted" inspiratory efforts are not perceived as uncomfortable, however, it is not clear that adjustments in ventilator settings are warranted. After all, increases in machine rate to match the rate of patient efforts may cause worsening dynamic hyperinflation and may compromise circulation. Alternatively, the use of large amounts of

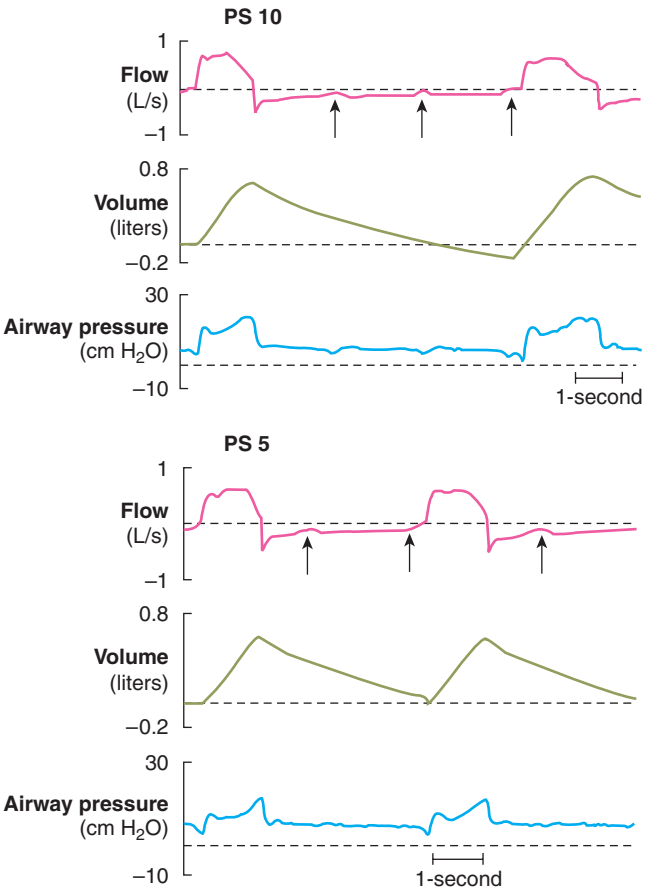

FIGURE 5-9 Flow, volume, and pressure tracings of a patient recorded during PSV with 10 cm H_2O (*upper panel*) and 5 cm H_2O (*lower panel*). Each *arrow* indicates an inspiratory effort. See the text for a further explanation. (Used, with permission, from Hubmayr RD. Coordinación de la musculatura respiratoria durante la desconexión de la ventilación mecánica en pacientes con enfermedades neurológicas (Respiratory muscle coordination during the weaning of patients with neurological diseases). sedatives to assure synchrony cannot be considered harmless.[168] Patients who have been heavily sedated, but whose lung function is beginning to recover, can be particularly challenging insofar as their spontaneous tidal volumes often exceed "safe" levels. Consequently, imposing lung-protective V_T settings is commonly met with "double triggering," in effect raising machine delivered V_T to 12 mL/kg predicted body weight. Because delirium and impaired airway protective reflexes often preclude extubation, the provider is faced with the difficult decision, whether to deepen sedation, institute neuromuscular blockade, reduce flow (i.e., prolong machine T_I) at the cost of flow-starving the patient and thereby increase the patient's work of breathing, or to ignore the high tidal volumes as a transient sedation/narcotics side effect. Although each of these options is defensible on theoretical grounds, most providers will slow deep breaths if liberation from endotracheal intubation is judged imminent.

ASSIST-CONTROL VENTILATION

6

Jordi Mancebo

Volume assist-control ventilation (ACV) is a ventilator mode in which the machine delivers the same tidal volume during every inspiration, whether initiated by the ventilator or by the patient. This occurs regardless of the mechanical load on the respiratory system and no matter how strenuous or feeble the inspiratory muscle effort. Current data indicate that ACV is still the most frequently used mode in intensive care units (ICUs).[1] Nowadays, the main reason for patients being admitted to an ICU is the need for mechanical ventilation,[2] and the most common reason to initiate mechanical ventilation is acute respiratory failure.[1,3,4] Approximately 60% of intubated, ventilated patients receive ACV.[5] This percentage is similar for patients ventilated for decompensated chronic obstructive pulmonary disease (COPD),[5] and even higher for those ventilated for acute respiratory distress syndrome (ARDS).[6]

BASIC PRINCIPLES

In ACV, mechanical breaths can be triggered by the ventilator or the patient. With the former, triggering occurs when a certain time has elapsed after the previous inspiration if the patient fails to make a new inspiratory muscle effort (Fig. 6-1). The frequency at which time triggering takes place is determined by the backup rate set on the ventilator. When patients trigger a mechanical breath, their spontaneous inspiratory effort is sensed by the machine, usually as a change in airway pressure or airflow. When such a change crosses the trigger-sensitivity threshold, the ventilator delivers the preset tidal volume. Chapter 3 provides a detailed explanation regarding the working principles of ventilators.

Mechanical breaths have precise mechanisms for being initiated (trigger variable), sustained (limit variable), and stopped (cycle variable). These are known as phase *variables*.[7] In ACV, the mechanical breaths are limited by volume and/or flow and cycled by volume or time. The inspiratory flow-shape delivery is usually a square (constant) during ACV, although some ventilators also permit sinusoidal and/or ramp (ascending or descending) gas flows.

PHYSIOLOGIC EFFECTS

Mechanical ventilation is a lifesaving supportive treatment that improves gas exchange and decreases the mechanical workload of the respiratory muscles while buying time for the patient to recover. The way mechanical ventilation is used is central to its short-term and long-term effects. Ventilator settings are a major determinant of the

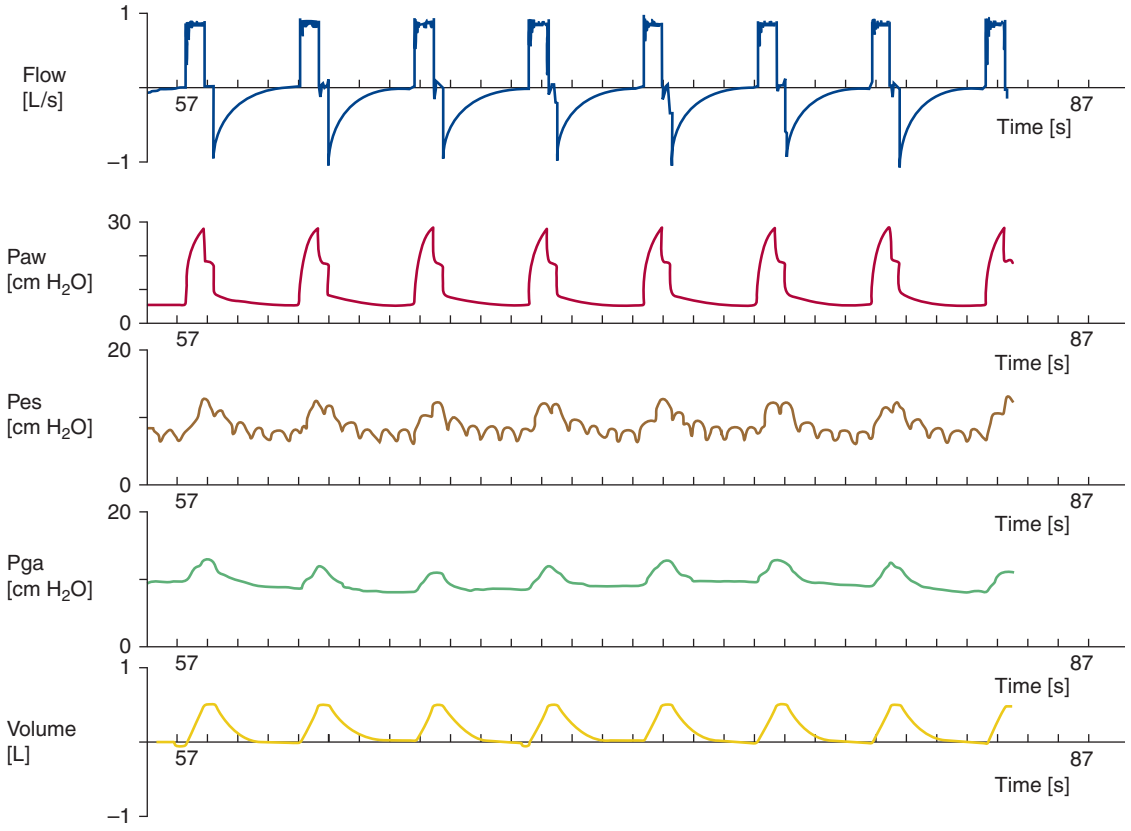

FIGURE 6-1 (*From top to bottom*) Tracings of airflow (*FLOW*), airway pressure (*Paw*), esophageal pressure (*Pes*), gastric pressure (*Pga*), and tidal volume (*VOLUME*). Each mark on the time axis denotes 1 second. These recordings were obtained in a passively ventilated patient. Each breath is time-triggered.

physiologic and clinical effects of ACV. Chapters 36 and 37 address the physiologic effects of ACV on gas exchange and cardiovascular function.

In every assisted mode, the ventilator responds to a patient's inspiratory effort. Both pressure-triggering and flow-triggering systems of modern ventilators offer high performance, and the differences are small in terms of the added work of breathing. A bench study comparing the performance of new-generation ventilators versus old-generation ventilators revealed that triggering function, pressurization capacity, and expiratory resistance are globally similar, thus suggesting that a technological ceiling has been reached.[8]

Inspiratory Muscle Effort

Marini et al[9] reported that decreases in trigger sensitivity increased the work of breathing. Although decreasing the inspiratory flow rate from 100 to 80 L/min did not affect the effort to breathe at a moderate minute ventilation (12 L/min), it increased the work expenditure significantly when the minute ventilation was doubled.[9] When inspiratory flow was reduced to 40 L/min and thus did not match the subject's demand, the work of breathing increased by 50%. Marini et al[10] later analyzed the inspiratory work at two inspiratory flow settings, 60 and 100 L/min, in twenty patients. Tidal volume was unchanged. The patients' work per liter of ventilation at both ACV inspiratory flow settings represented approximately 60% of the work dissipated during spontaneous breathing. Dead space was added in half the patients and led to marked increases in muscle effort. Patients' work of breathing did not correlate with minute ventilation, although it was highly correlated with respiratory drive and muscle strength. A decrease in inspiratory flow to 40 L/min (in five patients) led not only to an increase in effort but also to premature expiratory efforts, encroaching on the ventilator's inspiratory time. In total, these data demonstrated that inspiratory muscle effort persists throughout the inflation and that a substantial amount of muscle work is dissipated during ACV.

Ward et al[11] analyzed the inspiratory muscle effort at several inspiratory flow rates between 25 and 65 L/min and confirmed the findings by Marini et al. Cinella et al[12] compared ACV and assist pressure-controlled ventilation (PCV) and used two tidal volume settings (12 and 8 mL/kg) with an inspiratory time of 1 second and no end-inspiratory pause. At high tidal volumes, no differences were observed between the two modes in terms of breathing pattern or

indices of inspiratory muscle effort. When a tidal volume of 8 mL/kg was used (and thus inspiratory flow decreased with ACV), differences arose. Respiratory rate and occlusion pressure (a measure of respiratory motor output) tended to be higher with ACV, and indexes of inspiratory muscle effort showed a marked increase as compared with PCV. In the second part of this study,[12] the authors compared the effects of ACV and assist PCV using a fixed tidal volume (8 mL/kg) and two different settings for inspiratory time: 1 second and 0.6 second with no pause. With the longer inspiratory time, the differences were the same as stated previously. When inspiratory time was reduced and thus inspiratory flow increased during ACV, the differences between the modes virtually vanished. The study showed that both modes unloaded the respiratory muscles equally, provided that the inspiratory flow rate was set appropriately during ACV. These data confirm the importance of maintaining an inspiratory flow rate high enough to satisfactorily unload the respiratory muscles and also point out that moderate to low tidal-volume ventilation using high flow rates results in a short inspiratory time, which may not be optimal for some patients. The duration of diaphragmatic contraction was unaffected by the ventilator settings and always was shorter than 1 second.[12] Thus, it appears that the effects of high airflow settings on muscle unloading are mainly exerted at the very beginning of inspiratory efforts. Similar results were obtained by McIntyre et al[13] when comparing ACV with a pressure-limited volume-guaranteed dual mode. These authors, however, suggested that the pressure-limited breaths could reduce patient–ventilator flow dyssynchrony. These physiologic effects were confirmed in a subsequent study performed by the same group.[14]

Inspiratory Flow Settings and Breathing Pattern

A number of investigators have shown that patients[12,15–17] and healthy individuals[18,19] react to an increase in inspiratory flow with an increase in respiratory rate when tidal volume is kept constant. In these circumstances, the imposed ventilator inspiratory time shortens as flow increases. This leads to a decrease in neural inspiratory time. When tidal volume is increased by lengthening the duration of inspiratory flow, neural expiratory time increases, and respiratory rate tends to decrease. These changes have opposite effects on respiratory rate. The mechanisms explaining these responses are complex and include the Hering-Breuer reflex (inhibits inspiration and prolongs expiration), reflexes mediated by vagal mechanoreceptors, and perhaps consciousness-mediated reflexes.[20–22]

Airflow-induced changes in breathing pattern carry important clinical implications, especially in patients with dynamic hyperinflation. Because inspiratory time is made up of the time of flow delivery and inspiratory pause, Laghi et al[17] hypothesized that a decrease in ventilator inflation time would cause an increase in rate. In ten noninvasively ventilated stable patients with an obstructive airway disease, the investigators increased flow at constant tidal volume and decreased the inspiratory pause, keeping inspiratory flow and tidal volume constant. When inspiratory time was decreased (by increasing flow from 30 to 90 L/min), respiratory rate and expiratory time increased significantly. Intrinsic positive end-expiratory pressure (PEEP) diminished significantly despite the increase in respiratory rate. When inspiratory time was decreased by shortening the inspiratory pause, both respiratory frequency and expiratory time increased significantly. Again, intrinsic PEEP decreased significantly. Additionally, the higher inspiratory flow rates also decreased respiratory drive and inspiratory effort. These results suggest that imposed ventilator inspiratory time duration determines the respiratory rate and that the strategies that reduce ventilator inspiratory time, although accompanied by an increase in respiratory rate, also prolong the time for exhalation, thus decreasing intrinsic PEEP.

Respiratory Muscles

Mechanical ventilation per se can induce respiratory muscle damage,[23–25] and patients appear to exhibit diaphragmatic weakness after a period of mechanical ventilation.[26] The term *ventilator-induced diaphragm dysfunction* was coined to express the decrease in the force-generating capacity of the diaphragm that results after a period of passive controlled mechanical ventilation.[27] Le Bourdellès et al[28] showed that anesthetized, passively ventilated rats had lower diaphragmatic weight and a reduction in their force-generating capacity in comparison with spontaneously breathing control animals. Anzueto et al[29] studied sedated, paralyzed baboons under ACV for 11 days. Endurance time decreased over this period, and transdiaphragmatic pressure diminished by 25%, suggesting that the duration of passive ACV is also a relevant factor.

Sassoon et al[30] showed that 3 days of passive ventilation in rabbits led to a progressive decrease in the force-generating capacity of the diaphragm in comparison with control animals who received the same total amounts of sedatives but were breathing spontaneously. They also showed that significant diaphragmatic myofibril damage had occurred. Other authors have reported similar data.[31,32] Several investigators[33–36] have begun to elucidate the complex cellular, molecular, and gene expression mechanisms underlying passive ventilation-induced respiratory muscle damage. Such mechanisms include, among others, decreased protein synthesis, increased proteolysis, oxidative stress, and alterations in cytosol calcium metabolism.[27]

Subsequent findings by Sassoon et al[37] carry important clinical implications. The authors found that ACV, as compared with passive ACV, can attenuate markedly the decrease in diaphragmatic force induced by total inactivity in rabbits. Another investigation with clinical ramifications has shown that passive ACV improves diaphragmatic force production in rats challenged with intravascular endotoxin

as compared with equally challenged spontaneously breathing animals.[38]

An interesting issue is the combined effects of certain drugs (e.g., corticosteroids) on diaphragmatic function during passive ventilation. Maes et al[39] studied the effects of corticosteroid administration in rats (a single injection of 80 mg methylprednisolone/kg) on diaphragm function. The animals were ventilated with passive ACV for 24 hours. The main finding of this investigation was that a very high dose of corticosteroids protected the diaphragm against the deleterious effects of passive ACV. The diaphragm of treated animals maintained force, fiber dimension, and myogenin protein levels, whereas the diaphragm of nontreated animals exhibited a reduction in force, fiber atrophy, and reduced myogenin expression. The mechanism of this protective effect is the avoidance of muscle proteolysis, probably mediated by calpain. In a similar study with rabbits, Sassoon et al[40] showed that very high doses of methylprednisolone (60 mg/kg/day for 2 days) have no additive effects on diaphragmatic dysfunction induced by passive ACV. The same doses administered during ACV, however, produced a significant decrease in the maximal tetanic force elicited by the diaphragm.[40] Thus, the effects of high-dose methylprednisolone on diaphragmatic function depend on the mode of ventilation: if the muscle contracts, the effects are injurious, whereas if the muscle is passive, the effects are protective or neutral.

Important data have appeared in the last few years regarding the effects of ACV in human subjects. Levine et al[41] showed that complete diaphragmatic inactivity for 18 to 69 hours (mean: 34 hours) in brain-dead subjects resulted in marked atrophy of slow and fast-twitch fibers of the diaphragm as compared to matched controls (individuals who were ventilated for a scheduled surgery for 2 to 3 hours). The major mechanism explaining the diaphragmatic atrophy was increased muscle proteolysis. Peripheral skeletal muscles (pectoralis major) did not show histologic findings of atrophy. A subsequent study by Hussain et al,[42] conducted in humans and using a similar design, extended the findings and provided data suggesting that both protein synthesis and breakdown are involved in the diaphragmatic dysfunction.

Jaber et al[43] have investigated the time course of the decrease in diaphragm contractility in humans under passive ACV. The authors observed a progressive loss in diaphragmatic force, as reflected by measurements of tracheal pressure. The tracheal twitch pressure significantly decreased over time: mean reduction was 32% after 6 days of passive ventilation. The degree of muscle injury as detected by electron microscopy was significantly correlated with the duration of passive ACV. Again, upregulation of proteolytic systems played a major role in the ventilator-induced diaphragmatic injury induced by mechanical ventilation.

If passive ventilation is one extreme, the other is a fatiguing loading. Both extremes are harmful to the respiratory muscles. Normal subjects submitted to inspiratory-resistive loading up to a fatiguing threshold showed a decrease in diaphragmatic contractility lasting for at least 24 hours.[44] Jiang et al[45] showed diaphragmatic injury and inflammation at 3 days after a 90-minute period of acute moderate and high inspiratory-resistive loading in rabbits. The same group[46] subsequently reported a marked decrease in the force production of the diaphragm at 3 days after high inspiratory-resistive loading over the same time. Such stress also induces selective upregulation of a number of cytokines in the diaphragmatic fibers, and eventually may lead to systemic effects.[47,48] Toumpanakis et al[49] have further analyzed the effects of inspiratory resistive breathing in rat lungs. The animals received 100% oxygen during the experiments. The authors showed that after 3 to 6 hours of stressful breathing, the alveolar–capillary membrane permeability increased, the static lung compliance decreased, and significant lung inflammation developed, as manifested by changes in histology (appearance of interstitial and intraalveolar neutrophils) and cytokine expression (increase in tumor necrosis factor and interleukin levels in lung tissue).

Sleep

Research studies conducted in patients admitted to an ICU reveal that patients experience major sleep disturbances in terms of quantity and quality.[50–52] The acuity of illness, the use of medications (such as sedatives or opioids), caregiver interventions, and environmental elements are contributing factors.[50] Gabor et al[53] indicated that only 30% of sleep disruption in ventilated patients was attributable to elements of the ICU environment.

Parthasarathy and Tobin[54] sought to determine if sleep quality was influenced by the mode of ventilation. They hypothesized that sleep is more fragmented during pressure-support ventilation (PSV) as compared to ACV because of the development of central apneas. Eleven patients were ventilated with ACV at tidal volumes of 8 mL/kg, inspiratory flow rate 1 L/s, and a backup rate of four breaths below the total assisted rate. PSV was set to deliver the same tidal volume. Patients also received PSV with 100 mL of added dead space. During wakefulness, respiratory rate was similar with the two modes. During sleep, minute ventilation fell more during PSV than during ACV. Sleep fragmentation, measured as the number of arousals and awakenings, was significantly greater during PSV than during ACV (seventy-nine versus fifty-four events per hour). Six patients had apneas while receiving PSV, whereas none had apneas while receiving ACV. The percentage of patients who had congestive heart failure was significantly higher among patients exhibiting apneas than among patients free of apneas (83% vs. 20%). Minute ventilation during sleep was greater in patients who did not develop apneas, suggesting that increased drive protects against the development of apneas. The addition of dead space reduced the number

of apneas markedly: from fifty-four to four apneas per hour. These data suggest that settings that generate overassistance promote the occurrence of apneas during assisted ventilation.

Cabello et al[55] conducted a study in fifteen ventilator-dependent patients and compared three modes: ACV, PSV, and automatically adjusted PSV. The hypothesis was that PSV settings adjusted to patient ventilatory needs could improve sleep quality as compared to ACV. During ACV, settings were adjusted to provide a tidal volume of 8 mL/kg with a constant inspiratory flow of 1 L/s (and backup rate at 10 breaths/min). In the second arm, PSV was adjusted by clinicians to obtain a tidal volume of 6 to 8 mL/kg and a respiratory rate below 35 breaths/min. In the third arm, PSV was automatically regulated in a way that continuously adjusted the level of support so as to keep the patients within a comfort zone.[56] PEEP was kept constant at 5 cm H_2O, and patients were free of sedative drugs. The median tidal volumes (390 to 500 mL), respiratory rates (20 to 21 breaths/min), and minute ventilation did not differ between the three modes. Nine patients exhibited sleep apneas, and ten displayed ineffective efforts. The number of ineffective efforts per hour of sleep did not differ among the modes (mean: six to sixteen ineffective efforts per hour). The number of apneas was similar between the two PSV modalities (five to seven apneas per hour of sleep). Sleep fragmentation (arousals and awakenings per hour), sleep architecture, and sleep quantity did not differ among the modes. One explanation for the difference with the findings in the study by Parthasarathy and Tobin is that tidal volumes and minute ventilation were similar for all modes in the study of Cabello et al. The relative infrequency of ineffective efforts and apneas in this study suggests that patients were not overassisted. Together these data indicate that excessive ventilator support is central in the development of sleep fragmentation.

The clinical consequences of these sleep abnormalities are not known. Researchers have noted that sleep deprivation may generate immune suppression, loss of circadian hormonal secretion (melatonin and cortisol), profoundly alter respiratory muscles endurance and neurocognitive function, and modify the normal physiologic responses to hypoxia and hypercapnia.[51,52] Whether the sleep disturbances are a marker of brain dysfunction related to critical illness or represent a specific syndrome with an independent effect on outcomes is not known.

RATIONALE, ADVANTAGES, AND LIMITATIONS

The main reasons for using ACV are to unload the inspiratory muscles and to improve gas exchange. ACV permits complete respiratory muscle rest, which is usually the case when patients do not trigger the machine, and a variable degree of respiratory muscle work. ACV commonly achieves an improvement in gas exchange, and only a minority of ventilated patients die because of refractory hypoxemia.

During passive ventilation with ACV at a constant inspiratory flow, fundamental variables related to respiratory system mechanics, such as tidal volume, inspiratory flow, peak airway pressure, end-inspiratory plateau airway pressure, and total PEEP (the sum of external PEEP and intrinsic PEEP, if any), are measured easily (Fig. 6-2). These variables allow calculation of resistance, compliance, and the time constant of the respiratory system.

If airway pressure tracings are obtained during passive ACV as well as during patient-triggered ACV at the same settings, we can estimate a patient's work of breathing simply by superimposing the two tracings (Fig. 6-3). When patients are triggering the breaths, the end-inspiratory plateau pressure also can be influenced by the amount and duration of inspiratory muscle effort (Fig. 6-4). When mechanical breaths are triggered by the patient, the scooping on the airway pressure profile allows indirect evaluation of patient–ventilator interaction (Fig. 6-5). Such capabilities are unique to ACV. These capabilities represent a major advantage because they enable one to properly understand respiratory system mechanics and patient–ventilator interactions.

A major limitation of ACV is that it imposes a number of constraints on the variability of the patient's breathing pattern: inspiratory flow, inspiratory time, and backup rate. Adjusting ACV settings may be more complex than with pressure-limited modes. One reason is that manufacturers employ different algorithms for implementing the delivery of a tidal breath. The other reason is that during ACV it is difficult to pinpoint the inspiratory flow rate and tidal volume settings that are optimal for an individual patient. Some settings are almost impossible to achieve with ACV. For instance, the simultaneous adjustment of a moderate tidal volume at a high inspiratory flow rate will produce a short machine inspiratory time, which, under certain circumstances, may not match the patient's neural inspiratory time properly. In addition, the patient's varying ventilatory needs and the change in the mechanical properties of the respiratory system over the course of ventilation imply that periods of underassist are likely to be interspersed with periods of overassist (Fig. 6-6). These problems, however, are common to most ventilator modes.

INDICATIONS AND CONTRAINDICATIONS

ACV is indicated when a life-threatening physiologic derangement in gas exchange or cardiovascular dynamics has not been corrected by other means. Clinical manifestations of severely increased work of breathing or impending respiratory arrest are indications for instituting ACV.[57] Although there appear to be no absolute contraindications

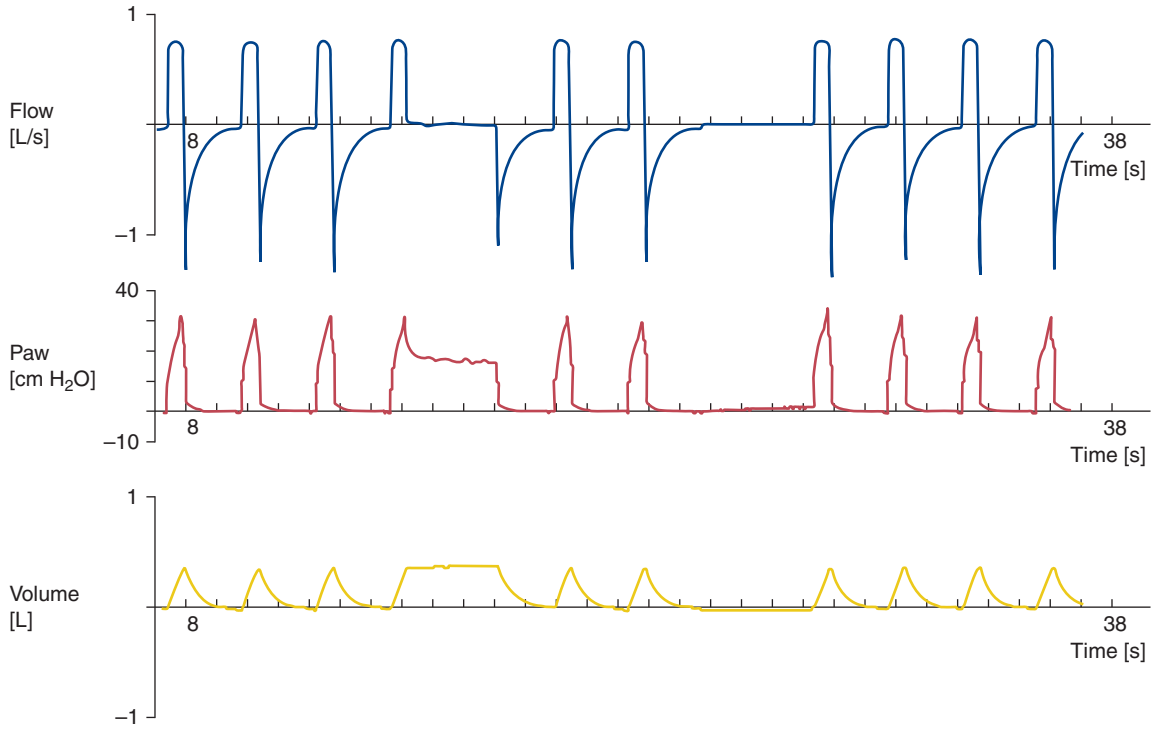

FIGURE 6-2 (*From top to bottom*) Tracings of airflow (*FLOW*), airway pressure (*Paw*), and tidal volume (*VOLUME*). Each mark on the time axis denotes 1 second. Note that expiratory flow is interrupted by the beginning of each breath, thus heralding dynamic hyperinflation. A prolonged end-inspiratory occlusion (fourth breath from the left) enables measurement of the static recoil pressure of the respiratory system. A prolonged end-expiratory occlusion (sixth breath from the left) illustrates the presence of intrinsic PEEP (3 cm H_2O). These values, together with peak airway pressure, inspiratory flow rate, and tidal volume, enable the calculation of resistance, compliance, and respiratory system time constant in passively ventilated patients.

to ACV, some of its shortcomings may prompt physicians to use other modes.

COMPARISON WITH OTHER MODES

Pressure-Controlled Ventilation, Airway Pressure Release, and Adaptive Support Ventilation in Acute Respiratory Failure Patients

During PCV, the ventilator functions as a pressure controller, and operates in a pressure-limited and time-cycled mode. With PCV, delivery of airflow and tidal volume changes according to the mechanical impedance of the respiratory system and patient inspiratory muscle effort. This mechanism implies that every increase in transpulmonary pressure is accompanied by an increase in tidal volume. Numerous studies[58–68] have compared the effects of PCV and ACV. In general, these studies included a limited number of patients and different adjustments were used. Taken together, no major differences in terms of gas exchange and major outcomes emerge between ACV and PCV.

Two studies[69,70] have analyzed outcomes between ACV and airway pressure release ventilation (APRV). APRV is similar to PCV except that it allows spontaneous breathing (in the form of continuous positive airway pressure) at any part of the ventilatory cycle. The study by Maxwell et al[70] was carried out in trauma patients: thirty-two received ACV and thirty-one were ventilated with APRV. Tidal volumes did not differ between the modes and, although patients ventilated with APRV had higher mean airway pressures, the Pa_{O_2}/FI_{O_2} ratios were similar. Days of mechanical ventilation, ICU length of stay, incidence of pneumothoraces, need for tracheostomy, and ventilator-associated pneumonia rates did not differ between the two modes. Sedative doses were similar between the modes and mortality was almost identical (approximately 6.4% in each group).

González et al[69] compared outcomes of assorted patients receiving ACV ($n = 234$) and APRV ($n = 234$) as a primary mode. The data were obtained from an observational multicenter cohort study, and a case-matched analysis on propensity score was performed. No differences in relevant clinical outcomes were detected between the modes: days of mechanical ventilation, ICU and hospital length of stay, reintubation rates, and hospital mortality. Surprisingly, the tracheostomy rate was significantly higher in the patients

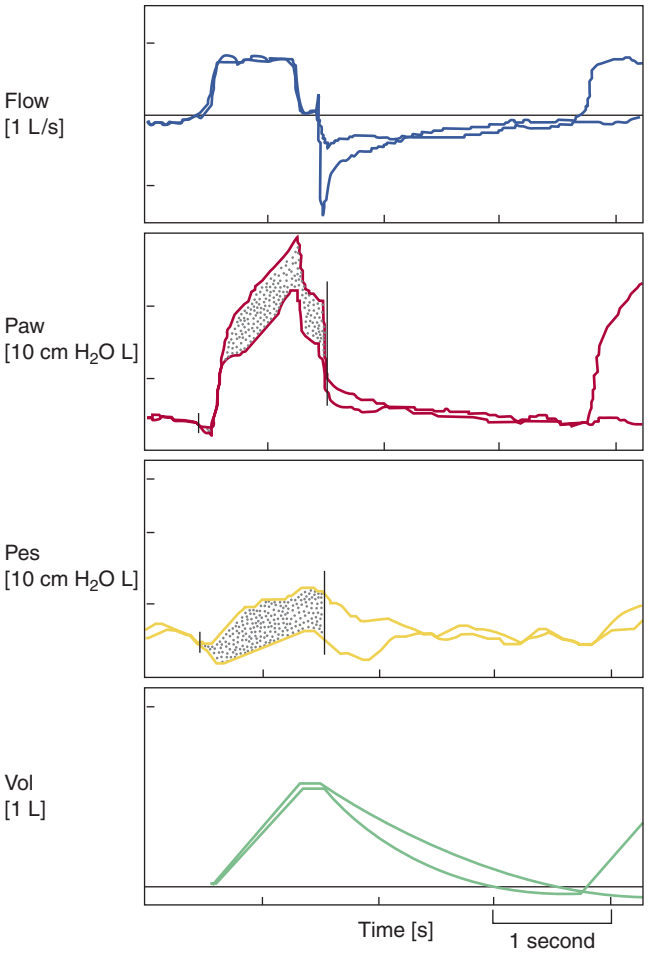

FIGURE 6-3 (*From top to bottom*) Tracings of airflow (*FLOW*), airway pressure (*Paw*), esophageal pressure (*Pes*), and tidal volume (*VOL*). Each mark on the time axis denotes 1 second. The tracings in each panel were obtained from the same individual at two different times. They were then superimposed. Ventilator settings were identical. The vertical line on the airflow, airway pressure, and esophageal pressure tracings indicates the end of ventilator's total inspiratory time. The *dotted areas* within the airway pressure and esophageal pressure tracings are identical. The *dotted areas* denote the amount of inspiratory muscle effort that the patient made during the assisted breath.

who were ventilated with APRV (20%) versus ACV (11%). Tidal volumes were similar (approximately 9 mL/kg) in both groups. The partial pressure of arterial oxygen (Pa_{O_2})-to-fractional inspired oxygen concentration (FI_{O_2}) ratio was significantly higher with APRV than with ACV (263 vs. 232 mm Hg), probably because expiratory pressure was lower with ACV (3 vs. 7 cm H_2O). The dominant factor associated with the use of this mode was geography: 196 of 234 patients receiving APRV were located in German ICUs.

Chung et al[71] compared high-frequency percussive ventilation and ACV in patients with acute respiratory failure secondary to severe burns. High-frequency percussion is pressure-limited and time-cycled at high frequency (above 300 breaths/min) and is superimposed on a biphasic inspiratory and expiratory pressure cycle set at a normal rate (approximately 10 to 15 cycles/min). A total of sixty-two patients were randomized—thirty-one to ACV and thirty-one to percussive ventilation. Patients treated with ACV received fixed tidal volumes (6 mL/kg) and PEEP levels were set according to an algorithm. Mean airway pressure was virtually identical with the two modes and a significantly better Pa_{O_2}-to-FI_{O_2} ratio was observed in the percussive ventilation group over the first 3 days. Sedation requirements and ventilator-free days did not differ between the groups. Although rescue ventilator therapy (29% vs. 6%) and barotrauma (13% vs. 0%) were more frequent during ACV as compared to percussive ventilation, no differences in mortality rates were observed between the two groups (19% each).

Adaptive-support ventilation is a closed-loop mode that selects a target ventilatory pattern based on patient weight, minimum minute volume, and a pressure limit. The ventilatory pattern is selected to minimize the total work of inspiration. Two studies have compared adaptive support ventilation with ACV. Sulemanji et al[72] conducted a bench test with different experimental scenarios of lung mechanics, PEEP levels and body weights. Target volume during ACV was 6 mL/kg and inspiratory time was 0.8 second. Adaptive-support ventilation was able to maintain a lower plateau pressure compared to ACV in settings of low compliance, high PEEP, and high minute volume. This resulted from the expected decrease in tidal volume during adaptive-support ventilation when facing a condition of high impedance, especially low compliance. During adaptive support ventilation, the plateau pressure was exceeded by approximately 2 cm H_2O, whereas in ACV the plateau pressure was exceeded by up to 10 cm H_2O.

This behavior of adaptive-support ventilation has been also reproduced in passively ventilated patients.[73,74] In the study of Iotti et al,[74] ACV (as set by the attending clinician) was compared to adaptive support ventilation (set to obtain the same minute ventilation). A total of eighty-eight patients were studied: twenty-two with no obvious lung disease, thirty-six with a restrictive disease, and thirty with obstructive disease. Adaptive support ventilation achieved a lower respiratory rate (17 vs. 19 breaths/min) and larger tidal volume than during ACV (9.4 vs. 8.4 mL/kg). Compared to ACV, adaptive support ventilation achieved a slight decrease in partial pressure of arterial carbon dioxide (Pa_{CO_2}) (from 41.6 to 40 mm Hg) and lower machine work (from 17.7 Joules/L to 14.6 Joules/L) when Pa_{CO_2} was kept constant. Compared to ACV, the obstructed patients received larger tidal volumes at lower respiratory rates. In restrictive patients, adaptive-support ventilation selected the lowest tidal volume (4.8 mL/kg) in patients with the shortest time constant (low compliance) and the highest tidal volume (10 mL/kg) in patients with normal time constant (near-normal compliance). These data suggest that adaptive support ventilation in passively ventilated patients is at least as efficient as ACV in terms of alveolar ventilation and work of breathing, and it is able to provide

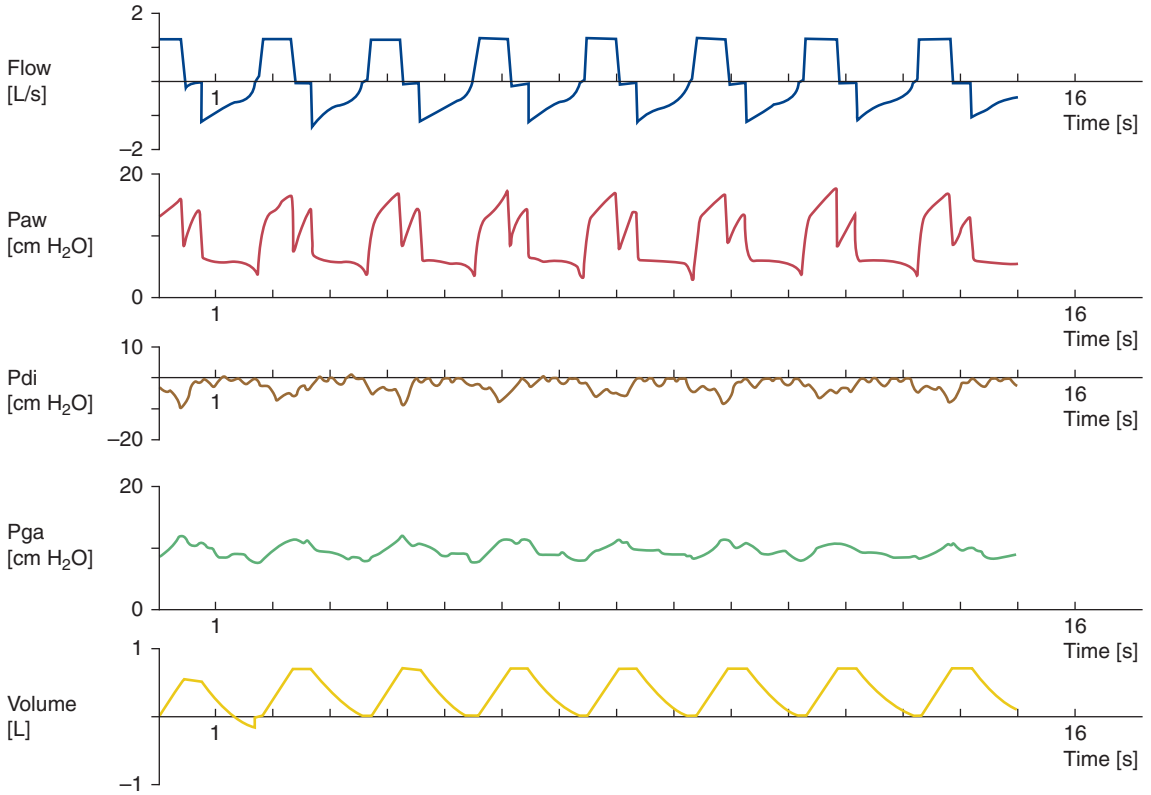

FIGURE 6-4 (*From top to bottom*) Tracings of airflow (*FLOW*), airway pressure (*Paw*), transdiaphragmatic pressure (*Pdi*), gastric pressure (*Pga*), and tidal volume (*VOLUME*). Each mark on the time axis denotes 1 second. The time of inspiratory flow is shorter than the duration of diaphragmatic contraction. This patient did not exhibit expiratory muscle recruitment, as indicated by the gastric pressure recording. Inspiratory muscles relax at the end of the inspiratory pause time, thus explaining the "M" wave shape on the airway pressure recording.

a breathing pattern tailored to the individual respiratory system mechanics.

Intermittent Mandatory Ventilation

Marini et al[75] compared ACV with intermittent mandatory ventilation (IMV) to provide 80%, 60%, 40%, 20%, and 0% of the ventilation observed during ACV (100% IMV). Tidal volume and flow settings during ACV were 10 mL/kg and 1 L/s, respectively, and average respiratory rate was 23 breaths/min. The total breathing frequency and spontaneous tidal volume increased as far as IMV assistance was decreased. Duration of inspiratory effort during assisted breaths was similar across the different IMV levels. At all levels of support, patients performed a substantial effort during the machine-assisted breaths that increased progressively as IMV assistance was withdrawn.

These data emphasize several points. Machine assistance does not suppress patient effort. There is a poor adaptation to ventilator assistance on a breath-by-breath basis, suggesting that the intensity of muscle effort is fixed before cycle initiation. Off-switching of inspiratory muscle contraction is independent of volume and flow ventilator settings. Viale et al[76] showed a rapid and gradual downregulation of inspiratory muscle effort and respiratory drive in ventilator-dependent patients with COPD, when they were switched from spontaneous unassisted breathing to PSV. This downregulation needed 6 to 8 breaths to achieve total stability, and the authors speculated that possible mechanisms explaining the gradual response were changes in Pa_{CO_2} and vagal stimulation.[76]

Leung et al[77] compared ACV, IMV (80%, 60%, 40%, and 20% levels of assist), PSV (100%, 80%, 60%, 40%, and 20% levels of assist), and a combination of IMV with PSV of 10 cm H_2O. No PEEP was used. Average tidal volume and respiratory rate during ACV were 600 mL and 17 breaths/min, respectively. The observed rate during ACV was considered equivalent to IMV 100%. PSV 100% (average: 17 cm H_2O) was the level of assistance that resulted in the same tidal volume as during ACV; this led to a respiratory rate of 16 breaths/min. Nontriggering attempts occurred with every mode and were most numerous at the highest levels of assistance. At 100% levels of assistance, the inspiratory effort and dyspnea sensation were similar among the modes, and both increased progressively when assistance was decreased. When the total inspiratory effort was partitioned between its triggering and posttriggering

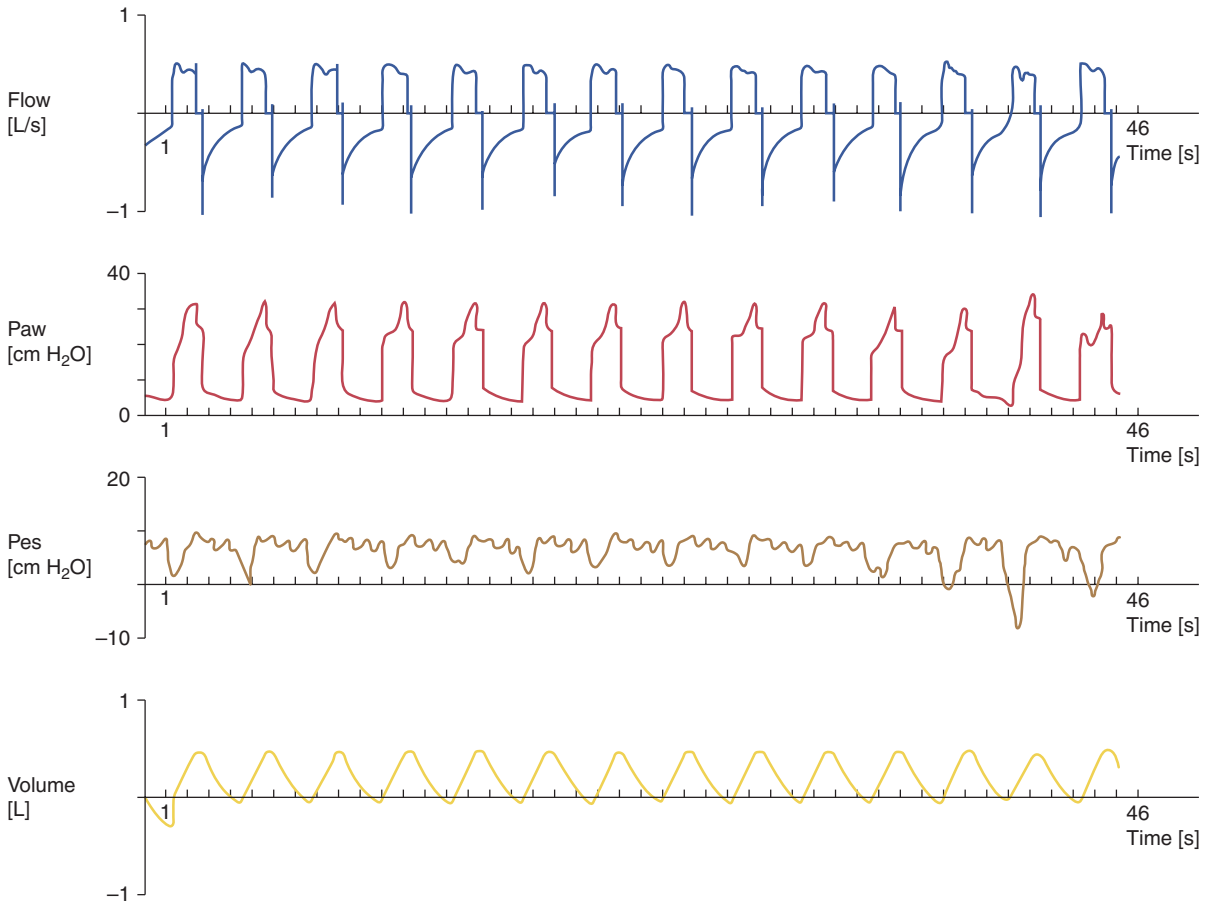

FIGURE 6-5 (*From top to bottom*) Tracings of airflow (*FLOW*), airway pressure (*Paw*), esophageal pressure (*Pes*), and tidal volume (*VOLUME*). Each mark on the time axis denotes 1 second. As seen easily on the esophageal pressure tracing, there is a highly variable inspiratory muscle effort over time, thus inducing permanent scooping on the airway pressure recording.

components, the former was unchanged despite varying levels of ventilator assistance. The posttriggering effort, however, was highly correlated with the respiratory drive at the beginning of the breath.

Outcomes in patients receiving synchronized IMV with PSV (n = 350) and patients receiving ACV (n = 1228) as primary ventilator support modes have been compared.[78] Physicians were more likely to select synchronized IMV with PSV in less-sick patients, and ACV was mostly used in severely ill patients. After adjusting for a propensity score, no differences between the modes were detected in the duration of weaning, rates of reintubation, tracheostomy, or mortality. The clinical relevance of these data is not straightforward, as the propensity score only had a moderate level of discrimination.

Pressure-Support Ventilation

Tokioka et al[79] compared ACV with PSV set to achieve the same value of peak airway pressure as during ACV. This resulted in PSV levels of 27 cm H_2O above a PEEP of 12 cm H_2O. With these settings, tidal volume was significantly higher and machine respiratory rate significantly lower during PSV. These data indicate that peak airway pressure during ACV is an inappropriate surrogate variable to adjust PSV to get similar levels of assistance. Tejeda et al[80] compared ACV with PSV in patients with respiratory failure of assorted etiologies. PSV was adjusted to deliver the same tidal volume as with ACV, although it actually resulted in significantly higher tidal volumes. The authors found a slightly better partial pressure of arterial oxygen (Pa_{O_2}) only in a subgroup of patients with restrictive disorders. Surprisingly, the calculated shunt in these patients (18% to 20%) was lower than in patients with COPD (26% to 29%). A significantly higher dead-space-to-tidal-volume ratio also was observed during PSV (24%) than during ACV (18%). These are extremely low values for patients with respiratory failure. For these reasons, the overall clinical significance of these findings is difficult to judge.

Kreit et al[81] analyzed work of breathing during ACV and PSV in eleven patients. During ACV, tidal volume was 10 to 12 mL/kg, and inspiratory flow was 75 to 80 L/min.

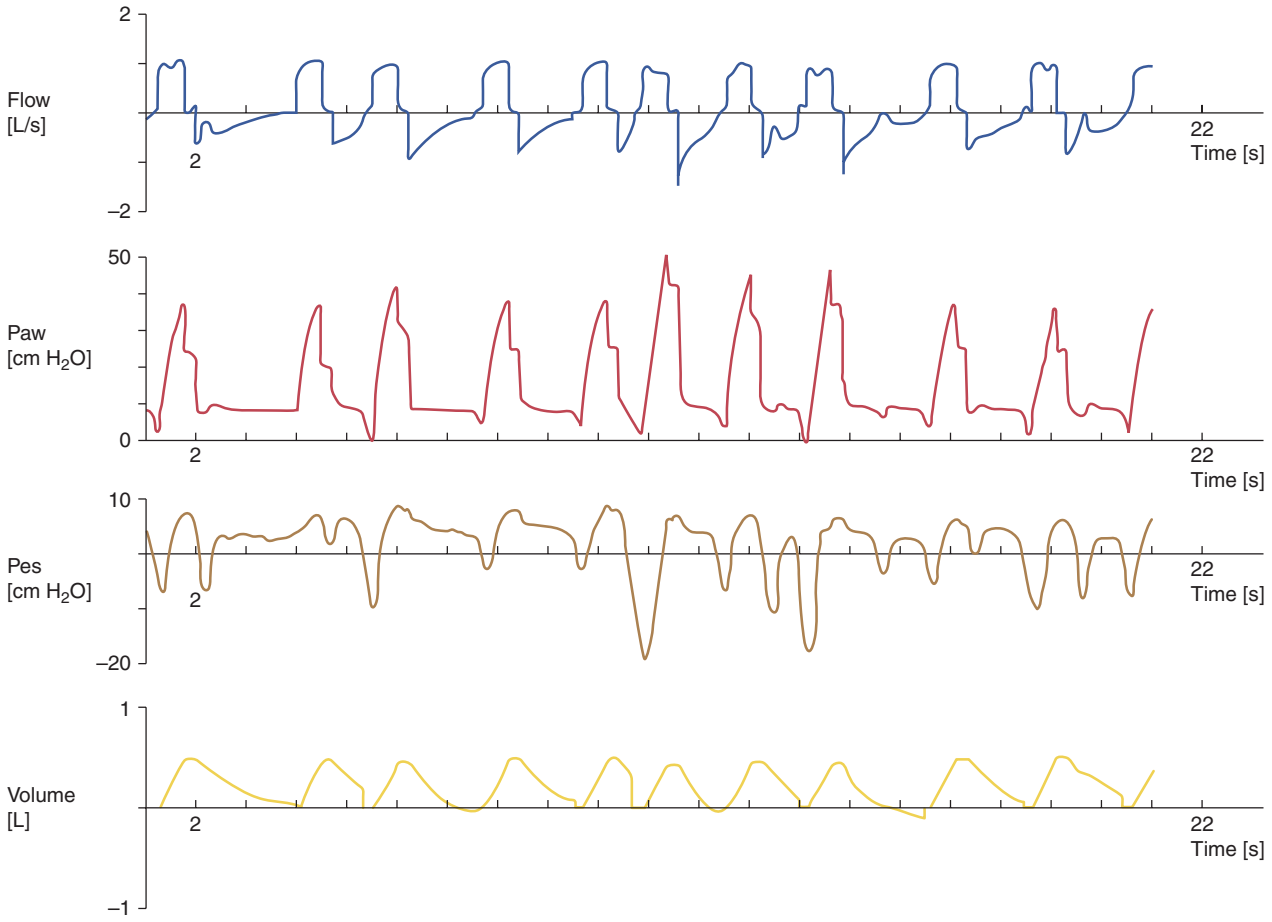

FIGURE 6-6 (*From top to bottom*) Tracings of airflow (*FLOW*), airway pressure (*Paw*), esophageal pressure (*Pes*), and tidal volume (*VOLUME*). Each mark on the time axis denotes 1 second. Note the marked breath-by-breath variability in inspiratory muscle effort (esophageal pressure swings) and airway pressure profile. There is profound patient–ventilator dyssynchrony, and numerous inspiratory attempts fail to trigger the ventilator. It is also remarkable how difficult it can be to estimate the end-inspiratory plateau airway pressure in such circumstances.

PSV was increased progressively to reach the same tidal volume as during ACV. This strategy resulted in an average pressure support of about 19 cm H_2O. The authors confirmed previous studies indicating that both work of breathing and respiratory rate vary inversely with the PSV level. With such adjustments, the patient work of breathing and minute ventilation were almost identical between the modes.

In a study not specifically designed to compare ACV with PSV, Aslanian et al[82] used the average tidal volume measured during clinician-titrated PSV for later adjustments of ACV. PSV levels were set at a target respiratory rate of between 15 and 30 breaths/min, which resulted in an average PSV of 16 cm H_2O and an average tidal volume of 500 mL. Settings during ACV were tidal volume 500 mL with an inspiratory flow rate at 50 L/min. With such adjustments, respiratory rate, minute ventilation, breathing pattern, and several indexes of inspiratory muscle effort were similar between the modes.

Chiumello et al[83] compared the effects of PSV at 5, 15, and 25 cm H_2O with assist PCV at the same levels of pressure and inspiratory time as during PSV and ACV. ACV was delivered with a square and decelerating flow pattern, both matched for the same tidal volume and peak inspiratory flow as during PSV. No differences among the modes were observed. The authors also compared clinician-titrated PSV (average 10 cm H_2O) with two ACV modes (square and decelerating flow), both at two flow settings (high and low). Tidal volume was always the same. The peak inspiratory flow obtained during PSV (0.78 L/s) was the high-flow setting for both ACV types. When high-flow settings were used, no differences were observed. The low-flow setting, approximately 0.64 L/s, induced a significant increase in work of breathing without differences in respiratory rate or gas exchange.

In a selected population of patients with acute lung injury, Cereda et al[84] studied the physiologic changes that appeared during the 48 hours after the transition from ACV to PSV. Hemodynamics and oxygenation were similar. An increase in minute ventilation and a lower Pa_{CO_2} were observed during PSV. Of forty-eight patients, ten did not tolerate PSV. These patients had a lower static

compliance and a higher dead-space-to-tidal-volume ratio when compared with patients who succeeded. These data suggest that PSV might be an alternative to ACV in carefully selected patients with acute lung injury.

Biologically Variable Ventilation

Tidal volume during ACV is, by design, delivered in a monotonous manner. To re-create the spontaneous variability of physiologic rhythms, mechanical ventilation using computer-generated biologic variability in respiratory rate and tidal volume has been used. The goal of this approach is to improve gas exchange and respiratory system mechanics, and to minimize ventilator-induced lung injury. Data comparing ACV with ventilation achieved with randomly variable tidal volumes and respiratory rates have been obtained in several experimental models of acute lung injury.[85–91] Models include different animal species (e.g., rodents, pigs, and dogs), different type of insults (e.g., chemical, mechanical, and biologic), and different ventilator settings (e.g., PEEP or no PEEP). In these short-term experiments, variable ventilation was matched to ACV in terms of minute ventilation.

All studies, except the study by Nam et al,[90] reported benefits of variable ventilation over ACV in terms of arterial oxygenation, lung mechanics, redistribution of pulmonary blood flow, degree of lung edema, proinflammatory cytokine production, histologic damage, or combinations of these. Variable ventilation may induce a better distribution of tidal volume—thereby matching ventilation to perfusion—better recruitment, and increased surfactant production. Whether these putative benefits are attributable directly to the ventilator mode per se, the type of injury, the animal species, the ventilator settings (degree of variability, PEEP levels), or the respiratory system mechanical characteristics is unclear. The physiologic effects of this new mode in patients with acute lung injury are still unknown.

VARIATION IN DELIVERY AMONG VENTILATOR BRANDS AND TROUBLESHOOTING

This section does not pretend to explain exhaustively the working principles of the dozens of different mechanical ventilators available on the market. The decision to stick with one style or another depends solely on the manufacturer. Some machines are user-configurable, but in different ways (inspiratory flow rate, inspiration-to-expiration ratio, and so on).

The fundamental settings during ACV are respiratory rate, tidal volume, and inspiratory flow rate. The backup respiratory rate determines the total breath duration, and both tidal volume and inspiratory flow rate determine the duration of mechanical inflation within a breath. The inspiratory pause, if used, appears immediately after the machine's flow delivery has ceased and thus increases the inspiratory time. The expiratory time is the only part of the breathing cycle that is allowed to vary when a patient triggers an ACV breath. For this reason, we consider machines that require inspiratory-to-expiratory ratio adjustment during ACV to be totally counterintuitive.

Some ventilators allow direct setting of respiratory rate, tidal volume, inspiratory flow rate, and inspiratory pause time. In my opinion, this is the most comprehensive approach, because the time for flow delivery depends on the tidal volume and inspiratory flow rate. Mechanical ventilators are lifesaving machines when used properly. Inappropriate use can be life-threatening. Because manufacturers follow different principles and strategies to build their machines, it is fundamental to get acquainted with the specifics of each ventilator and read the instruction manual carefully.

Recent bench studies[8,92] evaluating the performance of multiple ventilators, have shown that triggering delay, pressurization capacity during PSV, tidal volume delivery during ACV, and expiratory resistance significantly differ across a wide range of new-generation ventilators. It is interesting to note that new turbine-based ventilators perform better (on average) in terms of trigger function and pressurization quality when compared to conventional servo-valve ventilators and perform as well as the best compressed-gas ICU ventilators.

Comparisons between target tidal volume and actually delivered tidal volume during ACV at different impedance conditions, and taking into account the differences in gas temperature and humidity between inspiration and expiration, showed marked differences across various new-generation ICU ventilators.[92] Tidal volumes of 300, 500, and 800 mL were selected. Differences between targeted and delivered tidal volume ranged between −13% and +32%. Interestingly, ventilators that use compensation algorithms (which account for volume compensation when gas is compressed) delivered significantly larger tidal volumes (although less than 10% on average) than preset tidal volumes under body temperature and pressure-saturated conditions.[92] The clinical relevance of these differences needs to be carefully evaluated.

Solving problems related to mechanical equipment requires special skills and intuition. Some troubles are intrinsically related to machines and their own working principles/algorithms but can be minimized if manufacturers' recommendations are followed. It should be unnecessary to emphasize that thorough reading of the operator's manual is mandatory. Overall, the reported frequency of ventilator malfunctions seems to be very low.[93]

ADJUSTMENTS AT THE BEDSIDE

Settings to be adjusted in ACV are inspired oxygen concentration, trigger sensitivity (to be set above the threshold of autotriggering), backup rate, tidal volume, inspiratory

flow rate (or inspiratory time), end-inspiratory pause, and external PEEP, if any. When ACV is instituted after tracheal intubation, patients usually are sedated and passively ventilated. Proper measurement of end-inspiratory plateau airway pressure and calculations of compliance and airflow resistance may help in adjusting the ventilator's backup breathing pattern. The time constant of the respiratory system determines the rate of passive lung emptying. The product of three time constants is the time needed to passively exhale 95% of the inspired volume.[94,95] If expiratory time is insufficient to allow for passive emptying, this will generate hyperinflation.

During ACV, when a patient triggers a mechanical breath, the expiratory time is no longer constant. Consequently, exhaled volume might change on a cycle-to-cycle basis and modify the degree of dynamic hyperinflation. This may alter patient–ventilator synchrony and cause subsequent wasted inspiratory efforts, as is seen in patients with low inspiratory drive (i.e., patients who are sedated) and those with prolonged time constants (Fig. 6-7). One study showed that sedation level is a predictor of ineffective triggering[96] and at least two studies showed that patient–ventilator asynchrony (mainly ineffective triggering) is associated with worse outcomes: increased duration of mechanical ventilation, more tracheostomies, and lower likelihood of being discharged home.[97,98] Importantly, ineffective triggering is associated not only with sedatives and the presence of an obstructive disease, but also with excessive levels of support and excessive tidal volumes.[97–99]

Chapters 29 to 31 discuss mechanical ventilation in specific scenarios. Some general principles, however, are worth recalling. The goals of mechanical ventilation, in particular during ACV, have changed profoundly in the last years. Nowadays, moderate tidal volumes are customary, and achieving normocapnia is no longer required per se. This is the case for virtually all ventilated patients. One exception, however, is the patient with brain injury and relatively normal lungs, in whom a tight Pa_{CO_2} control is required to avoid undesirable episodes of brain ischemia or hyperemia.

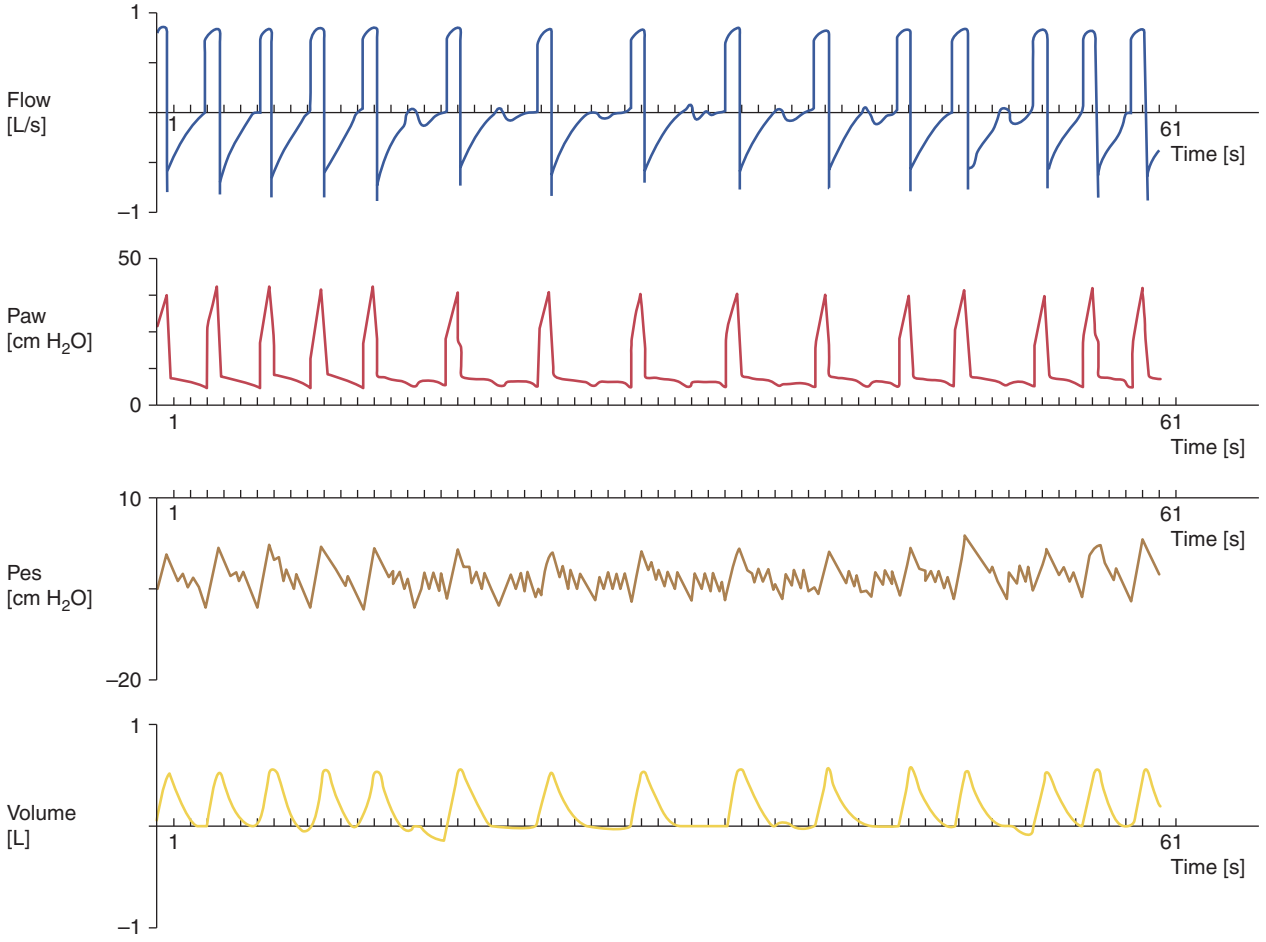

FIGURE 6-7 (*From top to bottom*) Tracings of airflow (*FLOW*), airway pressure (*Paw*), esophageal pressure (*Pes*), and tidal volume (*VOLUME*). Each mark on the time axis denotes 1 second. As can be seen from the esophageal pressure recordings, this patient was markedly unloaded and exhibited a feeble respiratory drive. As a result, multiple wasted inspiratory efforts are interspersed between the patient-triggered breaths.

In patients with COPD, data indicate that the quotient between tidal volume and expiratory time—mean expiratory flow—is the principal ventilator setting influencing the degree of dynamic hyperinflation.[94,100] An arterial oxygen saturation of approximately 90% is sufficient and is usually achieved with moderate oxygen concentrations. A respiratory rate of 12 breaths/min, tidal volume of approximately 8 mL/kg or lower, and a constant inspiratory flow rate of between 60 and 90 L/min are usually acceptable initial settings. These settings need to be readjusted, as needed, once basic respiratory system mechanics and arterial blood gases have been measured. In these patients, the goal is to keep a balance between minimizing dynamic hyperinflation and providing sufficient alveolar ventilation to maintain arterial pH near the low-normal limit, not a normal Pa_{CO_2}. When patients are receiving ACV and mechanical breaths are triggered by the patient, external PEEP counterbalances the elastic mechanical load induced by intrinsic PEEP secondary to expiratory flow limitation and decreases the breathing workload markedly.[101]

The ventilator strategy in acute asthma favors moderate tidal volumes, high inspiratory flow rates, and a long expiratory time.[102–108] These settings avoid large end-inspiratory lung volumes, thus decreasing the risks of barotrauma and hypotension. The main goal in asthma is to avoid these complications rather than to achieve normocapnia. A reasonable recommendation from physiologic and clinical viewpoints when initiating ACV is to provide an inspiratory flow of 80 to 100 L/min and a tidal volume of approximately 8 mL/kg, and to avoid end-inspiratory plateau airway pressures higher than 30 cm H_2O. The respiratory rate should be adjusted to relatively low frequencies (approximately 10 to 12 cycles/min) so as to minimize hyperinflation. These settings are accompanied most often by hypercapnia and respiratory acidosis and require adequate sedation, even neuromuscular blockade in some patients. Ventilator settings should be readjusted in accordance with the time course of changes in gas exchange and respiratory system mechanics.

Most patients with ARDS require mechanical ventilation during their illness. In this setting, mechanical ventilation is harmful when delivering high tidal volumes.[99,100] There is general agreement that end-inspiratory plateau airway pressure should be kept at values no higher than 30 cm H_2O. End-inspiratory plateau airway pressure, however, is a function of tidal volume, total PEEP level, and elastance of both the lung and chest wall. Importantly, patients with ARDS have small lungs with different mechanical characteristics of the lungs and chest wall,[101,102] and recommending a single combination of tidal volume and PEEP for all patients is not sound. Patients with more compliant lungs possibly can receive somewhat higher tidal volumes and PEEP levels than those delivered to patients with poorly compliant lungs. As in any other disease state, individual titration of tidal volume and PEEP according to underlying physiologic abnormalities and to the time course of the disease seems the most reasonable.[109] Besides, such an approach serves as a control for comparison purposes.

IMPORTANT UNKNOWNS AND THE FUTURE

Mechanical ventilation is instituted mainly to improve gas exchange and to decrease respiratory muscle workload. The clinical response to this lifesaving treatment in terms of gas exchange is usually evaluated by means of intermittent arterial blood-gas measurements, continuous pulse oximetry monitoring, and, less often, monitoring end-tidal CO_2. These measurements provide an objective way to titrate therapy. Although gas exchange is the main function of the lungs, the respiratory system also has a muscular pump that is central to its main purposes. The way we evaluate the function of the respiratory muscles clinically during the course of ACV and patient–ventilator interactions is rudimentary. Knowing how much effort a particular patient is making and how much unloading is to be provided is very difficult to ascertain on clinical grounds. Too much or too low respiratory muscle effort may induce muscle dysfunction, and this eventually could delay ventilator withdrawal.

When ACV is first initiated, the ventilator usually overcomes the total breathing workload. How long the period of respiratory muscle inactivity is to be maintained is unknown. When ACV is triggered by the patient, multiple factors interplay between the patient and the ventilator. Although high levels of assistance decrease the sensation of dyspnea, they also increase the likelihood of wasted inspiratory efforts (see Fig. 6-7). How ACV is adjusted, in particular concerning inspiratory flow rate and tidal volume settings, is a major determinant of its physiologic effects. If the settings are selected inappropriately, these may lead the physician to erroneously interpret that the problem lies with the patient and perhaps administer a sedative agent when, in reality, the patient is simply reacting against improper adjustment of the machine.

When patients are receiving ACV, they are at risk of undergoing periods of underassistance alternating with periods of overassistance. This is so because of the varying ventilatory demands (see Fig. 6-5) and because the mechanical characteristics of the respiratory system also change over time. The frequency of such phenomena and their clinical consequences are unknown. The effects of permanent monotonous tidal volume delivery, as well as whether or not sighs are to be used in this setting, also remain to be elucidated.

The only way to interpret clinically whether the patient is doing well or not during ACV is to evaluate respiratory rate and the airflow and airway pressure trajectories over time. During patient-triggered ACV, muscle effort can be estimated by superimposing the current and the passive airway pressure trajectories. Airway occlusion pressure is an important component of the airway pressure trajectory during patient-triggered breaths. This variable is a good

estimate of the central respiratory drive and is highly correlated with the inspiratory muscle effort. Such measurements would allow clinicians to analyze trends and estimate patient–ventilator interactions objectively. It is surprising that such sound noninvasive monitoring possibilities have yet to be widely implemented, and it is ironic to realize how many new ventilator modes are introduced without having passed rigorous physiologic and clinical evaluations.

SUMMARY AND CONCLUSION

The most widely used ventilator mode in mechanically ventilated patients continues to be ACV. Many of its physiologic effects are well characterized, and it is conceivable that, in the main, its purposes are met. ACV is also very versatile because it offers ventilator support throughout the entire period of mechanical ventilation. As with any other mode, the effects depend on the way ACV is implemented. The necessity to impose a number of fixed settings, in essence, tidal volume and inspiratory flow rate, implies that the respiratory pump may be unloaded suboptimally and contraction of the respiratory muscles may asynchronous with the ventilator. The clinical consequences of these phenomena are not negligible.

Since its introduction, ACV implementation has undergone considerable changes, and it is presently applied less aggressively than in the past. Thanks to an enormous amount of physiologic and clinically oriented research, we have learned that ACV can be harmful to patients, injuring both the lungs and the respiratory muscles. Future research should help us to deliver ACV in such a manner that a patient's clinical needs are served more optimally.

INTERMITTENT MANDATORY VENTILATION

Catherine S. Sassoon

Intermittent mandatory ventilation (IMV) allows the patient to breathe spontaneously between machine-cycled or mandatory breaths. This concept originated in 1955 with an unnamed ventilator designed by Engstrom.[1,2] In the early 1970s, Kirby et al[3,4] introduced IMV as a means of ventilator support of infants with respiratory distress syndrome. In 1973, Downs et al[5] were the first to propose IMV as a method to facilitate discontinuation from mechanical ventilation in adults. Those investigators[6,7] also pioneered IMV use as a primary means of ventilator support during acute respiratory failure. Subsequently, breath-delivery design has been modified. Mandatory breaths initially delivered regardless of respiratory timing are synchronized with the patient's inspiratory effort.[8,9] This mode of ventilation has been termed *intermittent demand ventilation,*[8] *intermittent assisted ventilation,*[9] and *synchronous intermittent mandatory ventilation* (SIMV). SIMV is an established partial mechanical ventilation mode in critically ill patients, both adult[10] and neonate, worldwide.[11] Currently, however, SIMV application in adults has declined except in North America[12] and Australia–New Zealand,[13] whereas in neonates, SIMV application remains prevalent.[14] This chapter uses the terms *IMV* and *SIMV* interchangeably unless specifically indicated for clarification.

BASIC PRINCIPLES

Description

IMV is a means of ventilator support in which a preset number of positive-pressure (mandatory) breaths are delivered while the patient breathes spontaneously between the mandatory breaths. The mandatory breaths can be in the form of a preset volume (flow-limited, volume-cycled), pressure (pressure-limited, time-cycled),[15] or a combination of pressure and volume (dual control).[16] In principle, IMV is similar to controlled mechanical ventilation (CMV), in which the patient receives a predetermined number of mandatory machine-triggered breaths independent of spontaneous breathing effort. Likewise, SIMV is similar to assist-control ventilation (ACV), in which mandatory breaths are triggered by the patient. In contrast to CMV and ACV, however, in both IMV and SIMV the patient is allowed to breathe spontaneously between the mandatory breaths. In addition, with IMV and SIMV, the clinician can vary the ventilator support level according to the set IMV rate. At a high IMV rate, in which the patient's spontaneous effort is suppressed, IMV provides full ventilator support. At a zero IMV rate, it provides no support, and all breaths are spontaneous. Between these extremes, IMV provides partial ventilator support.

System Design

Three types of IMV systems are described: continuous-flow IMV and pressure-triggered and flow-triggered SIMV systems.

CONTINUOUS-FLOW IMV

The original IMV design uses a continuous-flow system.[3] Two parallel circuits—one for the patient's spontaneous breaths and the other for the mechanical breaths—are connected through a sidearm and a one-way valve, and share a common oxygen and air source. The continuous-flow IMV setup can be either an open or a closed system.[17] The open system employs a reservoir tube that has a capacity of at least 1.5 times the patient's tidal volume (V_T) and is open to the atmosphere (Fig. 7-1). For this reason, continuous positive airway pressure (CPAP) cannot be applied during the spontaneous breathing cycles. To reduce inspiratory resistance, the side port of the spontaneous breathing circuit is placed between the patient Y and the humidifier. The continuous flow of fresh gas is humidified using a venturi nebulizer. The reservoir tubing's considerable length and the inability to maintain a CPAP level make this open system cumbersome.

The closed system employs a reservoir bag (Fig. 7-2) that minimizes airway pressure fluctuations because the inspired gas flow rate may be limited by the maximum flow generated by the hospital's compressed air and oxygen source. In addition, constant positive airway pressure can be maintained during both the mandatory (i.e., positive end-expiratory airway pressure [PEEP]) and spontaneous breaths (i.e., CPAP). During spontaneous breathing, the patient breathes from the reservoir bag via the one-way valve. When the ventilator cycles, the one-way valve closes, and a positive-pressure breath is delivered to the patient. During the mechanical breath, excess gas in the reservoir bag is vented through a relief valve. Exhalation occurs through the ventilator's exhalation circuit, which is supplied with a PEEP valve.

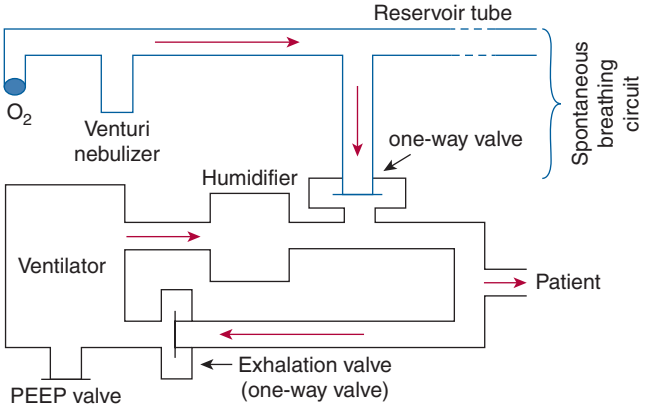

FIGURE 7-1 Continuous-flow intermittent mandatory ventilation setup with a reservoir tube. The sidearm of the spontaneous breathing circuit is connected through a one-way valve to the inspiratory limb of the ventilator circuit. The sidearm is placed between the humidifier and the patient Y. See text for further explanation. *PEEP*, positive end-expiratory pressure.

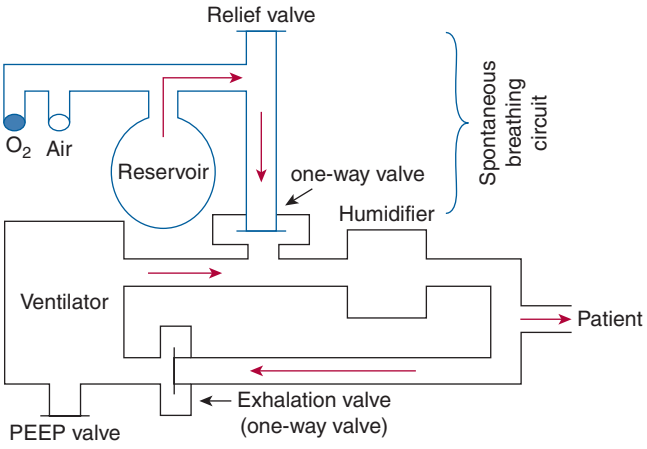

FIGURE 7-2 Continuous-flow intermittent mandatory ventilation setup with a reservoir bag. The sidearm for the spontaneous breathing circuit is connected through a one-way valve to the inspiratory limb of the ventilator circuit. The sidearm is placed proximal to the humidifier. See text for further explanation. *PEEP*, positive end-expiratory pressure.

In a continuous-flow IMV system, the inspired gas flow rate within the spontaneous breathing circuit must exceed the patient's peak inspiratory flow rate to minimize airway pressure fluctuations and hence the patient's inspiratory work. When set appropriately, spontaneous breathing in continuous-flow IMV should resemble breathing from the atmosphere.

Continuous-flow IMV has several disadvantages.[18–23] In addition to gas wastage, inaccurate V_T measurement and extra circuitry requirement, patient–ventilator asynchrony potentially can occur because mandatory breaths are not delivered in concert with the patient's inspiratory effort (Fig. 7-3A). Whereas asynchrony has no significant effect in adults,[24] in neonates, particularly preterm infants,[25] asynchrony associated with continuous-flow IMV resulted in large fluctuations of V_T[26] and lower partial pressure of arterial oxygen (Pa_{O_2})[27,28] than with SIMV. The effect of IMV on Pa_{O_2} was confirmed in a large randomized multicenter trial.[29] The degree and duration of hypoxia appear to result from active exhalation,[30] while muscle relaxant improves oxygenation.[31,32] Furthermore, the application of SIMV is superior to IMV in terms of reduced duration of mechanical ventilation, requirement for reintubation, incidence of intraventricular hemorrhage, and bronchopulmonary dysplasia.[33] In term infants and children (ages 1 month to 4 years), however, IMV or SIMV plus pressure support has similar effects on duration of mechanical ventilation, weaning, and intensive care unit length of stay.[34]

A technologically advanced continuous-flow IMV or CPAP is the flow-regulated IMV or CPAP.[35] Flow within the circuit is polled, for example, every 20 minutes and used as a feedback signal to increase the basal flow to match the patient's ventilatory demand during inspiration and subtract it during exhalation. Flow-regulated IMV or CPAP eliminates airway fluctuations and decreases imposed work during both

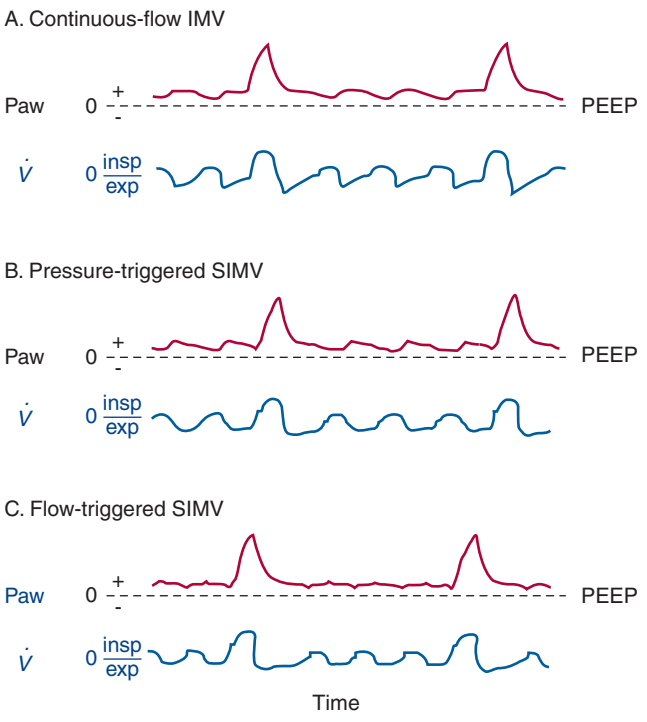

FIGURE 7-3 A. Continuous-flow intermittent mandatory ventilation (IMV). Airway pressure (*Paw*) and flow tracings ($\dot{V}$). The vertical *dashed line* indicates the onset of inspiratory flow. Minimal fluctuations of Paw are a result of circuit resistance. Large fluctuations of Paw occur when inspiratory flow rates are insufficient and a reservoir bag is not used. *exp*, Expiration; *insp*, inspiration; *PEEP*, positive end-expiratory airway pressure. **B.** Pressure-triggered synchronous intermittent mandatory ventilation (SIMV). A period of zero flow before the onset of flow (indicated by the vertical *dashed line*) can be detected on the flow tracing. Zero flow coincides with patient triggering to open the proportional valve. During the unassisted breathing after flow onset, Paw continues to drop during inspiration because of inadequate flow delivery. **C.** Flow-triggered synchronous intermittent mandatory ventilation (SIMV). Triggering phase is significantly shorter than with pressure-triggered SIMV. During the unassisted breathing following patient triggering, Paw is maintained at or slightly above the PEEP level, suggesting adequate flow delivery during inspiration.

inspiration and exhalation. Using a mechanical lung model with flow-regulated CPAP of 5 cm H_2O, the total imposed work was 3.4 mJ/breath versus 43.5 mJ/breath with a continuous-flow CPAP device and an added 20-L reservoir bag.[35]

DiBlasi et al[36] described a modified continuous-flow IMV, a combination of continuous-flow IMV and low-to-moderate frequency oscillatory ventilation. It is also called Bubble IMV (B-IMV), intended as an inexpensive means of ventilator support in infants. The device is equipped with a microprocessor-controlled rate, inspiratory timing, and pinch valve. The pinch valve regulates the path of gas exiting the system into a water-seal chamber (Fig. 7-4). The inhalation path controls the peak inspiratory pressure level of the mandatory breaths, and the exhalation path allows spontaneous breaths (i.e., CPAP), and control PEEP level. The exhalation path outlet is connected to an adjustable bubbler with three configurations: a bubbler angle of 0 degrees, 90 degrees, and 135 degrees. The bubbler angle determines the oscillation amplitudes in airway pressure (Paw). Only the bubbler angle of 135 degrees is associated with the largest pressure oscillations at a frequency of 2 to 5 Hz, and, hence, the largest change in volume (Fig. 7-5A).[37] In paralyzed juvenile rabbits with saline lavage-induced lung injury, B-IMV provided comparable peak inspiratory and mean Paw, PEEP, and Pa_{O_2} as with CMV, irrespective of the bubbler angle (Fig. 7-5B).[36] B-IMV_{135}, however, was associated with consistently low mean partial pressure of arterial carbon dioxide (Pa_{CO_2}; 35 mm Hg). Mean Pa_{CO_2} with B-IMV_{90}, B-IMV_0, and CMV was 45, 45, and 55 mm Hg, respectively. The low Pa_{CO_2} with B-IMV_{135} is caused by additional volume produced by the oscillatory pressures (DiBlasi, personal communication) (Fig. 7-5A). At this time, B-IMV is an experimental ventilator, its potential application in preterm infants with respiratory distress syndrome and its efficacy when compared with SIMV remains to be determined.

PRESSURE-TRIGGERED AND FLOW-TRIGGERED SIMV

SIMV is currently the standard for clinical use.[10,11] SIMV incorporates a demand valve that is triggered by the patient with each spontaneous breath and delivers a mandatory breath in concert with the patient's inspiratory effort. If the patient ceases to trigger the ventilator, mandatory breaths will be triggered by the machine and delivered according to the preset rate. The demand valve can be triggered by either a fall in pressure (pressure-triggered) or a change in flow (flow-triggered). In pressure-triggered SIMV, a preset pressure sensitivity must be achieved before the ventilator delivers fresh gas into the inspiratory circuit.[38,39] A noticeable delay in opening the demand valve occurs between onset of inspiratory effort and flow delivery (see Fig. 7-3B). Flow-triggered SIMV uses a preset flow sensitivity as the trigger mechanism.[38,39]

The pressure-triggering and flow-triggering characteristics of the spontaneous breaths (CPAP) are an important component of the imposed work of a SIMV system (see Chapter 3).[40,41] This situation arises because there is little adaptation to the mandatory breaths' ventilatory assistance unless the system is set at a substantial assistance level.[42] Fortunately, most modern microprocessor-based ventilators employ a remarkably responsive proportional solenoid valve such that the work imposed during the trigger phase (the interval from onset of patient effort to valve opening or flow delivery) is a small percentage of the total inspiratory work of breathing (<10% with pressure-triggered SIMV).[43] Nevertheless, flow triggering has become the preferred triggering method not only for SIMV but also for various other ventilation modes because of its faster response time and therefore shorter triggering phase compared with pressure triggering (see Fig. 7-3C).[44] In the posttrigger phase (the interval from onset of flow delivery to the end of inspiration), flow delivery with pressure triggering may not be adequate during the spontaneous breaths.[38] The feedback signal for flow delivery is the gradient between a manufacturer-determined target pressure and circuit pressure. As

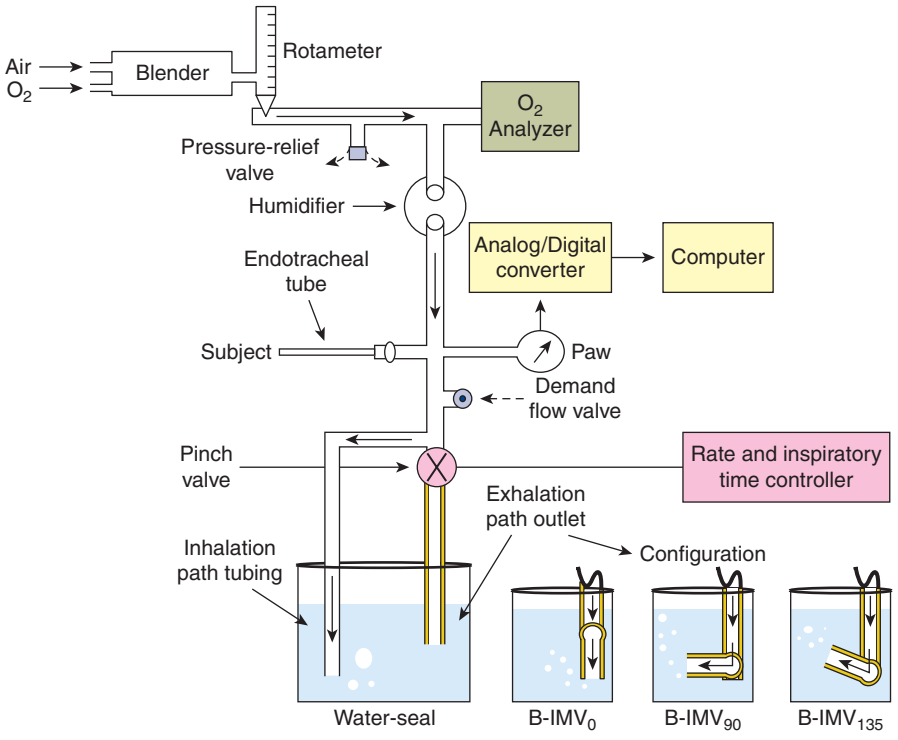

FIGURE 7-4 Bubble-intermittent mandatory ventilation (B-IMV). A modified continuous-flow IMV is equipped with a rotameter to control bias flows of air and oxygen. In line of patient's circuit are a high-pressure relief valve set to a limit of 40 cm H_2O, oxygen analyzer, humidifier, airway pressure monitor, a demand flow valve that allows room air to enter the circuit if the bias flow does not meet the patient's flow demand, and a pinch valve with a rate and inspiratory time controller. The pinch valve controls the path of gas exiting the system, either through the inhalation path with the tube placed deep in the water-seal chamber to control peak inspiratory pressure level of the mandatory breaths, or through the exhalation path to allow spontaneous breaths (continuous positive airway pressure [CPAP]) and control positive end-expiratory airway pressure (PEEP) level. The exhalation path outlet is connected to a bubbler with the angles adjustable to 0 degrees, 90 degrees, and 135 degrees (B-IMV$_0$, B-IMV$_{90}$ and B-IMV$_{135}$, respectively). (Adapted, with permission, from DiBlasi RM, Zignego JC, Smith CV, et al. Effective gas exchange in paralyzed juvenile rabbits using simple, inexpensive respiratory support devices. *Pediatr Res.* 2010;68:526–530.)

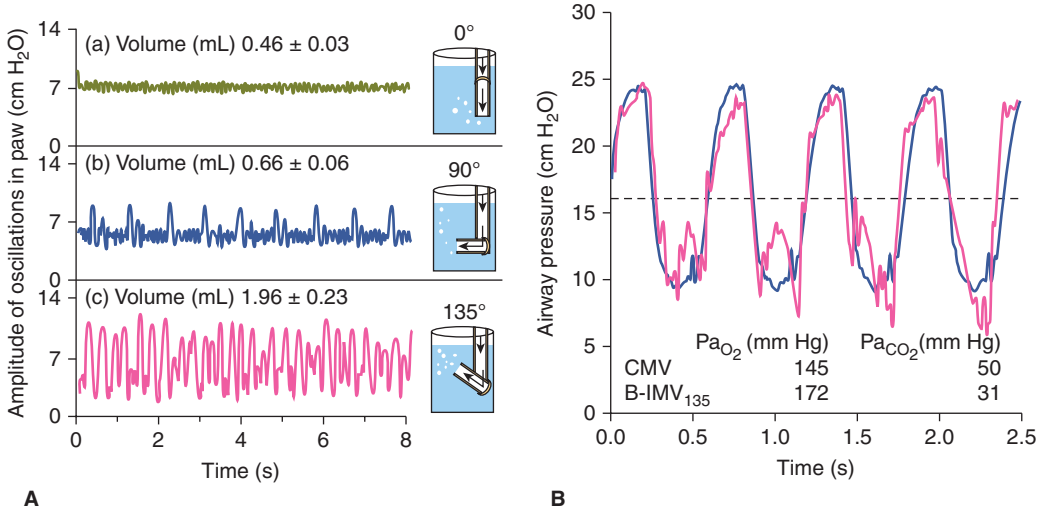

FIGURE 7-5 **A.** Effects of bubbler angle configuration on airway pressure (*Paw*) oscillations. Bubble-continuous positive airway pressure connected to a test lung with a bias flow set at 8 L/min. Bubbler angle of 135 degrees produces the largest airway pressure oscillations at a frequency of 2 to 5 Hz, and largest change in volume. **B.** Superimposed airway pressure waveform during CMV (*solid black*) and bubble-intermittent mandatory ventilation with bubble angle of 135 degrees (*B-IMV$_{135}$*) (*double gray line*) in an animal with lung injury. *Horizontal dashed line* represents mean airway pressure. (Adapted, with permission, from DiBlasi RM, Zignego JC, Tang DM, et al. Noninvasive respiratory support of juvenile rabbits by high-amplitude bubble continuous positive airway pressure. *Pediatr Res.* 2010;67:624–629.)

the pressure gradient increases, flow delivery increases. This pressure gradient can be enhanced by adding pressure support or sensing the circuit pressure at the distal end of the endotracheal tube.[45,46] From a practical standpoint, adding pressure support is preferable. Alternatively, flow delivery during the spontaneous breaths may be augmented by using changes in flow instead of pressure as a feedback signal for adding and subtracting flow from the base flow during inspiration and exhalation, respectively.[35]

The mandatory breaths can be in the form of volume-limited or pressure-limited. In preterm infants, pressure-targeted ventilation is prevalent,[14] with similar efficacy as with volume-targeted ventilation in maintaining oxygenation.[47] Augmenting flow delivery during the mandatory breaths can be accomplished by setting the pressure-attack rate sufficiently high when pressure-limited mandatory breaths are employed.[48,49] To maintain a constant V_T with pressure-limited mandatory breaths, both pressure-limited and volume-limited breaths can be combined in the form of dual control within breaths[50] or breath-to-breath ventilation (see Chapter 15).[51] Several microprocessor-based ventilators are equipped with dual-control breath-to-breath ventilation that can be applied in the SIMV mode.[52] In essence, this form of mandatory breath is a pressure-limited, time-cycled breath that uses V_T as feedback control for continuously adjusting the pressure limit to attain the set V_T. The volume signal used as feedback to the ventilator controller is the volume exiting the ventilator and not the exhaled V_T. This step prevents runaway of airway pressure that could occur if a leak in the circuit caused inaccurate measurement of exhaled volume. As an additional safety feature, if the volume exiting the ventilator exceeds 150% of the set V_T, then the ventilator exhalation valve opens, ending the mechanical inspiration. With SIMV, most microprocessor-based ventilators are able to apply pressure support and dual-control breathing to the spontaneous and mandatory breaths, respectively, to improve flow delivery and maintain a set V_T during pressure-limited mandatory breaths. In preterm infants, because changes in respiratory system mechanics occur frequently, the set V_T of the mandatory dual-control breaths not only provides a guaranteed volume when respiratory system compliance decreases but also prevents overinflation when compliance improves.[53,54] In fact, a recent report demonstrates a decrease in mortality and chronic lung disease with volume-targeted compared with pressure-targeted ventilation.[55]

PHYSIOLOGIC EFFECTS

The physiologic effects of IMV not listed in this section are discussed in comparison with other ventilation modes.

Control of Breathing and Breathing Patterns

In early IMV development, it was thought that inspiratory muscle activity is downregulated during the mandatory breaths and that IMV allows a combination of unassisted breathing with respiratory muscle rest to promote weaning.[5,56] By adjusting mandatory breath frequency, inspiratory effort could be modified until the patient resumed complete control of spontaneous breathing. Several studies, however, disproved this hypothesis.[42,57–60] Imsand et al[57] studied the neuromuscular output of patients recovering from acute exacerbation of chronic obstructive pulmonary disease who were receiving pressure-triggered SIMV. The mandatory-breath V_T was set at 10 to 12 mL/kg. Neuromuscular output was estimated from the amplitude of the integrated diaphragmatic electrical activity (Edi), measured using bipolar esophageal electrodes. Sternocleidomastoid muscle electrical activity was recorded using surface electrodes. Neuromuscular output, occlusion esophageal pressure ($Pes_{0.1}$, another index of neuromuscular output), and neural inspiratory time (T_I) were measured at three ventilator support levels: >60%, 50% to 20%, and 0% of total support. Total support was defined as the support at which Edi was suppressed completely. Only at the highest machine assistance rate did Edi decrease significantly, whereas sternocleidomastoid muscle electrical activity did not (Fig. 7-6). Moreover,

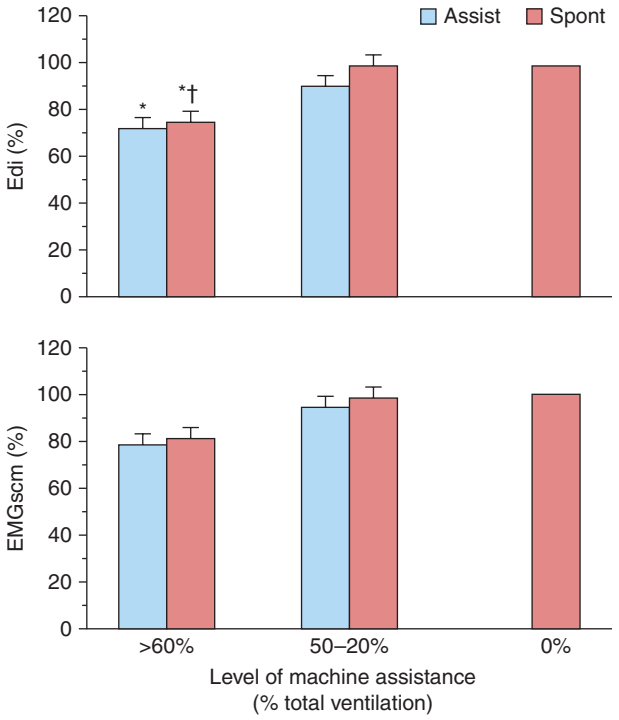

FIGURE 7-6 Peak inspiratory amplitude of integrated electrical activity of the diaphragm (*Edi*) and sternocleidomastoid muscles (*EMGscm*) at three levels of machine assistance during SIMV, expressed as a percentage of mean value of 0% of or minimal (4 breaths/min) machine assistance. Values are mean ± standard error. *$P < 0.01$ compared with 0% of machine assistance. †$P < 0.05$ compared with spontaneous cycles at 50% to 20% of assistance. *Assist*, Machine-assisted breaths; *spont*, intervening spontaneous breaths. (Adapted, with permission, from Imsand C, Feihl F, Perret C, et al. Regulation of inspiratory neuromuscular output during synchronized intermittent mechanical ventilation. *Anesthesiology.* 1994;80:13–22.)

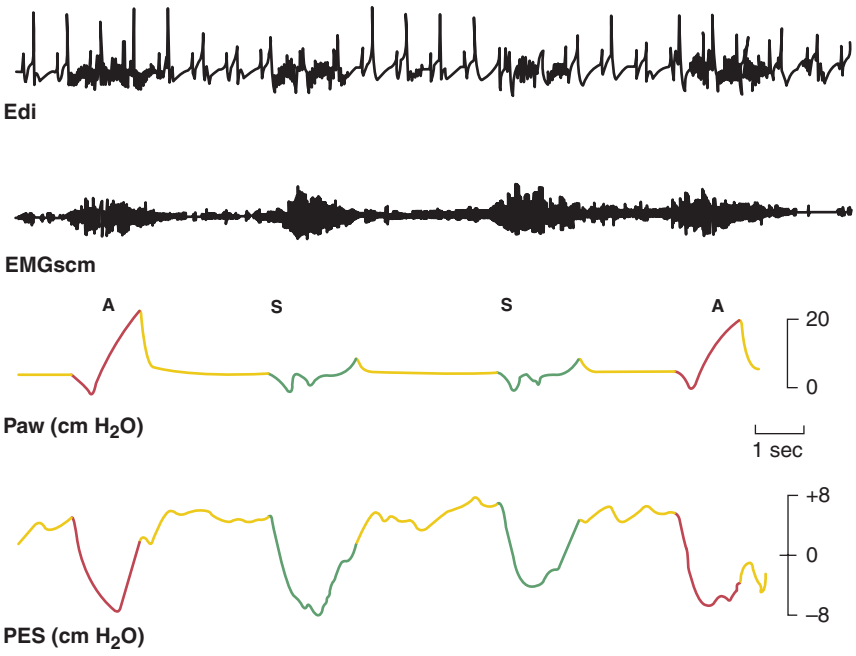

FIGURE 7-7 Electrical activity of the diaphragm (*Edi*) and sternocleidomastoid muscles (*EMGscm*) in a patient receiving SIMV. Intensity and duration of electrical activity in successive assisted (*A*) and intervening spontaneous (*S*) breaths are similar. The regular spikes in the Edi tracing are the QRS complex of the electrocardiogram signal. *Paw*, Airway pressure; *Pes*, esophageal pressure; *red lines* and *green lines*, inspiratory phase of the assisted and spontaneous breaths, respectively; *yellow lines*, expiratory phase. Regulation of inspiratory neuromuscular output during synchronized intermittent mechanical ventilation. *Anesthesiology.* 1994;80:13–22.)

across all levels of ventilator support, both Edi (Fig. 7-7) and $Pes_{0\cdot1}$ of the unassisted and machine breaths were similar. $Pes_{0\cdot1}$, however, tended to increase with decreasing machine assistance. Likewise, neural T_I, defined as the interval from onset to peak Edi, was equivalent for unassisted and machine breaths.

In another study, Uchiyama et al[58] applied continuous-flow IMV to anesthetized rabbits and measured Edi with implanted electrodes into the diaphragm. The IMV rate was set at 0, 5, 10, 15, and 20 breaths/min, at which Edi was suppressed completely. Edi was expressed as percent of Edi at zero IMV rate per minute. Compared with spontaneous breathing, Edi decreased significantly only at an IMV rate of 15 breaths/min (75% of total support). In contrast with the study of Imsand et al,[57] at an IMV rate of 10 and 15 breaths/min, Edi of the mandatory breaths was absent. The difference in neuromuscular output response during mandatory breaths in the study of Uchiyama et al[58] may be related to the effect of anesthesia and the large V_T applied (15 mL/kg), causing vagally mediated inspiratory inhibition.[59] It appears that in anesthetized animals at ventilator support of 50% or greater, breath-by-breath adaptation to ventilator assistance occurred, but it was not observed in conscious humans.

In unsedated preterm infants with acute respiratory failure receiving flow-triggered SIMV, Beck et al[60] measured Edi and neural timing of mandatory breaths and the unassisted breaths immediately preceding and following the mandatory breaths using miniaturized electrodes mounted on a feeding tube. The set SIMV rate ranged from 5 to 25 breaths/min. Both Edi and neural T_I amplitude were similar for the mandatory and unassisted breaths (Fig. 7-8). In contrast to improved triggering in adults,[57] during the mandatory breaths, a substantial delay was observed from onset of Edi to flow delivery, an average of 95 milliseconds (range: 5 to 110 milliseconds). Because most of the infants had bronchiolitis and likely were hyperinflated, the authors attributed the trigger delay or inspiratory asynchrony to neuroventilatory uncoupling (a delay from onset of diaphragmatic activation to flow generation)[61] rather than to the ventilator triggering system. Neural expiratory time (T_E) of the mandatory breath, defined as the interval from peak to Edi onset of the subsequent breath, was prolonged. The relative increase in neural T_E during the mandatory breaths was related to the time the ventilator continued to inflate beyond the end of neural T_I ($R^2 = 0.66$; $P = 0.01$). This extended time was consistent with a vagally mediated reflex when pulse inflation was delivered into early expiration.[62,63] Both inspiratory asynchrony and expiratory asynchrony were present during every mandatory breath and constituted, on average, 53% of the total breath duration (Fig. 7-9). Expiratory asynchrony may result in increased peak airway pressure as the subject attempts to terminate inspiration by recruiting the expiratory muscles.[64] It also may result in increased work of breathing and discomfort and manifest as a patient "fighting the ventilator,"[65] potentially dictating sedation.

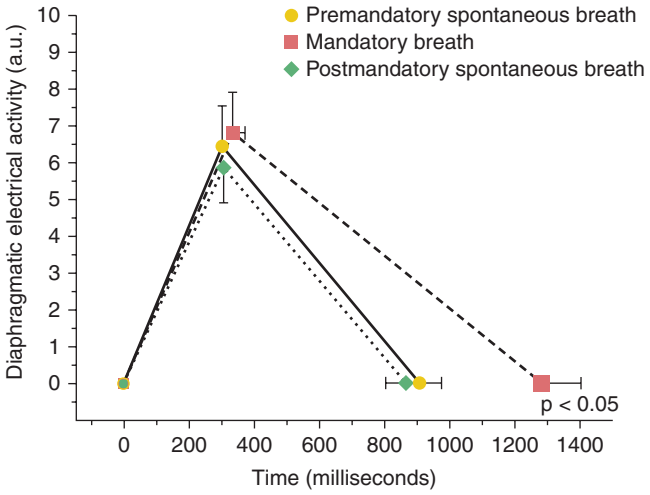

FIGURE 7-8 Diaphragmatic electrical activity (Edi) time profile for group mean data. No significant difference exists between peak Edi amplitude and neural timing on inspiration for the premandatory spontaneous breaths (*solid line*), mandatory breaths (*dashed line*), or after mandatory spontaneous breaths (*dotted line*). Neural expiratory time was prolonged significantly for the mandatory breaths (*dashed line*). The plot does not represent the shape of the Edi recruitment pattern but simply represents three points: the onset of Edi, peak of Edi, and onset of Edi of subsequent breath. Values are mean ± standard error. (Adapted, with permission, from Beck J, Tucci M, Emeriaud G, et al. Prolonged neural expiratory time induced by mechanical ventilation in infants. *Pediatr Res.* 2004;55:747–754.)

Using airway occlusion pressure ($P_{0.1}$) and mean inspiratory flow rate (V_T/T_I) as indices of neuromuscular output, Weiss et al[66] examined the effect of IMV on respiratory drive in stable ventilator-dependent patients who received mechanical ventilation for 12 to 24 hours each day. The IMV rate was initially set at 10 breaths/min and reduced gradually to 6, 3, 2, and 1 breath/min, and each level was maintained

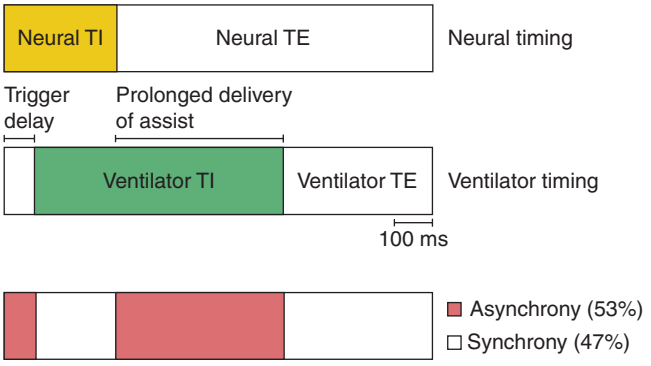

FIGURE 7-9 Inspiratory and expiratory asynchrony during mandatory breaths. Schematic of patient neural timing (*upper bar*) and ventilator timing (*middle bar*) during mandatory breaths. Upper bar shows the neural inspiratory time (T_I) (*yellow area*) and neural expiratory time (T_E) (*white area*). Middle bar shows periods of ventilator timing, including trigger delay, ventilator T_I (*green area*), and ventilator T_E. Bottom bar shows periods of infant–ventilator synchrony (*white area*) and asynchrony (*red area*). (Adapted, with permission, from Beck J, Tucci M, Emeriaud G, et al. Prolonged neural expiratory time induced by mechanical ventilation in infants. *Pediatr Res.* 2004;55:747–754.)

for 10 minutes. The V_T of the mandatory breaths was set at 8 to 12 mL/kg. End-tidal partial pressure of carbon dioxide (P_{CO_2}) and arterial oxygen saturation did not change as the IMV rate was reduced. In the presence of stable chemical input, $P_{0.1}$ and V_T/T_I measured during spontaneous breathing varied inversely with IMV rate. Increases in V_T/T_I with IMV rate reduction primarily were the result of progressive V_T augmentation because inspiratory time (T_I) and the duty cycle (T_I/T_{TOT}) remained unchanged at all IMV support levels. This V_T response probably was related to changes in CO_2 production that stimulated chemoreceptors. In acutely ill patients,[42] the effect of IMV on $P_{0.1}$, measured during spontaneous breathing, is similar to that in stable patients.[66] Using another index of neuromuscular output, dP/dt (change in pressure over change in time) of esophageal pressure at the onset of ventilator triggering, Leung et al[43] also demonstrated an inverse relationship between dP/dt and machine-assistance level.

As with neuromuscular output, IMV's effects on breathing patterns are determined by assistance level. Both V_T and unassisted breath frequency increase progressively with a decreasing IMV rate.[42,43,57,67] Because V_T of the unassisted breaths is relatively small compared with the mandatory breaths, dead-space-to-tidal-volume ratio inevitably increases. Consequently, spontaneous breathing frequency increases to maintain constant alveolar ventilation. Indeed, Pa_{CO_2} remained constant at all machine-assistance levels.[67]

The sensation of dyspnea during SIMV depends on the assistance level when applied without pressure-support ventilation (PSV) but was independent of assistance level when 10 cm H_2O of pressure support was added to the unassisted breaths.[43] During low assistance levels, dyspnea probably is secondary to increased inspiratory effort, whereas the high rate of nontriggering efforts may be responsible for the dyspnea at higher assistance levels. Knebel et al[68] also demonstrated that during the weaning trial on SIMV, the sensation of dyspnea and patient anxiety were independent of support level. In that study,[68] a PEEP of 5 cm H_2O was maintained, which might have offset the increased inspiratory muscle work with a decreasing IMV rate.[69,70]

In summary, with IMV, the neuromuscular output of both the mandatory and unassisted breaths is downregulated only at high machine-assistance levels (approximately 75% to 80% of total machine assistance).[57,58] Breath-by-breath adaptation to machine assistance does not occur. The fact that Edi was the same during assisted and preceding unassisted breathing suggests that neuromuscular output during the mandatory breaths must be determined at least in part by factors operating during the previous breath. This could be accounted for by the central neural feedback mechanism in the manner of a "memory" phenomenon as described by Eldridge[71] (see below). Neuromuscular output increases inversely with the set IMV rate. Whereas V_T and frequency increase when IMV rate decreases, neural inspiratory timing of the mandatory and unassisted breaths is of the same duration across all levels of machine assistance. Neural expiratory timing of the mandatory breaths is prolonged secondary to

mechanical T_I encroaching into neural T_E, causing expiratory asynchrony. Respiratory timing asynchrony, however, can be substantially mitigated by using inspiratory and expiratory neural triggering with a neurally adjusted ventilatory assist.[61,72,73]

Work of Breathing and Inspiratory Effort

The effect of IMV on inspiratory muscle work and inspiratory effort is, as expected, determined by the level of machine assistance, and the response is similar in adults[42,43,57] and neonates.[67] A higher number of mandatory breaths reduces total workload and inspiratory effort in patients during acute respiratory failure[42] or recovery.[43,74,75] Marini et al[42] measured work of breathing per liter of ventilation (joules per liter) and pressure-time product per breath during ACV and at SIMV support levels of 80%, 60%, 40%, 20%, and 0% of the ACV rate. When the SIMV support level was less than 80% of the ACV rate, the patient's total workload increased markedly compared with that during ACV. Moreover, at all SIMV levels, the patient expended a similar effort during both the mandatory and spontaneous breaths, as gauged by pressure-time product per breath, which reflects the energy consumed by contracting respiratory muscles (patient effort). The patient does not vary effort on a breath-by-breath basis in response to machine unloading, as confirmed by others on the basis of Edi recording.[57,60] It appears that during SIMV the heightened respiratory activity during the spontaneous breath is carried over to the subsequent mandatory breath in the manner of an "after discharge" or "memory" phenomenon.[71] In fact, when 10 cm H_2O of pressure support was applied during the intervening spontaneous breaths, inspiratory muscle effort decreased not only during the intervening breaths but also during the mandatory breaths (Fig. 7-10).[43] This afterdischarge phenomenon is central in origin and unrelated to chemoreceptor or mechanoreceptor feedback or the state of sleep or wakefulness.[71,76]

The patient workload during IMV is determined not only by machine-assistance level, but also by the IMV system employed.[74,75] Patient workload or inspiratory effort during spontaneous breathing cycles with flow-triggered SIMV was significantly less than with a pressure-triggered SIMV system,[74,75] particularly at a relatively low SIMV rate.[75] The effect, however, of the triggering system on patient mandatory breath workload is conflicting. Sassoon et al[75] demonstrated that the triggering system had no effect on patient mandatory-breath workload. In contrast, Giuliani et al[74] found that patient mandatory-breath workload was significantly less with flow-triggered than with pressure-triggered SIMV irrespective of the mandatory-breath type (whether SIMV was flow-limited or pressure-limited). Moreover, patient workload with combined flow-triggered and pressure-limited mandatory breaths was lower than the other combinations of triggering and mandatory-breath types (flow-triggered flow limit and pressure-triggered flow and pressure limit).[74] The decrease was so substantial that the pressure-time product per breath of the mandatory breath was significantly less than that of the intervening spontaneous breaths. It is not clear as to why the data of Giuliani et al[74] differed from the data of others[42,43,57,60] who demonstrated the lack of breath-by-breath adaptation to machine unloading.

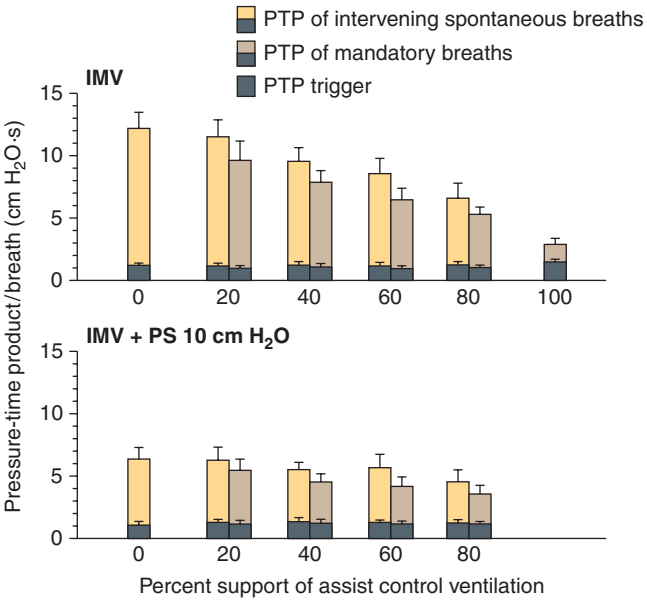

FIGURE 7-10 Pressure-time product (PTP) per breath during synchronous intermittent mandatory ventilation (IMV) in the presence and absence of pressure support (PS). The addition of 10 cm H_2O PS to the intervening spontaneous breaths decreased the overall PTP per breath. PTP per breath, however, did not differ between the mandatory and intervening spontaneous IMV breaths at each level of machine assistance, irrespective of whether PS was present or absent. (Adapted, with permission, from Leung, et al. *Am J Respir Crit Care Med.* 1997;155:1940–1948. Reprinted with permission of the American Thoracic Society. Copyright © American Thoracic Society.)

In summary, during acute respiratory failure or recovery, patient workload during SIMV remains substantial unless the SIMV support is equivalent to or greater than 80% of the support during ACV.[42,43] IMV often allows adequate gas exchange at lower support levels[77] (see the section Intermittent Mandatory Ventilation and Assist-Control Ventilation) but at the expense of increased patient workload.[42,43,57]

RATIONALE, ADVANTAGES, AND LIMITATIONS

IMV was developed as an alternative to CMV and ACV. The rationale for developing IMV was based on the premise that by maintaining spontaneous breathing amid the mechanical breaths, (a) machine breaths can be titrated to adjust alveolar ventilation, thereby decreasing the incidence of respiratory alkalemia,[78] (b) distribution of inspired gas and ventilation-perfusion to the lung base improves, and physiologic dead space decreases,[79] (c) mean airway pressure and pulmonary vascular resistance decrease, allowing PEEP titration

and therefore more effective treatment of hypoxemia,[80] and (d) pleural pressure decreases, resulting in better venous return and cardiac output.[79] Unfortunately, subsequent clinical trials did not support some of the rationales (see the section Intermittent Mandatory Ventilation and Controlled Mechanical Ventilation).

IMV's flexibility in providing a range of support levels makes it advantageous for use as a primary means of ventilator support[81] and as a method for discontinuing mechanical ventilation.[5] An inherent limitation of IMV is the fixed rate of machine breaths. When set at a very high rate, IMV functions as CMV that has been shown to rapidly lead to diaphragmatic muscle atrophy in both experimental animals[82,83] and humans.[84,85] During weaning from mechanical ventilation, the pace of decreasing the IMV rate potentially can prolong weaning when it is inappropriately slow.

INDICATIONS AND CONTRAINDICATIONS

IMV has been used as a primary means of ventilator support in postoperative patients[86] and during acute respiratory failure of various etiologies.[6,7,87–91] For treatment of acute respiratory failure in adults, North Americans apply SIMV with pressure support more frequently than ACV (49% vs. 27%, respectively).[12] A similar trend is observed in Australia and New Zealand, 41% versus 17% with other mandatory pressure-limited modes of ventilation.[13] In preterm neonates, the frequency of SIMV application in acute respiratory failure is higher than in adults, 60% versus 31% with ACV.[14] However, it needs to be emphasized that in preterm infants in addition to the ventilatory strategy used, early treatment with surfactant is essential.[92] The level of machine assistance must be tailored to the patient's ventilatory requirement. The optimal mandatory-breath settings are similar in principle to those for ACV.[93–95] A low IMV setting is contraindicated when the patient's ventilatory demand is high; likewise, the setting should not be left high after the patient's ventilatory requirement has decreased. A gradual decrease in the IMV rate is unwarranted when discontinuation from mechanical ventilation is imminent.

COMPARISON WITH OTHER MODES

Intermittent Mandatory Ventilation as a Primary Means of Ventilator Support

INTERMITTENT MANDATORY VENTILATION AND CONTROLLED MECHANICAL VENTILATION

Unlike IMV, CMV imposes a fixed breathing pattern. Hence, to some extent, a comparison favors IMV, which has been claimed to be superior to CMV for the following reasons: (a) it prevents the patient from "fighting the ventilator," reducing the need for sedation and paralysis; (b) it prevents respiratory alkalosis; (c) it improves intrapulmonary gas distribution; (d) it lowers mean airway pressure, benefiting cardiac output and preventing barotrauma; (e) it decreases oxygen consumption ($\dot{V}_{O_2}$); (f) it prevents muscle atrophy and discoordination; and (g) it improves renal function.

1. *IMV prevents the patient from "fighting the ventilator," reducing the need for sedation and paralysis.* Because the patient has no autonomy to alter breathing pattern with CMV, the patient will increase inspiratory effort, which is manifested as "fighting the ventilator" when ventilatory demand rises.[78] No studies, however, have compared the respective sedative doses used during CMV and IMV.
2. *IMV prevents respiratory alkalosis.* In a prospective study comparing IMV and CMV in patients with acute respiratory failure, CMV resulted in a mean pH of 7.49 and a Pa_{CO_2} of 32.3 mm Hg, whereas IMV resulted in a mean pH of 7.44 and a Pa_{CO_2} of 39.9 mm Hg.[7] The CMV rate, however, was set to suppress spontaneous respiratory effort, whereas, during IMV, the rate was adjusted downward continuously as long as pH remained greater than 7.30. Hence the result in favor of IMV is to be expected. When a normal pH is achieved at a low IMV rate, subsequent data suggested that it was at the expense of increased work of breathing.[42,74] Moreover, some patients on mechanical ventilation who are allowed to set their own Pa_{CO_2} do not always choose a normal level (e.g., patients with brain injury). These patients will have persistent respiratory alkalosis regardless of ventilation mode.[77,96]
3. *IMV improves intrapulmonary gas distribution.* This hypothesis is based on the premise that in the supine position, spontaneous breathing causes inspired gas to be distributed preferentially to dependent lung regions because the dependent diaphragm, which is displaced cephalad, operates at an improved mechanical advantage.[97] Conversely, during mechanical ventilation, ventilation is distributed preferentially to nondependent lung regions because the diaphragm is not used, and the nondependent lung and chest wall are more compliant.[98] Therefore, IMV's combination of spontaneous and mechanical breaths theoretically should result in a better matching of ventilation and perfusion.[99] A comparison study evaluating IMV and CMV ventilation–perfusion distribution with the inert-gas elimination technique[100] was performed in stable patients recovering from major abdominal aortic surgery.[101] During CMV, V_T was set at 14 to 16 mL/kg with a set rate of 8 to 10 breaths/min. During SIMV, the rate was set at 50% of the CMV rate (4 to 5 breaths/min); a pressure support of 5 to 8 cm H_2O was added to the intervening spontaneous breaths to overcome the ventilator circuit and endotracheal tube resistance.[102] Each ventilator mode was maintained for 45 minutes. Compared with CMV, physiologic dead space increased with SIMV (22.0% vs. 26.8%, respectively; $p < 0.05$) and was associated with a significant increase in $\dot{V}_E$, resulting in a similar Pa_{CO_2}. The SIMV perfusion distributions remained unaltered. This study, using the inert-gas elimination technique, shows that IMV does not improve ventilation–perfusion distributions.

4. *IMV lowers mean airway pressure, benefiting cardiac output and preventing barotrauma.* Because IMV intersperses spontaneous breaths between mechanical breaths, mean airway pressure averaged over time is lower than with CMV. The lower mean airway pressure results in maintenance of cardiac output. Several studies have shown a higher cardiac output with IMV than with CMV.[90,91,103] The interactions between intrathoracic pressure associated with mechanical ventilation and cardiac performance, however, are quite complex.[104] Right-ventricular and left-ventricular interaction, direct pressure on the heart, and changes in systemic and pulmonary venous return all play a role. The net effect of this interaction depends on left-ventricular filling pressure and reserve. Mathru et al[105] compared the effect of CMV, IMV with 5 cm H_2O PEEP (IMV–5PEEP), and IMV with 0 cm H_2O PEEP (IMV–0PEEP) in two groups of patients following aortocoronary bypass surgery. V_T and ventilator rate were adjusted to achieve a Pa_{CO_2} of between 35 and 40 mm Hg. One group had normal left-ventricular function. The second group had decreased left-ventricular reserve: left-ventricular diastolic pressure of greater than 16 mm Hg and ejection fraction of less than 0.6. In the first group, IMV–0PEEP resulted in an increase in cardiac output of 27% compared with CMV. In the second group, however, IMV resulted in a significant decrease in cardiac output (19%) compared with CMV. IMV–5PEEP affected cardiac output similarly to CMV. These data indicate that when compared with CMV, IMV improves cardiac output in patients with normal left-ventricular function or hypovolemia, but it may be harmful in patients with poor left-ventricular reserve.

   The frequency of barotrauma with IMV and CMV was compared in a retrospective study of 292 postoperative and nonsurgical patients who received mechanical ventilation for 24 hours or more.[106] The ventilator V_T was set at 12 to 15 mL/kg. The IMV rate was set at 6 breaths/min or lower, provided that normocapnia was maintained. If hypercapnia developed, it was treated by increasing V_T to 15 mL/kg and, if necessary, by increasing the IMV rate to 8 breaths/min. No sedation or muscle relaxants were used. In the CMV group, the rate was set at 12 breaths/min. Hypercapnia was corrected by increasing V_T. The patients were sedated and paralyzed. Compared with the CMV group, patients receiving IMV had a significantly higher peak airway pressure (34 vs. 51 cm H_2O, respectively) and PEEP/CPAP (15 vs. 27 cm H_2O, respectively). Yet the barotrauma was 22% in the CMV group compared with 7% in the IMV group. The authors speculated that the less frequent barotrauma with IMV was related to the smaller number of mechanical breaths with large V_T. Mean transpulmonary pressure, which may be responsible for the barotrauma, was not measured in either group.
5. *IMV decreases oxygen consumption*. Downs et al[7] found that $\dot{V}_{O_2}$ was lower both during mechanical ventilation and 15 minutes after its discontinuation in patients ventilated with IMV versus CMV. The authors speculated that the higher $\dot{V}_{O_2}$ on CMV could be ascribed to respiratory alkalosis[107,108] and abrupt withdrawal from mechanical ventilation rather than reflecting metabolic work of breathing. In contrast, Wolff et al[103] showed that CO_2 production ($\dot{V}_{O_2}$) tended to be lower with CMV than with IMV. Because the respiratory quotient was similar with both ventilation modes, it is reasonable to assume that $\dot{V}_{O_2}$ during CMV was lower than that during IMV. In this study, Pa_{CO_2} was 39 and 44 mm Hg on CMV and IMV, respectively, suggesting that pH was within the normal range.[103] This observation suggests that, in the absence of alkalemia, $\dot{V}_{O_2}$ is lower on CMV than on IMV.
6. *IMV prevents muscle atrophy and discoordination*. Maintaining spontaneous breathing activity during IMV has been proposed to achieve respiratory muscle conditioning and preserve respiratory muscle function.[5] The periodic hyperinflation also may reinforce coordinated breathing.[5,109] During CMV, muscle atrophy[84,85,110,111] and myofibrillar damage,[82,112,113] which account for ventilator-induced diaphragmatic dysfunction, have been demonstrated in both experimental animals and humans.[84,85] Like in experimental animals, in the human diaphragm the atrophic protein kinase B–forkhead Box-O (AKT-FOXO) signaling plays an important role in activating the ubiquitin-proteasome pathway.[114] Overexpressions of the atrophic genes, atrogin-1 and muscle ring finger-1 (MuRF-1) of the ubiquitin-proteasome pathway, are responsible for myofibril degradation and atrophy with CMV-induced diaphragm muscle inactivity.[114] Conversely, maintaining diaphragmatic activation with ACV attenuates expression of atrogin-1 (muscle atrophy F-box [MAF-box]; see Chapter 43).[83] With IMV, diaphragmatic electrical activity of both mandatory and spontaneous breaths persists. Thus, it is possible that IMV prevents respiratory muscle atrophy. This hypothesis remains to be tested.

   Respiratory muscle discoordination with IMV and CMV has not been compared. IMV's efficacy in counteracting respiratory muscle discoordination was demonstrated by Andersen et al[109] in a study of twenty-eight patients during discontinuation of mechanical ventilation. The mandatory breaths were increased gradually to 75% of the patient's $\dot{V}_E$. In contrast, Gibbons et al[115] failed to show similar results when IMV was applied to six patients receiving prolonged mechanical ventilation. The lowest spontaneous breathing rate was 29 breaths/min at the lowest IMV rate of 10 breaths/min. Gas exchange was adequate. Five of the six patients manifested breathing discoordination in the form of either ribcage or abdominal paradox. In the patients whose diaphragmatic electrical activity was measured, an electromyographic fatigue pattern also was observed. In this study, IMV was insufficient to reduce respiratory muscle workload, as reflected by the relatively high spontaneous breathing rate. IMV's efficacy in counteracting respiratory muscle discoordination appears to depend primarily on the extent of respiratory muscle unloading.

7. *IMV improves renal function*. Steinhoff et al[116] studied the effect of CMV and IMV on renal function in patients with acute respiratory failure. With CMV, the ventilator rate was set to suppress inspiratory efforts, which averaged 10 to 16 breaths/min. IMV was set at 4 to 10 breaths/min. PEEP was maintained constant during both CMV and IMV. With CMV, urinary flow and creatinine and osmolal clearance decreased, with a net effect of water retention, in comparison with IMV. Impaired renal function during CMV was attributed to the increased intrathoracic pressure, which caused stimulation of atrial stretch receptors and release of antidiuretic hormone. A more important factor may be that increased intrathoracic pressure during CMV decreases venous return, and the consequent decrease in cardiac output produces a decrease in renal plasma flow. Hence the effects of CMV and IMV on renal function are related directly to their respective effects on cardiac function.

INTERMITTENT MANDATORY VENTILATION AND ASSIST-CONTROL VENTILATION

Comparison of IMV with ACV is more appropriate than comparison of IMV with CMV because both IMV and ACV provide partial ventilator support. Few studies have compared IMV with ACV. As discussed below, these studies primarily concern effects on cardiac output,[117,118] $\dot{V}_{O_2}$,[117–119] and respiratory alkalosis.[77,117,120] (Because IMV's effects on work of breathing were discussed extensively earlier, comparison of IMV with ACV is limited to its application in the neonate.[121,122])

1. *Effect on cardiac output*. Groeger et al[117] studied the effect of SIMV and ACV in forty patients with acute respiratory failure of various etiologies other than chronic obstructive pulmonary disease. SIMV, at a set V_T of 10 to 15 mL/kg, was the initial ventilation mode in all patients, and the mandatory rate was adjusted to the minimum required to maintain a normal pH and Pa_{CO_2}. When the combined mandatory and spontaneous breathing rates were greater than 35 breaths/min, the IMV rate was increased to ensure patient comfort. The ventilator mode was then switched to ACV, and V_T, PEEP, inspiratory flow rate, and inspired oxygen fraction (FI_{O_2}) were held constant. After 30 minutes on SIMV or ACV, hemodynamic variables were measured. At this point, mean IMV rate was 7 breaths/min, with a total rate of 34 breaths/min, whereas the ACV rate was 15 breaths/min. Cardiac output, measured by thermodilution, was 6% higher with SIMV than with ACV. Likewise, studying twelve patients recovering from acute respiratory failure of various etiologies, Sternberg and Sahebjami[118] demonstrated that cardiac index was significantly higher with SIMV than with ACV (3.6 vs. 3.3 L/min/m^2). (The investigators also compared SIMV with PSV, which is discussed in the section Intermittent Mandatory Ventilation and Pressure-Support Ventilation.) The average V_T with ACV was 715 mL, whereas with SIMV it was 491 mL. The SIMV mandatory breaths were set at 75% of the ACV rate. Although the cardiac output with SIMV was significantly higher than with ACV, the changes fall within the variability of the thermodilution technique.[123] Despite the limited differences in cardiac output with IMV and ACV, IMV may be helpful in patients who demonstrate significant hemodynamic deterioration during ACV. In the original description of intrinsic PEEP (PEEPi),[124] two patients with chronic obstructive pulmonary disease developed hemodynamic compromise secondary to significant PEEPi while receiving ACV. The institution of IMV and fluid repletion produced an improvement, although cardiac output was not measured directly during either IMV or ACV. The conflicting data concerning the effects of ACV and IMV on cardiac output underscore the complex interaction between intrathoracic pressure and cardiac function.
2. *Effect on oxygen consumption*. In the above-mentioned study by Groeger et al,[117] $\dot{V}_{O_2}$ was comparable for both pressure-triggered SIMV and ACV. When the patients were grouped according to the ratio between $\dot{V}_E$ achieved by the mandatory breaths and total $\dot{V}_E$, however, the mean $\dot{V}_{O_2}$ for patients with a ratio of less than 0.5 was significantly higher during SIMV than during ACV (320 vs. 296 mL/min/m^2, respectively; $p \leq 0.05$). Conversely, in the study of Sternberg and Sebahjami,[118] when the mandatory breaths during SIMV were set at 75% of the ACV rate, $\dot{V}_{O_2}$ was unaltered during SIMV despite total frequency being higher with SIMV than with ACV (20 breaths/min vs. 12 breaths/min). In healthy subjects breathing via a mouthpiece on SIMV or ACV, $\dot{V}_{O_2}$ (measured with a metabolic cart) also was similar with the two modes.[119] With SIMV, both the V_T and mandatory-breath rate were equivalent to those of the ACV. These studies[117–119] demonstrate that compared with ACV, the degree of machine assistance during IMV determines $\dot{V}_{O_2}$.
3. *Effect on respiratory alkalosis*. Three prospective studies[77,117,120] comparing IMV and ACV showed a significantly lower pH and higher Pa_{CO_2} during IMV than during ACV (Table 7-1). Groeger et al[117] suggested that the higher Pa_{CO_2} during IMV was related to an increased dead-space-to-tidal-volume ratio, because $\dot{V}_{CO_2}$ and $\dot{V}_E$ were similar for both IMV and ACV. Conversely, Hudson et al[77] showed that the higher Pa_{CO_2} during IMV came at the expense of a high patient workload given elevated CO_2 and an unchanged alveolar ventilation level. Regardless of the mechanisms of the elevated Pa_{CO_2} during IMV, all three groups of investigators concluded that the decrease in pH and increase in Pa_{CO_2} were minimal and of questionable clinical significance. Furthermore, in studies where IMV was compared with ACV in a subgroup of patients with preexisting respiratory alkalosis, respiratory alkalosis persisted during IMV.[77,120]
4. *Effects on work of breathing in the neonate.* Kapasi et al[122] undertook a comparison of the effects of pressure-limited ACV, SIMV, and IMV on work of breathing and inspiratory effort of clinically stable neonates with respiratory distress syndrome. The mandatory breath

Sources: Adapted, with permission, from Hudson et al,[77] Groeger et al,[117] and Culpepper et al.[120]

rate with both SIMV and IMV was set the same as that of the ACV (range: 14 to 25 breaths/min). Average total respiratory rate was not significantly different among the modes (IMV, 56.3 breaths/min; SIMV, 58.3 breaths/min; ACV, 58.8 breaths/min). The work of breathing was estimated using the esophageal pressure, calculated using the Campbell diagram.[125,126] Both work of breathing and inspiratory effort were least with ACV and highest with IMV; SIMV had values between ACV and IMV. Patient–ventilator asynchrony occurred only with IMV. Jarreau et al[121] reported a similar result when comparing IMV, ACV with inspiratory pressure set at 10 to 15 cm H_2O, and spontaneous breathing on CPAP. Work of breathing with IMV was similar to that with CPAP: 0.81 versus 0.90 J/L. Work of breathing fell significantly only during ACV to 0.48 to 0.47 J/L at inspiratory pressures of 10 and 15 cm H_2O, respectively. Thus, in neonates, patient-triggered ACV provides better patient–ventilator synchrony and unloading of workload than does continuous-flow IMV.

In summary, the limited number of studies suggests minimal differences between the effects of high levels of IMV and ACV on cardiac output, $\dot{V}_{O_2}$, and respiratory alkalosis. Because of lower mean airway and intrapleural pressures, IMV should help to improve cardiovascular function in patients who exhibit hemodynamic compromise during ACV. In neonates, ACV is more effective in unloading the work of breathing and providing synchrony than IMV.

INTERMITTENT MANDATORY VENTILATION AND PRESSURE-SUPPORT VENTILATION

As with IMV, PSV provides the patient with some autonomy to alter breathing patterns in response to ventilatory demand. PSV is a form of ventilatory support in which the patient's inspiratory effort is assisted by the ventilator up to a preset inspiratory pressure level and remains at that level until a fixed[127,128] or operator-adjustable[129] ventilator cycle-off algorithm is activated. Unlike IMV, in which the number of mandatory breaths is fixed, PSV assists every breath, and the ventilator contribution to total workload is variable. Because the set inspiratory pressure is fixed with PSV, when patient ventilatory demand increases, inspiratory effort may exceed the ventilator contribution to total workload (see Chapter 8).[130,131] PSV can be added to IMV to unload inspiratory muscle work during the spontaneous breathing cycles. The addition of a small amount of PSV (5 cm H_2O) to pressure-triggered SIMV is adequate to overcome the lack of flow delivery observed with some pressure-triggered SIMV systems.[41] Higher levels of PSV not only help in overcoming the ventilator circuit and endotracheal tube resistance[132,133] but also augment V_T and unload the elastic work of the spontaneous breaths.[134,135] In one study of a small number of patients with acute respiratory failure,[136] PSV application at levels of up to 30 cm H_2O during SIMV (IMV rate of 6 to 10 breaths/min) and PEEP of 3 to 13 cm H_2O did not result in cardiovascular compromise. In clinically stable preterm infants, application of pressure support to the intervening spontaneous breaths to deliver V_T of 5 to 8 mL/kg stabilized breathing pattern,[137] and prevented an increase in inspiratory effort when SIMV rate was reduced.[138] Comparison between IMV and PSV is discussed pertaining to cardiac output,[118] ventilation–perfusion distribution,[139] and unloading of patient effort.[84]

1. *Effects on cardiac output.* Hemodynamics during SIMV and PSV were studied in critically ill patients by initially applying ACV to the patients.[118] The V_T of the mandatory breaths with SIMV then was set the same as that of ACV, at a rate of 75% of the ACV rate. With PSV, the inspiratory pressure was set to produce a V_T similar to that of ACV (average pressure of 21 cm H_2O). Cardiac output

(measured by thermodilution), oxygen transport, and $\dot{V}_{O_2}$ were the same for both ventilation modes. As a primary means of ventilatory support, both SIMV and PSV have comparable effects on hemodynamics.

2. *Effects on ventilation–perfusion*. Valentine et al[139] studied the effect of SIMV, PSV, and airway pressure-release ventilation (see in the section Intermittent Mandatory Ventilation and Airway Pressure-Release Ventilation) on ventilation–perfusion distribution in post–cardiac surgery patients who were ready to be weaned; this section discusses only the comparison between SIMV and PSV. SIMV was the initial ventilatory support mode. The IMV rate was adjusted to maintain a pH of greater than 7.35. With PSV, pressure was titrated to achieve a mean end-tidal P_{CO_2} of 40 mm Hg. Ventilation–perfusion distribution was assessed using the inert-gas elimination technique.[100] The dispersion of ventilation–perfusion ratios, calculated as the logarithmic standard deviation of perfusion (log SD$\dot{Q}$) and ventilation (log SD$\dot{V}$), was similar for SIMV and PSV. Right-to-left intrapulmonary shunt and fractional dead-space ventilation did not differ significantly. Table 7-2 shows the effects on arterial blood gases, respiratory mechanics, and $\dot{V}_{O_2}$. Differences in arterial blood gases were of questionable clinical significance. Peak airway pressure was significantly higher with SIMV, but mean transpulmonary pressure was comparable. As sole ventilator support, SIMV and PSV provide comparable and adequate gas exchange in postoperative patients who were ready to be weaned. No study has yet compared the efficacy of IMV and PSV as a primary means of ventilator support during acute respiratory failure.

3. *Effects on patient effort*. Leung et al[43] carried out a head-to-head comparison of the efficacy of SIMV and PSV in unloading inspiratory effort at various levels of assistance. The rate of change in inspiratory effort with increasing assistance levels, estimated as pressure-time product per minute, did not differ between the two modes. Unloading efficacy, however, differed according to the level of assistance. From 0% to 60% of maximum, the decrease in pressure-time product per minute was greater with PSV than with SIMV. At a higher assistance level, the converse was observed (Fig. 7-11). Frequency decreased linearly with increase in PSV. With SIMV, frequency changed little until a high assistance level was provided (Fig. 7-11).[140] Thus, when a high assistance level is needed, both SIMV and PSV provide comparable assistance. At low to medium assistance levels, however, a greater decrease in patient effort with PSV makes it more useful clinically than SIMV. Leung et al[43] also assessed the patient's wasted efforts or nontriggered attempts during both SIMV and PSV. The number of nontriggered attempts is proportional to the assistance level and highest at 100% of machine assistance (29% with SIMV and 26% with PSV). The breaths preceding the nontriggered attempts had a shorter total duration and expiratory time, higher V_T, and higher dynamic PEEPi than did the breaths preceding triggered breaths. This observation suggests that nontriggered attempts resulted from an inspiratory effort that was insufficient to overcome the elevated recoil pressure associated with dynamic hyperinflation. Thus, increasing the ventilator assistance level decreases inspiratory muscle effort but also increases ineffective triggering.[43,141] Ineffective

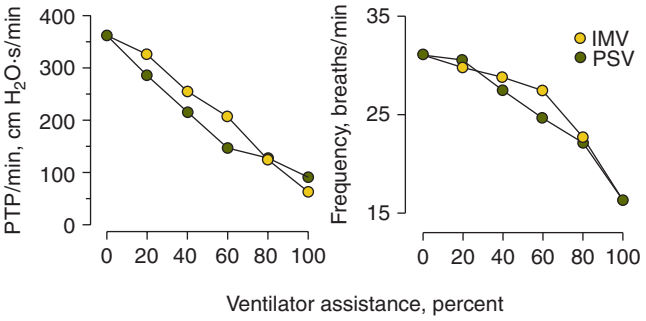

FIGURE 7-11 Changes in PTP per minute (*left panel*) and frequency (*right panel*) as intermittent mandatory ventilation (IMV) and pressure-support ventilation (PSV) were increased progressively. PSV of 100% represents the level necessary to achieve a V_T equivalent to that during ACV (10 mL/kg); IMV 100% is the same ventilator rate and V_T as during ACV. triggering is associated with prolonged duration of mechanical ventilation.[142]

INTERMITTENT MANDATORY VENTILATION AND AIRWAY PRESSURE-RELEASE VENTILATION

Airway pressure release ventilation (APRV) consists essentially of two CPAP levels with a transient decrease or "release" of airway pressure from a higher CPAP to a lower CPAP for a set release time. Spontaneous breathing is allowed to occur between airway pressure releases.[128,143–145] The pressure gradient between the two CPAP levels and the frequency of releases determine the level of ventilator support (see Chapter 11). The original version of APRV used a short release time, and in the absence of spontaneous breathing, APRV resembled pressure-controlled inverse-ratio ventilation.[143] The modified version, in which the inspiration-to-expiration (I:E) ratio is adjustable, is termed *biphasic intermittent positive airway pressure*.[145] The primary indication for APRV is the provision of ventilation during an oxygenation crisis.[143] Although the indications and operating principles of IMV and APRV differ significantly, both modes allow the patient to breathe spontaneously between machine-cycled breaths.[143,144] Comparison of IMV with APRV is discussed with regard to its efficacy as a primary means of ventilator support in patients with acute respiratory distress syndrome (ARDS)[146] in relation to gas exchange,[139,146–149] hemodynamics,[146,148,150] lung recruitment,[151] breathing comfort,[148,152] intubation duration, and sedative use.[146,153]

Varpula et al[146] undertook a randomized, controlled comparison of pressure-limited SIMV (with 10 cm H_2O of pressure support added to the unassisted breaths) and APRV in patients with ARDS. The primary end point was the number of ventilator-free days from the time of randomization to day 28. The secondary end points were the effect on gas exchange, hemodynamics, and sedative use. PEEP was set slightly above the lower inflection point on the pressure-volume curve obtained during paralysis (or if not detected, at 10 cm H_2O). The upper inflection point was never exceeded (or if not detected, the inspiratory pressure was set at less than 35 cm H_2O). The pressure-release frequency with APRV and the machine assistance rate with SIMV were similar at 12 breaths/min. The I:E ratio with APRV was set at 4:1; with SIMV, it was set at 1:2 and adjusted to 2:1. Ventilator-free days, gas exchange, hemodynamics, and sedative dosage were comparable with the two modes, although average inspiratory pressure was significantly lower with APRV than with SIMV (25.9 vs. 28.6 cm H_2O). Moderate hypercapnia developed during the first study day in both groups but returned toward normal after 4 days. The effects of SIMV and APRV on gas exchange and hemodynamics appear comparable in patients with lung injury[147,148] or after cardiac surgery.[139] In contrast to earlier studies, recently, one trial in patients with ARDS demonstrated the superiority of APRV over SIMV in terms of gas exchange and mortality.[149] Mortality was 31% with APRV compared to 59% with SIMV. Unfortunately, this study was a retrospective trial conducted over 6 years with SIMV applied in the first 3 years followed thereafter with APRV; consequently, ventilator settings were not well matched.[149] Application of short-term APRV also proved superior to SIMV in patients who underwent coronary artery bypass surgery.[150] Intubation duration was approximately 4 hours shorter with APRV than with SIMV (mean: 10.1 vs. 14.7 hours). Analgesic and sedative dosage also was less with APRV than with SIMV. This study, however, was a nonrandomized, open clinical trial.

In a recent, prospective, randomized trial in acute lung injury using similar ventilator settings as above,[146] Varpula et al[151] compared the effects APRV ($n = 13$) and SIMV plus PSV ($n = 10$) in recruiting nonaerated lungs. The investigators hypothesized that a strategy employing spontaneous breathing with active diaphragmatic contractions, as with APRV, is associated with better aeration of the dependent lung region.[98] The degree of lung recruitment was estimated using computer-assisted tomographic densitometry technique at the beginning of randomization, and after 7 days of the assigned ventilator mode. On day 7, the median peak Paw was significantly lower with APRV than with SIMV: 24.0 versus 30.4 cm H_2O. The computer-assisted tomographic number (in Hounsfield units) was similar with both APRV and SIMV at both the carinal and dependent diaphragmatic level. Thus, APRV did not appear to improve aeration of the consolidated lung parenchyma.

Breathing comfort during SIMV and APRV were evaluated in inexperienced healthy subjects breathing via a mouthpiece and compared with PSV. SIMV was set at 8 breaths/min, V_T at 5 mL/kg, and PEEP at 5 cm H_2O. The low and high PEEP levels with APRV were set at 5 and 10 cm H_2O, the release rate was 8 breaths/min, and the I:E ratio was 1:2. PSV was set at 10 cm H_2O with PEEP of 5 cm H_2O. Breathing comfort was measured with a visual analog scale (0 to 10 cm). PSV achieved the greatest comfort, SIMV the worst, and APRV fell between PSV and SIMV (2.03, 5.38, and 4.12 cm, respectively). Unfortunately, flow-limited SIMV was employed rather than pressure-limited SIMV (both APRV and PSV are pressure-limited ventilation modes).

INTERMITTENT MANDATORY VENTILATION AND PROPORTIONAL-ASSIST VENTILATION, ADAPTIVE-SUPPORT VENTILATION, PRESSURE-REGULATED VOLUME CONTROL VENTILATION, AND VOLUME SUPPORT VENTILATION

Proportional-Assist Ventilation. Proportional-assist ventilation (PAV) is a mode in which the ventilator instantaneously generates pressure in proportion to the patient's effort (see Chapter 12).[154] The ventilator amplifies the patient's inspiratory effort without any preselected target volume or pressure. A randomized crossover comparison of continuous-flow IMV versus PAV was conducted in

thirty-six preterm infants.[155] The inspiratory pressure with IMV was set to deliver a V_T of 4 to 6 mL/kg. The IMV rate was not reported. With PAV, the volume-assist gain was adjusted to decrease lung elastance to its normal value, whereas the flow-assist gain was set at −20 cm H_2O/L/s. Each mode was applied for 45 minutes. With PAV, peak and mean airway pressures and transpulmonary pressure were significantly lower, frequency was higher, and V_T was comparable to that with IMV, resulting in a higher $\dot{V}_E$. Pa_{CO_2}, however, remained the same as with IMV, and Pa_{O_2} was higher. There were no significant differences in the number of apneic or hypoxemic episodes. The lower transpulmonary pressure with PAV might help to prevent lung injury during prolonged mechanical ventilation. The results in preterm infants were similar to those in an earlier short-term trial in a few adult patients.[156]

Adaptive-Support Ventilation. Adaptive-support ventilation (ASV) is based on the work by Otis et al[157] and Mead et al,[158] who demonstrated that any given level of alveolar ventilation has an optimal respiratory frequency that is least costly in terms of respiratory work: the frequency at which the respiratory muscles develop the least-average force or tension.[158] ASV is a mode that can alternate between pressure control and pressure support, relying on closed-loop regulation of ventilator settings that respond to changes in respiratory system mechanics and spontaneous breathing efforts (see Chapter 15). ASV adjusts inspiratory pressure, I:E ratio, and mandatory rate to maintain the target minute ventilation and respiratory rate within a frame designed to avoid both rapid, shallow breathing and excessive inflation volumes.[159] Tassaux et al[160] compared the short-term effects of ASV versus SIMV plus pressure support on patient–ventilator interaction in patients ready to be weaned from mechanical ventilation. ASV achieved a $\dot{V}_E$ similar to that of SIMV. Central neural drive, however, estimated as $P_{0.1}$, and sternocleidomastoid electrical activity, measured with surface electrodes, were reduced markedly. Thus, ASV provided comparable total $\dot{V}_E$ but with a significantly decreased inspiratory load than did SIMV plus pressure support.

Pressure-Regulated Volume-Controlled Ventilation. Pressure-regulated volume-controlled ventilation (PRVCV) is a dual-control, breath-to-breath mode. PRVCV has both the benefits of pressure-controlled ventilation, with a constant V_T, and automatic weaning from pressure limit as patient compliance improves and/or patient effort increases (see Chapter 15). Four prospective, randomized trials have compared the efficacy of PRVCV and IMV with different primary goals in preterm infants.[161–164] Two trials were short-term in stable preterm infants during the weaning phase,[161,162] and two trials during acute respiratory failure.[163,164] In the stable infants, SIMV was compared with PRVCV on the effects of respiratory mechanics and gas exchange.[161,162] The SIMV mandatory breaths consisted of volume guarantee or pressure-regulated volume-controlled breaths. Abubakar and Keszler[161] concluded that SIMV resulted in higher work of breathing than PRVCV on the basis of a high respiratory rate, although work of breathing was not directly measured. Scopesi et al[162] demonstrated that SIMV was associated with lower mean Paw and higher variability in V_T than observed with PRVCV. From those studies[161,162] it is not clear whether PRVCV offers advantage over SIMV because the sample size was small (ten to twelve patients), and trial duration was short (20 minutes to 2 hours).

In infants with respiratory distress syndrome, Piotrowski et al[163] studied infants younger than 3 days old whose birthweight was less than 2500 g. Thirty infants received continuous-flow IMV, and twenty-seven received PRVCV; the average Paw were 18.6 and 16.2 cm H_2O, respectively. The IMV rate was selected by the clinician. With PRVCV, the V_T was set at 5 to 6 mL/kg. The primary end point was duration of mechanical ventilation and incidence of bronchopulmonary dysplasia. The secondary end point was complications from mechanical ventilation, consisting of air leaks, intraventricular hemorrhage, and hemodynamic instability. PRVCV did not decrease duration of mechanical ventilation or incidence of bronchopulmonary dysplasia, although it decreased the incidence of high-grade intraventricular hemorrhage (11% vs. 35%). The benefit may have occurred in part because PRVCV delivers a stable volume. In preterm newborns, large fluctuations in intrathoracic and arterial pressures cause variations in cerebral blood flow velocity that is a risk factor for intraventricular hemorrhage.[165] In the second trial, D'Angio et al[164] enrolled a large number of low-birthweight infants (500 to 1249 g) who were younger than 6 hours of age. Infants were assigned to pressure-limited SIMV (n = 108) or PRVCV (n = 104) until extubation, death, or meeting predetermined failure criteria on the assigned mode. With SIMV, no pressure support was applied to the spontaneous breaths. Average Paw measured at 6 hours and 12 hours after SIMV application were 15.0 and 14.0 cm H_2O, respectively, and after PRVCV were 13.8 and 12.7 cm H_2O, respectively. The average V_T for SIMV at 6 hours and 12 hours was 18.4 and 17.8 mL/kg, respectively; whereas V_T with PRVCV was 16.0 and 14.1 mL/kg, respectively. The average set ventilator rate with SIMV at 6 hours and 12 hours was 35 and 30 breaths/min, respectively; with PRVCV, the rate was 40 breaths/min at both 6 hours and 12 hours. Differences in measured ventilator variables between SIMV and PRVCV were not significant. The cumulative percentage of infants alive and extubated at 36 weeks (84%) was similar for both SIMV and PRVCV (88 out of 105 infants for SIMV; 87 out of 104 infants for PRVCV). The percentage of infants who failed the assigned mode tended to be less with PRVCV than with SIMV, 20% versus 33%. Complications associated with prematurity and mechanical ventilation such as bronchopulmonary dysplasia, intraventricular hemorrhage, or retinopathy of prematurity were similar. Interestingly, with both SIMV and PRVCV, V_T was remarkably higher than that recommended with a protective ventilatory strategy.[166] Yet, when ventilator settings are nearly matched, application of SIMV or PRVCV appears to have a similar impact

on survival, extubation rate, or complications rate in preterm infants with acute respiratory failure.

Volume-Support Ventilation. Volume-support ventilation (VSV), or PSV combined with volume guarantee, is PSV that uses V_T as feedback control for continuously adjusting the pressure-support level. All breaths are patient-triggered, pressure-limited, and flow-cycled.[52] Prospective comparisons between VSV and SIMV in preterm infants were conducted during the acute[167] and stable phase of respiratory failure.[162,168] Nafday et al[167] randomized preterm infants following surfactant treatment for respiratory distress syndrome into VSV (n = 16) or pressure-limited SIMV (n = 18) applied for 24 hours. V_T with VSV was set at 5 mL/kg. Ventilator settings were adjusted to achieve predetermined arterial blood-gas values. After 24 hours, attending physicians provided ventilation management as clinically indicated. Mean airway pressure decreased over time in both VSV and SIMV groups, although the decrease was faster in the SIMV group. Both groups had similar survival rates at the time of discharge (86% for VSV, and 94% for SIMV), and complications associated with prematurity and mechanical ventilation. That is, VSV did not offer improved clinical outcomes compared with SIMV.

Two prospective, short-term trials of stable preterm infants during the weaning phase compared VSV and pressure-limited SIMV for either 30 minutes[168] or 20 minutes.[162] In the first trial,[168] following either VSV or SIMV for 30 minutes, VSV was applied for 24 hours. The attending physician, however, had discretion to select a ventilation mode according to the infant's condition. VSV was successfully applied for 24 hours in twenty-one of 25 infants (84%), in those infants a significantly longer duration of rhythmic breathing was observed during the 30-minute trial. VSV provided comparable fluctuations in ventilation and oxygenation, but with a lower Paw than with SIMV (15.4 vs. 19.2 cm H_2O, respectively), and shorter T_I (0.29 vs. 0.35 seconds, respectively). In infants with high respiratory drive, however, hyperventilation occurred with VSV, which dictated a switch to SIMV.[168] Consistent with the first trial, the second trial also demonstrated lower Paw with VSV compared with SIMV (11.2 vs. 18.2 cm H_2O, respectively). In summary, VSV, in the short term, did not offer ventilatory advantage over SIMV in acute or stable preterm infants with respiratory distress syndrome, except for a lower Paw in the stable infants.

Intermittent Mandatory Ventilation as a Weaning Method

INTERMITTENT MANDATORY VENTILATION, PRESSURE SUPPORT, AND T PIECE

IMV was first used in adult patients as a means of discontinuing mechanical ventilation.[5] This method was claimed to be more efficient, safer, and more readily accepted by the patient, and it avoided the necessity of setting up a T-piece circuit. Although preceding ventilator support may be with either ACV or IMV, IMV is applied when the patient is ready to be weaned. The number of mandatory breaths is reduced gradually (1 to 3 breaths/min) at 1- to 4-hour intervals, provided that arterial pH remains greater than 7.30[7] or 7.35,[169] regardless of other physiologic measurements. An IMV rate of zero or close to zero is maintained for several hours, or for as long as 24 hours, before extubating the patient.

With PSV as a weaning method, the pressure level is set initially at a maximum, defined as the level that produces a V_T of 10 to 12 mL/kg; then the pressure support level is reduced according to the patient's respiratory frequency.[170] When the pressure support level reaches 5 cm H_2O, extubation is considered.

With a T piece, once the patient meets predefined weaning criteria, the patient is placed on a T-piece circuit.[171] Progressively longer intervals of spontaneous breathing through a T piece are alternated with ACV. Extubation is considered when the patient can sustain breathing through a T piece for 1 to 2 hours. The early claim for IMV's superiority over a T piece was not based on a controlled study, and subsequent retrospective[172] and prospective studies[173,174] failed to demonstrate IMV's superiority. Studies comparing IMV and PSV showed either a significantly reduced duration[175] or a tendency for a shorter weaning time[176] with PSV. As PSV grew in popularity, two prospective, randomized, controlled multicenter trials[177,178] simultaneously compared the three weaning modalities: SIMV, PSV, and T piece. These trials laid to rest IMV's claim to superiority over T piece and PSV.

Brochard et al[177] studied 109 patients who met three of the four defined weaning criteria and had failed a 2-hour T-piece trial. Patients were randomized to SIMV (n = 43), PSV (n = 31), and T piece (n = 35). Weaning failure was defined as continued inability to be weaned after 21 days on the same mode, the need for reintubation after 48 hours of extubation, or intercurrent events (e.g., cardiac ischemia or nosocomial pneumonia) within 72 hours in the selected mode. The initial SIMV rate was set at half the total frequency during ACV or CMV, keeping V_T and flow rates constant (mean initial SIMV rate of 9.5 breaths/min). Once or twice a day, the SIMV rate was decreased by 2 to 4 breaths/min if patients did not demonstrate signs of poor tolerance. When a patient demonstrated poor tolerance, the SIMV rate was increased to its preceding level. When a patient tolerated a SIMV rate of 4 breaths/min or less over 1 day, tracheal extubation was performed. The T-piece method consisted of a gradual lengthening of the periods of disconnection from the ventilator. The initial T-piece trial was set shorter than the initial tolerance duration (mean duration: 38 minutes). The number of T-piece trials depended on the length of disconnection and on nurse availability and varied from three to eight trials per day. The T-piece periods were lengthened incrementally twice a day. Between the T-piece trials, ACV was applied. When the duration of a T-piece trial had reached 2 hours with adequate gas exchange, tracheal extubation was performed. In the patients assigned to PSV,

	Time to Extubation (Days)		
	T Piece	**PSV**	**SIMV**
Brochard et al[177]	8.5 ± 8.3	5.7 ± 3.7	9.9 ± 8.2
Esteban et al[178]	3 (2, 6)	4 (2, 12)	5 (3, 11)

[a]Risk differences expressed as the difference in proportions of successfully weaned subjects between respective weaning methods. Negative numbers imply lower success rates and positive numbers higher success rates. The 95% confidence intervals follow risk differences in parentheses. Time to extubation is presented as either mean ± SD[177] or median (first and third quartiles).[178]

Sources: Adapted, with permission, from Brochard et al,[177] Esteban et al,[178] and Butler et al[179] for the risk-difference calculations.

the initial pressure was adjusted until the frequency ranged between 20 and 30 breaths/min. Twice a day, the pressure was decreased by 2 to 4 cm H_2O if the patient did not show any signs of poor tolerance; if tolerance worsened, pressure was increased to its preceding level. When the patient tolerated a PSV level of 8 cm H_2O or less throughout a 24-hour period, tracheal extubation was performed. During the 21-day trial, the probability of being weaned was twice as high with PSV compared with SIMV or T piece. Weaning duration did not differ between SIMV and T piece but was significantly shorter with PSV than with the other two modalities (6 vs. 9 days, respectively). The number of weaning success patients was significantly larger with PSV (77%) than with SIMV (58%) or T piece (57%) (Table 7-3).

In the study by Esteban et al,[178] 130 patients who met two of three weaning criteria and had failed a 2-hour T-piece trial were randomly assigned to one of four methods: SIMV ($n = 29$), PSV ($n = 37$), intermittent T-piece trials (two or more per day) ($n = 37$), and a once-daily T-piece trial ($n = 31$). The initial SIMV rate was set at half the frequency during ACV (average 10 breaths/min). When the patient tolerated it, SIMV was reduced twice a day by 2 to 4 breaths/min. Tracheal extubation was performed when the patient tolerated an SIMV rate of 5 breaths/min for 2 hours without signs of distress. With the PSV, the initial pressure was adjusted to achieve a frequency of 25 breaths/min or less (average pressure of 18 cm H_2O). According to patient tolerance, pressure was reduced at least twice a day by 2 to 4 cm H_2O. When the patient tolerated a PSV level of 5 cm H_2O for 2 hours, tracheal extubation was performed. With intermittent T-piece trials, the patient breathed through a T-piece circuit or a continuous-flow CPAP of 5 cm H_2O or less at least twice a day. Trial duration was increased gradually, and when the patient tolerated a 2-hour trial, extubation was performed. Between the T-piece trials, ACV was applied. With the once-daily T-piece method, the patient breathed through a T-piece circuit, after which ACV was resumed for 24 hours. Trial duration was increased gradually. When the patient tolerated a 2-hour trial, extubation was performed. Weaning failure was defined as the need for reintubation within 48 hours after extubation or the inability to extubate the patient after 14 days. The median successful weaning duration was 5 days for SIMV, 4 days for PSV, 3 days for intermittent T-piece trials, and 3 days for the once-daily T-piece trials. The rate of successful weaning for the once-daily T-piece method was three times faster than with SIMV (rate ratio: 2.83) and two times faster than with PSV (rate ratio: 2.05). The rate of success for intermittent or once-daily T-piece trials did not differ significantly. The percentage of patients weaned successfully was 69%, 62%, 82%, and 71% for SIMV, PSV, intermittent T piece, and once-daily T piece, respectively.

These two large randomized studies showed conflicting results. In the study of Brochard et al,[177] PSV was superior to T piece and SIMV. In the study of Esteban et al,[178] T piece was superior to PSV and SIMV. Despite the subtle differences in methodology, both trials demonstrated that weaning time

was the longest with SIMV.[179] Thus, both T piece and PSV were superior to SIMV (see Table 7-3).[180,181]

In weaning preterm infants, Dimitriou et al[182] compared pressure-limited SIMV with ACV in two separate randomized, controlled trials. With both SIMV and ACV (n = 20 each), inspiratory pressure was reduced in decrements of 2 cm H_2O until a defined target pressure tailored to the infant's body weight was reached. With SIMV, in addition to decreasing pressure, the SIMV rate was reduced in decrements of 5 breaths/min until a target rate of 20 breaths/min was reached in the first trial. In the second trial, the target was 5 breaths/min. The frequency of decrements in pressure or SIMV rate was not reported. When the infants tolerated the target pressure (for ACV) or target pressure and rate (for SIMV), ventilation was switched to CPAP for 1 hour before extubation. The end-expiratory pressure was maintained at 3 cm H_2O throughout the study. Weaning failure was defined as either the failure to achieve a reduction in ventilator support within 48 hours or requirement for reintubation within 48 hours of extubation. Reintubation was indicated when respiratory acidosis developed or frequent apneas or one major apnea occurred. In the first trial, there were no significant differences in the success rate with ACV or SIMV (70% vs. 75%) or the duration of successful weaning (median: 33 vs. 30 hours). In the second trial, differences between the weaning success rates were not significant, but the median weaning duration was significantly shorter with ACV (24 hours) than with SIMV (50 hours) ($P < 0.05$). A reduction in inspiratory pressure alone with ACV is favored in weaning preterm infants from mechanical ventilation than with SIMV, in which both inspiratory pressure and rate are reduced.

In weaning children ages 1 month to 4 years, Moraes et al[34] compared pressure-limited IMV (n = 35) and SIMV plus pressure support (n = 35). Weaning began when peak inspiratory pressure was less than 25 cm H_2O and $FI_{O_2} \leq 0.6$ (Time 0). Respiratory rate was reduced gradually by 3 to 5 breaths/min to 10 breaths/min. Then, PEEP was gradually reduced to 7 cm H_2O. These ventilator settings were maintained for 12 to 24 hours. Extubation readiness was assessed daily for 2 hours while on $FI_{O_2} \leq 0.5$ with oxygen saturation as measured using pulse oximetry (Sp_{O_2}) ≥95%, and PEEP 5 cm H_2O; in patients on SIMV plus pressure support, the pressure support level was tailored to the size of the endotracheal tube (pressure support of 10, 8, and 5 cm H_2O for endotracheal tube size of 3.0 to 3.5; 4.0 to 4.5; and >5.0, respectively).[183] The average duration of weaning to extubation was 1 day (range: 1 to 6 days) for both groups. The frequency of extubation failure of 5.7% (because of upper respiratory distress) was also similar in both groups. Unlike adults[177,178] or preterm infants,[182] the ventilator mode has no effects on the outcome of discontinuation from mechanical ventilation in children.[34]

INTERMITTENT MANDATORY VENTILATION AND MANDATORY MINUTE VOLUME, ADAPTIVE-SUPPORT VENTILATION

Mandatory minute ventilation (MMV) allows the patient to breathe spontaneously yet ensures that a preset minute ventilation is maintained should the patient's spontaneous ventilation decline below the set level.[184] MMV was developed to overcome certain ineffective features of IMV.[185] When the set mandatory IMV rate is less than required to achieve adequate ventilation, alveolar hypoventilation will ensue whenever a patient's total minute ventilation falls below a critical level. This drawback of IMV can be circumvented with MMV, which actuates a feedback control so that the ventilator provides pressurized breaths of a fixed volume to achieve a preset total minute ventilation.

Weaning with IMV and MMV was studied prospectively in forty patients recovering from acute respiratory failure caused by parenchymal lung injury and chronic airflow obstruction.[186] After meeting defined weaning criteria, the patients were randomized to IMV (n = 18) or MMV (n = 22). In the IMV group, IMV rate was decreased by 2 breaths/min at 3- to 4-hour intervals during the daytime only until the IMV rate was equal to zero. Weaning was considered complete after 4 hours of breathing on CPAP. In the MMV group, MMV was set at 75% of the total minute volume preceding the weaning trial; this was achieved by decreasing frequency while maintaining a V_T of 12 mL/kg as a reference value. Weaning was considered complete after 4 hours of independent spontaneous breathing. Weaning failure was defined as an inability to complete the trial or the need for ventilator support for the same underlying disease. Successful weaning was comparable: 86% for IMV and 89% for MMV. The weaning trial was longer in the IMV group (33 hours) than in the MMV group (4.75 hours).

In neonates with healthy lungs who were intubated for medical or surgical procedures, Guthrie et al[187] conducted a crossover design, short-term trial (2 hours) of MMV versus SIMV. Mandatory breaths with both MMV and SIMV were flow-limited, volume-cycled (V_T 4 to 6 mL/kg), whereas spontaneous breaths were augmented with pressure support. Both modes had comparable efficacy in carbon dioxide removal, yet with lower mean Paw with MMV. Mean rate of the mandatory breaths was also significantly lower with MMV than with SIMV (4.1 vs. 24.2 breaths/min, respectively). The authors postulated that both the reduced rate of the mandatory breaths and low mean Paw with MMV potentially reduced bronchopulmonary dysplasia complications associated with mechanical ventilation. Nevertheless, a prospective long-term follow-up is required. Moreover, SIMV as a weaning method has not been compared with MMV in neonates.

SIMV and ASV were compared as weaning modalities in a prospective, randomized study in post–cardiac surgery patients.[188] With both ASV (n = 18) and SIMV (n = 16), the patients underwent three ventilation phases. With ASV, in phase 1, the initial settings were the ideal body weight, the desired minute volume at the default value of 100 mL/kg of ideal body weight, and peak airway pressure of less than 25 cm H_2O. Adjustment of minute volume was dictated by a Pa_{CO_2} of less than 38 or greater than 50 mm Hg. Phase 1 ended when there were no controlled breaths for 20 minutes. Phase 2 was a continuation of phase 1; it ended when pressure support was decreased to 10 cm H_2O (±2 cm H_2O)

and maintained for 20 minutes. The patient then entered into phase 3, where pressure support was set manually at 5 cm H_2O for 10 minutes. When the patient showed satisfactory tolerance, tracheal extubation was performed. The initial settings for phase 1 in the SIMV group consisted of a V_T of 8 mL/kg and an SIMV rate adjusted to achieve a Pa_{CO_2} of between 38 and 50 mm Hg. The SIMV rate was then set at 12 breaths/min. When spontaneous breaths exceeded 6 breaths/min for 20 minutes, the patient was switched to PSV of 10 cm H_2O (phase 2). The patient was reassessed 20 minutes later for further reduction of PSV or returned to SIMV. If the patient tolerated it, PSV was reduced to 5 cm H_2O (phase 3), as in the ASV group. There was no difference in duration of tracheal intubation, and all patients except for two (one in each group) were extubated within 6 hours. In the ASV group, patients required fewer manipulations of ventilator settings and endured fewer high inspiratory pressure alarms. This study was performed in postoperative patients who had received mechanical ventilation for less than 24 hours before weaning attempts. Because mechanical ventilation duration before weaning influenced the weaning success rate,[189] the response of critically ill patients to the preceding weaning methods may be different.

VARIATION IN DELIVERY AMONG VENTILATOR BRANDS

No study has yet evaluated the response of various ventilators in the SIMV mode to patient flow demand or vice versa. As part of a study evaluating the response of muscle pressure generation to various unloading conditions with assisted ventilation, Mecklenburgh and Mapleson[190] evaluated the response of three ventilators—Hamilton Veolar, Engstrom Elvira, and Puritan Bennett 7200—in the SIMV mode in healthy subjects. V_T was set at 1.5 times the spontaneous V_T and the SIMV rate at 6 breaths/min. The flow waveform was set to "sine wave." Muscle pressure was calculated using the equation of motion from instantaneous airway pressure, flow, and volume with the respiratory system's known resistance and elastance.[191] Amplitude of muscle pressure generation was similar across the three ventilators. Contraction time for mechanical breaths was shortest with the Engstrom Elvira at 1.03 seconds versus 1.38 seconds for the Hamilton Veolar and 1.37 seconds for the Puritan Bennett. For unassisted breaths, contraction time again was shortest with the Engstrom Elvira (1.33 vs. 1.58 seconds for the Hamilton Veolar and 1.70 seconds for the Puritan Bennett). Because V_T was set constant for all three ventilators, the short contraction time led to higher peak airway pressures with the Engstrom Elvira (9.4 vs. 3.9 cm H_2O for the Hamilton Veolar and 4.0 cm H_2O for the Puritan Bennett). Despite the set sine wave, the Engstrom Elvira flow waveform that accounted for the short contraction time was more of a ramp than a sine wave. The investigators concluded that differences in subject responses to different ventilators were related to flow or pressure waveforms and that different subjects may prefer different waveforms.

ADJUSTMENT AT THE BEDSIDE AND TROUBLESHOOTING

SIMV settings consist of the trigger sensitivity, V_T, flow, and the IMV rate for the flow-limit volume-cycled mandatory breaths. For pressure-limit time-cycled breaths, the ventilator settings include the trigger sensitivity, inspiratory pressure, inspiratory time, pressure attack rate, and IMV rate. If the dual hybrid breath-to-breath volume guarantee is applied, V_T is set instead of inspiratory pressure. With either flow-limited or pressure-limited mandatory breaths, pressure support, but not volume support, can be added to the spontaneous breaths to overcome circuit and endotracheal tube resistance, and unload inspiratory muscle work.[43] Monitoring of the patient and the ventilator output waveforms cannot be overemphasized.[192] For example, palpable abdominal contractions suggest expiratory muscle recruitment and possible encroachment of mechanical inspiratory time into neural expiratory time.[64] Adjustment to reduce mechanical inspiratory time can be made by increasing flow rate (flow-limited breaths) or reducing inspiratory time (pressure-limited breaths). Despite the risk associated with tachypnea when mechanical inspiratory time is reduced, Laghi et al[193] demonstrated an increase in exhalation time and decrease in intrinsic PEEP, changes conducive to improved patient–ventilator interaction.

IMPORTANT UNKNOWNS

IMV has stood the test of time since its clinical application as a primary means of ventilator support in the early 1970s. To date, advanced technology enables most ventilators to be equipped with closed-loop ventilation, which allows full ventilator support with gradual support reduction. Unfortunately, few large, randomized, controlled trials have compared the efficacy of closed-loop ventilation with SIMV with or without pressure support in terms of mechanical ventilation duration, patient–ventilator interaction, sensation of dyspnea, and ventilator-associated complications.

Studies show that inspiratory muscle activity is of the same intensity during machine assistance as during the intervening spontaneous breaths,[57] and that SIMV prolongs weaning.[177,178] Given that the diaphragm is activated with each breath, it is possible that SIMV protects the respiratory muscles from disuse atrophy, which occurs with CMV.[82,84,85] Alternatively, the increased workload at low levels of machine assistance actually may cause overload[194,195] and prolong mechanical ventilation duration or weaning time. Which of those two factors plays a role during a low assistance level of SIMV is unknown.

THE FUTURE

Several studies demonstrate a decline in the application of combined SIMV and pressure support in acute respiratory failure,[10,196] except in less-severity-of-illness, postoperative,

and trauma patients.[12] In patients with ARDS, the proportion of patients managed with SIMV has declined from 22% in 1996 to 3% in 2005.[196] With the availability of closed-loop ventilation with improved patient–ventilator synchrony,[72] SIMV will likely be displaced. In contrast to use of SIMV in adults, the ability to employ simple ventilator settings with SIMV and the options of combining it with pressure support and of guaranteeing volume with use of pressure-limited mandatory breaths, ensures that SIMV will remain an important primary ventilator mode in critically ill pediatric patients.[14]

SUMMARY AND CONCLUSIONS

Few ventilator modes have advanced our understanding of the mechanisms that underlie patient–ventilator interaction as has SIMV. As primary means of ventilator mode in less critically ill and postoperative patients in adults and critically ill pediatrics, SIMV remains one of the most widely used modes of ventilation, as does ACV. No mortality difference has been observed between SIMV and ACV. To date, no large randomized study has compared SIMV with more technologically advanced modes as primary methods of ventilation. As a weaning technique, SIMV has been shown to be inferior to T piece and PSV.

PRESSURE-SUPPORT VENTILATION

Laurent J. Brochard
Francois Lellouche

Pressure-support ventilation (PSV) is a mode of partial ventilator support. Such modes are widely used in intensive care units (ICUs) because most ventilated patients (unless deeply sedated) have preserved respiratory drive. The use of these modes helps to reduce need for sedation, an important issue in the ICU,[1,2] and potentially prevents disuse atrophy of the respiratory muscles that can result from controlled ventilation.[3,4] This preventive effect has been shown experimentally with different modes of partial support.[3,5] Finally, partial support may facilitate both the screening process for detecting patients able to breathe spontaneously as well as the weaning of patients with prolonged or difficult weaning.[6] An ideal mode of partial support should be able to supply both full ventilator support and optimal support during weaning; optimize patient–ventilator synchronization and comfort while reducing the need for sedation and the risk of cardiovascular consequences; and, if possible, facilitate or reduce the duration of the weaning. PSV meets several of these requirements, at least partially, as discussed in this chapter. PSV also has limitations, which are delineated. One important limitation is that overassistance of the patient can be easily reached and improvement in the delivery of the optimal PSV level continues as a field of research.

PSV can be remarkably effective in reducing patient effort and avoiding respiratory distress, and can offer a comfortable ventilator support to many patients. PSV can also deliver support much in excess of patient needs and results in excessive delivered volume, excessive duration of inspiration relative to neural inspiratory time (T_I), or both. Much recent research has been undertaken to understand and analyze the consequences of delivering of excessive pressure. Many benefits of PSV, which provides greater freedom to the patient than traditional modes, can be obscured by improper usage.

EPIDEMIOLOGY

Some clinicians view PSV primarily as a mode devoted to weaning and only consider its use until late in a patient's course.[6] An international survey on mechanical ventilation in 361 ICUs in twenty countries was conducted in 1998 (published in 2002).[7] On the first day, PSV was used in less than 10% of all patients; the combination of SIMV with PSV was used in almost 15%, and assist-control in approximately 60% of the patients. A low level of PSV was used to perform a once-daily weaning attempt in 28% of such attempts, a gradual reduction of PSV was used as the sole weaning method in 21% of cases, and a gradual reduction of synchronized intermittent mandatory ventilation (SIMV) and PSV was used in 22% of all cases. Overall, PSV was used (one way or another) for 45% of weaning attempts, suggesting that clinicians consider weaning as the main indication for PSV.

In 2004, Esteban et al repeated the prospective international observational cohort study, employing a nested comparative study performed in 349 intensive care units in twenty-three countries, and compared the findings with the 1998 cohort.[8] Whereas the use of a T piece was the most common initial method for spontaneous breathing trials, the use of low levels of pressure support for weaning trended upward over time (10% vs. 14%). Among patients not extubated, methods for gradual withdrawal differed: there was a decrease in the use of SIMV and of SIMV combined with PSV, and a major increase in the use of PSV for weaning (19% vs. 55%) between the two observation periods. This international survey was repeated a third time, on a larger scale in 2010 and included more than 8000 patients. The initial results indicate that after more than 6 days of mechanical ventilation, PSV was now the most frequently used ventilator mode, indicating progressive dissemination in the use of this technique over the years.[9]

DIFFERENCES AMONG MECHANICAL VENTILATORS DEFINITION AND PHASES

PSV is a pressure-targeted (or limited) mode in which each breath is patient-triggered and supported.[10–13] It provides breath-by-breath support by means of a positive-pressure boost synchronized with inspiratory effort: patient initiated and flow terminated (Fig. 8-1). During inspiration, airway

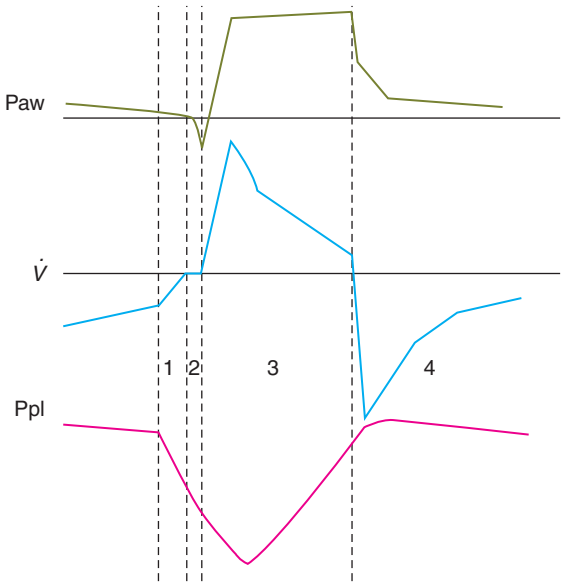

FIGURE 8-1 A pressure-supported breath with tracings of airway pressure (*Paw*), flow ($\dot{V}$), and pleural pressure (*Ppl*). Four phases of patient effort can be discerned. Phase 1 is still expiratory and corresponds to an effort performed against intrinsic positive end-expiratory pressure; it occurs before the triggering system of the ventilator can detect any signal that indicates the onset of patient inspiratory effort. Phase 2 is the time required to activate the triggering system of the ventilator (also called the initiation phase). Phase 3 is the insufflation phase during which the ventilator pressurizes the airway at the level set by the clinician. This phase is terminated by the cycling-off criterion. Patient inspiratory effort may terminate before the end of this phase. Phase 4 is the expiratory phase.

pressure is raised to the preset pressure-support level. The speed of pressurization is system specific but most recent ventilators offer the possibility of adjusting this pressurization rate. Throughout the inspiratory phase, the ventilator works as a pressurized demand-flow system at a predetermined pressure level. PSV is maintained until the machine determines the end of expiration, supposedly reflecting the end of patient demand. The expiratory trigger mechanism is based on decay of inspiratory flow. When inspiratory flow falls below a threshold value, which should indirectly indicate that the inspiratory muscles have relaxed, the ventilator cycles to the expiratory phase releasing the PSV and opening its expiratory port. A level of positive end-expiratory pressure (PEEP) lower than the inspiratory plateau pressure can then be applied. PSV can thus be defined as a patient-initiated (pressure or flow), pressure-targeted, flow-cycled mode of mechanical ventilation.

Three phases of PSV can be distinguished: (a) recognition of the beginning of inspiration, (b) pressurization, and (c) recognition of the end of inspiration. These phases constitute the working principles of PSV, and can vary from one ventilator to another (see Fig. 8-1). As discussed in the section Differences Among Mechanical Ventilators, these variations may induce differences in the effect of PSV for similar levels of pressurization.

Initiation of the Cycle

Triggering of inspiration is initiated by patient effort and is detected by a pressure or flow sensor. Trigger sensitivity is adjustable. This mechanism requires an active effort by the patient, the intensity of which depends on the characteristics of the valve. The opening time delay varies between 50 and 250 milliseconds, depending on the ventilator.[14–18] The most recent data indicate that most ventilators now respond in less than 100 milliseconds.[19–22]

Opening of the demand valve can be triggered by a fall in pressure or a difference in the flow signal between inspiratory and expiratory flows (referred to as *flow-by*). For the latter, a constant flow is delivered to the circuit during the expiratory phase; inspiratory effort is then detected as a small difference between inspiratory and expiratory flow. Flow-triggering avoids the need for a closed demand valve. Aslanian et al[23] showed that the difference between pressure-triggered and flow-triggered systems has become quite small on modern ventilators. The triggering phase represents less than 10% of a patient's overall effort to breathe. A flow-triggering system makes a statistically significant difference but of limited clinical importance.

Pressurization

Once inspiration has been initiated, the ventilator delivers a high inspiratory flow, which rapidly decreases throughout the rest of inspiration. A servo regulatory mechanism maintains the proper flow to reach the appropriate preset PSV level and keeps this pressure approximately constant until expiration occurs. Flow regulation varies among ventilators, thus determining the pressure waveform. Usually, the servo valve is continuously controlled during the breath, such that delivered pressure closely approximates target pressure set by the clinician. In general, the aperture of the proportional servo valve is progressively reduced as the monitored pressure gets closer to the target pressure. For this reason, the wave shape often constitutes a pressure ramp rather than a true square wave. The pressure level can be adjusted between 0 (spontaneous breathing through the ventilator circuit) and a maximum of 30 or 60 cm H_2O (even more with some ventilators). In clinical settings, pressure levels above 30 cm H_2O are rarely used.

Pressure increases according to a rate that is system-specific; formerly, it was nonadjustable. A high speed of pressurization produces a square pressure wave; low achievement of the preset PSV level attenuates this shape. Many ventilators now allow adjustment of the rate of pressurization. Its influence is discussed in the section Pressurization Rate and Inspiratory Flow.

Cycling of Expiration

During PSV, cycling to exhalation is primarily triggered by a decrease of inspiratory flow from its peak to a system-specific threshold value. This critical decrease of inspiratory flow is taken as indirect evidence that the inspiratory muscles have begun to relax. Expiration is triggered when either an absolute level of flow (between 2 and 6 L/min) or a fixed percentage of peak inspiratory flow (12% or 25%) is reached, depending on the ventilator model (Table 8-1). The threshold value for cycling, which can be viewed as sensitivity of the expiratory trigger, was formerly nonadjustable. Adjustment is now offered to clinicians on many ventilators.

Detection of a small degree of pressure (1 to 3 cm H_2O) above the fixed PSV level, consequent to sudden expiratory effort by the patient, can also be used (alone or combined with the flow criteria) to stop inspiratory assistance. Finally, a time limit for inspiration is usually included. This serves as a safety mechanism if a leak develops in the circuit and the two previous methods of terminating inspiration become inoperative. Complications have been reported in the absence of this time-limit mechanism, whereby constant insufflation (at the PSV level) creates a high level of continuous positive airway pressure.[24]

Other Settings

Because no mandatory breath is present with PSV, a safety feature is often available in case of apnea. This may be an automatic feature, or a minimal frequency, or minute ventilation to be set. The time delay for apnea may be adjustable. This safety feature is not available on all ventilators.

PSV can be used in conjunction with SIMV.[25–28] Two approaches have been used: addition of a fixed level of PSV during spontaneous breathing to overcome endotracheal tube (ETT) or circuit resistance,[29] or use of a variable level of PSV between the mandatory breaths. The second approach introduces considerable complexity into ventilator management of patients.

DIFFERENCES AMONG MECHANICAL VENTILATORS

During PSV, specific characteristics of the ventilator may interfere with patient respiratory activity. These differences may be determined by the manufacturer's algorithm to deliver pressure, such as speed of pressurization and/or initial peak flow setting, ability to maintain a plateau pressure and quality of regulation, and termination criteria used to cycle from inspiration to expiration. Nonspecific features include characteristics of the demand valve and/or triggering mechanism, and flow-impeding properties of the expiratory circuits, including PEEP devices.[22] These differences may also vary with the type of ventilator, whether it is designed only for delivery of noninvasive PSV or a full intensive care ventilator.[20,21,30,31] The relative weight of each factor is difficult to determine and may vary from one patient to another. This consideration should, however, be kept in mind when interpreting the results of clinical studies of PSV using various ventilators. One study with old-generation ICU ventilators compared three of them and found major work differences,[32] showing that different characteristics of PSV could

TABLE 8-1: TECHNICAL CHARACTERISTICS OF PRESSURE SUPPORT VENTILATION AND AVAILABLE SETTINGS ON INTENSIVE CARE VENTILATORS

		Inspiratory Trigger		Pressurization	Cycling-off Criterion

have a major influence on its efficacy (Fig. 8-2). Fortunately, most recent ventilators have designed much better systems of regulation, providing more homogeneous delivery of PSV, but clinically relevant differences still exist.[22]

As with other assisted modes, the triggering mechanism is a key determinant of the efficacy of PSV. A poorly functioning demand valve has two consequences: it imposes an effort to open the valve, and it prolongs the time before

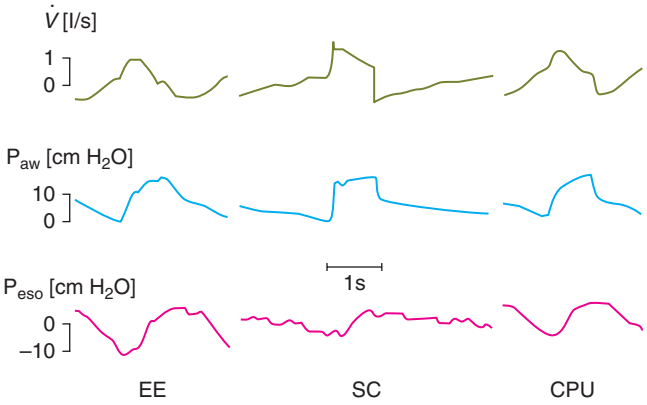

FIGURE 8-2 The influence of a ventilator and its specific algorithm on patient effort. Three ventilators were studied at 15 cm H_2O of PSV. Flow, airway pressure (*Paw*) and esophageal pressure (*Peso*) are presented. Note the different airway and flow profiles, and the impact on esophageal pressure swing. Work of breathing was significantly less with SC. Although modern ventilators tend to homogenize the delivery of PSV, differences still exist and illustrate the effects of varying the pressure ramp. *CPU*, CPU1, Ohmeda, Maurepas, France; *EE*, Erica Engstrom, Bromma, Sweden; and *SC*, Servo 900 C, Siemens, Lund, Sweden. FIGURE 8-3 The method used to calculate the trigger characteristics and pressurization phase during pressure support ventilation based on the airway pressure-time curve. The total trigger phase is evaluated by the time delay (*TD*) between the onset of simulated effort and the time at which airway pressure becomes positive after experiencing a pressure fall (Δ*Paw*). The quality of pressurization is best quantified as the area measured at 0.3 second. (With kind permission from Springer Science and Business Media: Cox D, Tinloi SF, Farrimond JG. Investigation of the spontaneous modes of breathing of different ventilators. *Intensive Care Med*. 1988;14:532–537.)

assistance is delivered. Assisted modes, like PSV, are primarily devoted to reducing or optimizing this effort. Demand valves function with an unalterable delay before delivering gas flow to the patient. For instance, if 200 milliseconds is required between the beginning of an inspiratory effort and the opening of the valve, nearly one-third of the duration of inspiratory effort in a tachypneic patient may take place without any gas entering the lungs. If auto (or intrinsic) PEEP is present, another 200 milliseconds may be wasted (while the respiratory muscles work against this positive alveolar pressure) before any inspiratory flow can start.[33] In addition, if the speed of pressurization of PSV is low, another 200 milliseconds is required to reach the plateau pressure. Thus, assistance will be delivered to the patient 600 milliseconds after the beginning of inspiratory effort, which may correspond to the end of that patient's inspiratory effort.[34]

Comparison of the triggering functions of various ventilators demonstrates that the most recent generation of ventilators, using pressure-sensitive mechanisms, flow-sensitive mechanisms, or both, usually require less effort and open faster than the older generation. This was extensively studied by Richard et al,[19] and subsequently by Thille et al[22] who compared different generations of ventilators, including the new turbine ventilators (Figs. 8-3 to 8-5). The ability of different ventilators to pressurize the airway during PSV was investigated. Different levels of simulated inspiratory demand were used. Pressurization was assessed through the net area of the inspiratory airway pressure-time tracing over the first 0.3 second, 0.5 second, and 1 second at different levels of PSV (Figs. 8-3 and 8-4). Triggering sensitivity was assessed independently by measuring the time delay and the pressure fall with different levels of inspiratory drive (Figs. 8-3 and 8-5). Ventilators released after 1993 achieved significantly better results than most previous generation ventilators regarding the pressure-time area at 0.3 seconds and triggering delay, indicating large improvements in terms of triggering and pressurization. Regarding PSV and trigger performances, this generation of ventilators outperformed most previous generation ventilators; this was also the case for some piston and turbine-based ventilators, including several of those specially designed for noninvasive ventilation (NIV). Six years later, trigger function, pressurization capacity and accuracy of pressure measurements during simulated PSV, and expiratory resistance were again evaluated in a similar bench study.[22] In 2006, new-generation turbine-based ventilators performed as well as, or better than, the best compressed-gas ventilators. The newest ventilators did not perform significantly better than the 2000 ventilators, suggesting that a technological ceiling may have been reached.

Dedicated Noninvasive Ventilators

NIV using PSV can be performed with either turbine ventilators, specially conceived to provide NIV, or conventional ICU ventilators originally designed for invasive ventilation. The rate of use of each of these is variable depending on the care setting, the etiology of respiratory failure, the specialist, and even the geographic region.[35–37] Ventilators delivering PSV and PEEP, termed *bilevel ventilation*, and designed for home ventilation have been evaluated in stable, awake patients with chronic ventilatory failure.[38] Despite some variability in the delivery of pressure, no difference was found in terms of comfort or improvement in inspiratory muscle unloading. These differences, however, might have greater impact in patients with acute respiratory failure.

The presence of air leaks around the mask is a major problem related to use of NIV. When ICU ventilators are not capable of compensating for leakage, leaks generate

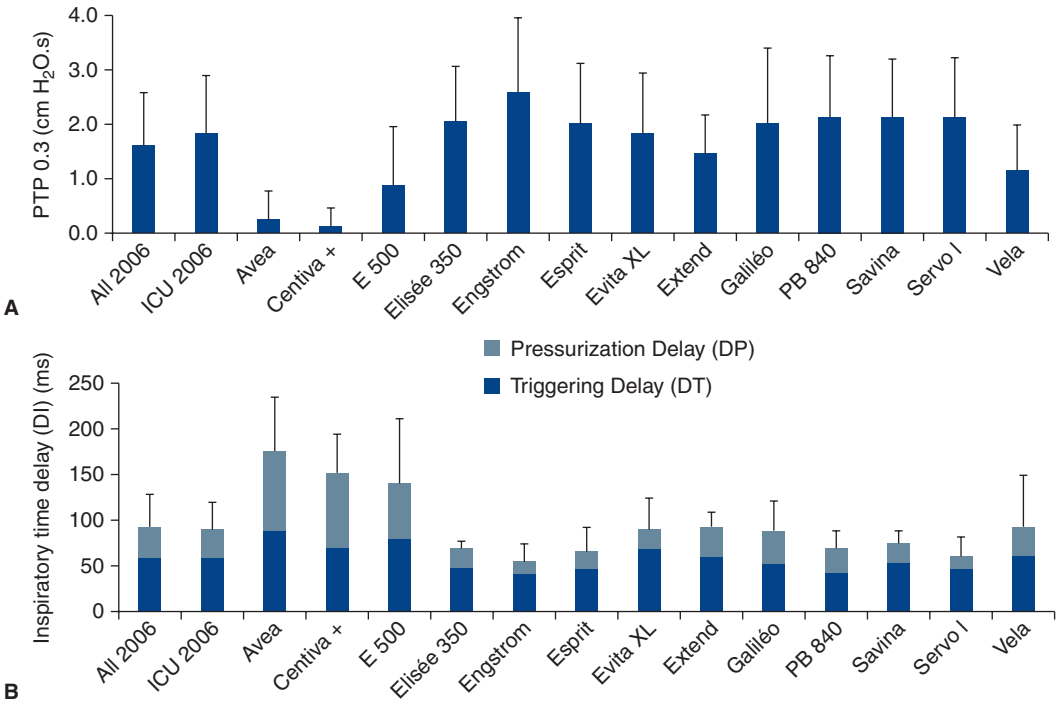

FIGURE 8-4 **A.** Inspiratory area, measured as the integral of the airway pressure-time trace over the first 0.3 second of inspiration (see legend of Fig. 8-3), for a PSV level of 15 cm H_2O for the same simulated level of inspiratory demand. **B.** Inspiratory time delay in milliseconds measured during the same tests, separated into triggering and pressurization delay. The new-generation ICU ventilators proposed in 2006 were evaluated. These included Avea and Vela (Viasys Healthcare, Conshohocken, PA), E 500 (Newport Medical Instruments, Costa Mesa, CA), Elisee 350 (Resmed-Saime, North Ryde, Australia), Engstrom and Centiva (General Electric, Fairfield, CT), Esprit (Respironics, Murrysville, PA), Extend (Taema, Antony, France), Savina and Evita XL (Dräger, Lubeck, Germany), Galileo (Hamilton, Rhäzuns, Switzerland), PB 840 (TYCO, Carlsbad, CA), and Servo I (Maquet, Solna, Sweden). Of these thirteen ventilators, four were turbine-based (Elisée 350, Esprit, Savina, Vela) and nine were conventional servo-valve compressed-gas ventilators. Seven were viewed as ICU ventilators (Avea, Evita XL, Engstrom Extend, Galileo, PB 840, Servo I) and six were mid-level ICU ventilators (Centiva, E 500, Elisee 350, Esprit, Savina, and Vela). The mean values for all ventilators or only ICU ventilator is also presented. (With kind permission from Springer Science and Business Media: Thille AW, Lyazidi A, Richard JC, Galia F, Brochard L. A bench study of intensive-care-unit ventilators: new versus old and turbine-based versus compressed gas-based ventilators. *Intensive Care Med.* 2009;35:1368–1376.)

autotriggering, prolonged cycling, ineffective efforts, and a poor pressurization capacity of the ventilator. For these reasons, manufacturers have developed specific algorithms, called *NIV modes,* which aim to minimize the negative impact of leaks on ICU ventilator performance. Dedicated NIV ventilators are designed to function with leaks and have developed sophisticated algorithms that evaluate online the magnitude of a leak and readjust the triggering thresholds. Several bench studies show variable performance in the ability to ameliorate these key ventilator functions with the activation of the NIV mode,[39,40] and an overall better performance for dedicated NIV ventilators. The clinical effect of "NIV modes" on patient–ventilator interactions has also been evaluated in two recent short-term clinical studies. Vignaux et al compared four ICU ventilators, with and without the activation of the NIV mode, showing a reduction in patient–ventilator asynchronies with the NIV mode.[41] A second study, employing the same schema but also testing a specific NIV ventilator, showed a significant reduction in the rate of these events with the latter.[42] Although clinical studies are needed to clarify this issue, it is advisable to use NIV modes on ICU ventilators or dedicated ventilators.

MAIN PHYSIOLOGIC EFFECTS OF PRESSURE-SUPPORT VENTILATION

Breathing Pattern

During PSV, the patient maintains control over respiratory rate, and has partial control of T_I and tidal volume (V_T). As such, PSV seems to allow the patient to breathe in a "physiologic" way. This is only partially true, because there is a complex interaction between ventilator support and patient control of breathing. This interaction depends on the pressure level and PSV characteristics. For instance, a change in the criterion for cycling from inspiration to expiration will result in a different T_I, different V_T, and may result in more (or less) dynamic hyperinflation.

The addition of PSV modifies the spontaneous breathing pattern.[43–48] Most patients develop an increase in V_T and decrease in respiratory rate with increasing levels of PSV. The breathing pattern adapts rapidly under PSV when the respiratory muscles face a new workload.[49] Adjustment of the PSV level can be guided by noting the breathing pattern response:

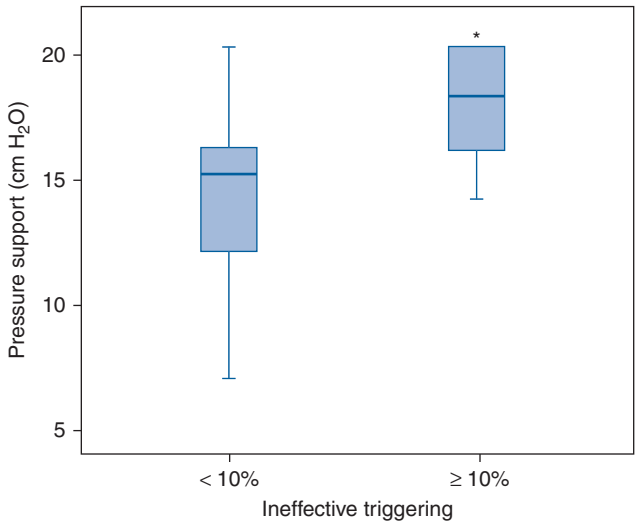

FIGURE 8-5 Relationship between the level of PSV and the frequency of ineffective triggering in a cohort series of sixty-two consecutive patients requiring mechanical ventilation for more than 24 hours. *Box plots* show median, interquartile range (25th to 75th percentiles), and outliers (5th to 95th percentiles) of PSV in patients with and without a high prevalence of ineffective triggering (>10%). PSV was higher in patients with a high incidence of ineffective triggering. *$p < 0.05$. (With kind permission from Springer Science and Business Media: Thille AW, Rodriguez P, Cabello B, Lellouche F, Brochard L. Patient-ventilator asynchrony during assisted mechanical ventilation. *Intensive Care Med*. 2006;32:1515–1522.)

changes in breathing pattern in response to loading conditions usually occur within 1 to 2 minutes.[49,50] Importantly, evaluation of a patient during a low level of PSV is different from evaluation of during a T-tube trial, for instance, even if the clinical outcome of the two approaches may be similar. Two studies show that the use of a low level of PSV during a "spontaneous breathing trial" modifies the thresholds that may be used to predict weaning success or weaning failure.[51,52]

Excessive levels of support, however, can generate hyperinflation, respiratory alkalosis, respiratory depression with apnea, or appearance of missing efforts.[53] A high level of support-induced hyperinflation may indeed result in an inability to trigger the ventilator (so-called ineffective triggering), with a substantial difference in the ventilator's displayed respiratory rate and the patient's true respiratory rate.[54] The frequent occurrence of these findings (discussed below in Degree of patient-ventilator synchrony or asynchrony) illustrates the fact that the insufflation during PSV is often terminated after cessation of the patient's inspiratory time, especially in case of airway obstruction.[55] The higher the pressure level, the longer is this prolongation.[56] Thus, to some extent, PSV artificially forces the patient to decrease respiratory rate as a way of trying to maintain a sufficient expiratory time.[54] As the PSV level is increased, an imbalance almost inevitably occurs between prolongation of the insufflation time and shortening of expiratory time, promoting severe asynchrony.

In patients with acute lung injury, factors other than respiratory muscle load influence respiratory drive. Pesenti et al reported that variation in arterial oxygen (O_2) saturation between 85% to 90% and 100%, obtained by modifying fractional inspired oxygen concentration (FI_{O_2}), had a significant effect on respiratory drive in patients with acute lung injury receiving PSV.[57] Volta et al reported similar findings: modulation of FI_{O_2} produced variation in dyspnea, occlusion pressure, and respiratory frequency.[58]

The influence of PSV on the duty cycle (fractional inspiratory time, T_I/T_{TOT}) is variable and influenced by the setting of the pressure ramp on the ventilator.[59] A decreasing duty cycle with increasing PSV levels was observed in several studies.[44–46]

The influence of PSV on minute ventilation is variable, producing an increase or no change.[43–47] An increase in minute ventilation is often observed when PSV is compared with unassisted breathing through the ventilator circuit. More frequently, an increase in PSV fails to substantially modify minute ventilation whereas it modifies alveolar ventilation. Consequently, the breathing pattern may be markedly modified without significant change in minute ventilation.[43–48] Thus, monitoring minute ventilation is of little help when titrating the level of PSV.

Gas Exchange and Distribution of Ventilation and Perfusion

The primary goal of PSV is to support patient effort while allowing a satisfactory gas exchange. PSV is not primarily aimed at improving oxygenation. The effects of PSV on gas exchange are primarily explained by increased alveolar ventilation resulting from changes in breathing pattern. Indeed, despite lack of change in minute ventilation, an increase in V_T produces a decrease in the ratio of dead space to tidal volume (V_D/V_T). Thus, alveolar ventilation is often increased. Other factors may influence arterial blood gases, such as changes in O_2 consumption, modification of total dead space, and altered distribution of ventilation. During the weaning of patients with hypercapnic respiratory failure, addition of PSV produced a correction of the partial pressure of arterial carbon dioxide (Pa_{CO_2}) and respiratory acidosis compared to spontaneous breathing.[43] In normal, nonintubated subjects, PSV 10 cm H_2O produces significant decreases in Pa_{CO_2} below normal levels.[53] PSV can thus correct hypoventilation but also induce hyperventilation that is not counteracted by respiratory motor output.[60] Consequently, although PSV permits correction of hypercapnia resulting from rapid shallow breathing or helps patients with chronic CO_2 retention to choose their own target Pa_{CO_2}, the level of PSV requires fine adjustment as respiratory alkalosis can easily occur.

Although breathing pattern, especially respiratory frequency, is in part controlled by the patient, an interaction exists between the level of PSV and alveolar ventilation, which is not fully controlled by respiratory center command. MacIntyre and Leatherman showed in a lung model that a biphasic effect can occur with increasing levels of PSV.[61] Above a certain limit, passive (hyper-) inflation will result with high levels of PSV. That excessive assistance with

PSV may induce respiratory alkalosis not controlled by the patient's respiratory centers and has important consequences. Parthasarathy and Tobin found that during sleep PSV was associated with numerous episodes of apneas, desaturation, and microarousals leading to sleep fragmentation.[62] This could be prevented by adding dead space to the circuit. Not tested in this study was the likelihood that reductions in the level of PSV might prevent this problem.

The distribution of ventilation and perfusion during PSV has been assessed in a few studies.[63–68] Valentine et al[63] compared SIMV, PSV, and airway pressure release ventilation in nine patients a few hours following cardiac surgery. The major characteristics of ventilation–perfusion ($\dot{V}_A/\dot{Q}$) distributions were similar with all modes.[63] Dead space was lower during airway pressure release ventilation than during either SIMV or PSV. Gas exchange was assessed with the six-inert-gas technique in a study comparing controlled mechanical ventilation, unassisted spontaneous breathing, and PSV 10 cm H_2O.[64] Using isotopic scanning, they evaluated regional distribution of $\dot{V}_A/\dot{Q}$ ratios in eight patients with chronic obstructive pulmonary disease (COPD). Ventilator discontinuation was associated with rapid shallow breathing and an increase in perfusion to low $\dot{V}_A/\dot{Q}$ regions. Isotopic scans revealed a horizontal craniocaudal difference of $\dot{V}_A/\dot{Q}$ with all modes, and the lowest $\dot{V}_A/\dot{Q}$ ratios were found at the bases. Abnormalities in $\dot{V}_A/\dot{Q}$ distribution observed during spontaneous breathing were also present during 10 cm H_2O PSV, but to a smaller extent.

Ferrer et al assessed whether PSV could improve $\dot{V}_A/\dot{Q}$ imbalance during the transition between positive-pressure ventilation and spontaneous breathing in seven intubated patients with COPD during weaning.[66] PSV avoided $\dot{V}_A/\dot{Q}$ worsening during this transition. Hemodynamics, blood gases, and $\dot{V}_A/\dot{Q}$ distributions were equivalent during PSV and assist-control ventilation (ACV) when the two modes provided similar levels of assistance. Diaz et al studied the reasons for improvement in partial pressure of oxygen (P_{O_2}) and partial pressure of carbon dioxide (P_{CO_2}) in ten patients with acute hypercapnic exacerbations of COPD who were switched from spontaneous breathing to PSV during NIV.[65] Improvement in blood gases was primarily mediated by a higher alveolar ventilation, and not improvement in $\dot{V}_A/\dot{Q}$ relationships. Although O_2 uptake tended to decrease, the respiratory exchange ratio increased, explaining a slight increase in arterial-to-alveolar O_2 difference secondary to increased clearance of body stores of CO_2 during NIV. These results suggested that attaining an efficient breathing pattern rather than high inspiratory pressures should be the primary goal for improving arterial blood gases during NIV with PSV in this type of patient. Lastly, a recent study assessed gas exchange and changes in lung volume through the use of lung diffusion capacity for carbon monoxide (DL_{CO}) in sixteen patients without COPD.[69] An increase in PSV of 5 cm H_2O neither affected lung volume nor increased the volume of the lung participating in gas exchange, but was associated with a slight but significant deterioration in DL_{CO}. Thus, a target V_T closer to 6 mL/kg than to 8 mL/kg of predicted body weight during PSV was associated with better gas exchange.

The effect of PSV on oxygenation varies and depends on many factors, such as the induced changes in alveolar ventilation, O_2 consumption, dead space, and mean airway pressure.[43–46] Most investigators have not found significant changes in arterial oxygenation when PSV was compared with other modalities (primarily spontaneous breathing or SIMV) delivered at the same $F_{I_{O_2}}$. Compared with continuous positive pressure ventilation in surgical ICU patients, Zeravik et al suggested that only patients with a low level of extravascular lung water had improved oxygenation with PSV among patients with moderate acute respiratory failure.[70]

Work of Breathing and Respiratory Effort

A major goal of PSV is to assist respiratory muscle activity in a way that improves the efficacy of patient effort and decreases workload. Many of the initial studies on PSV have focused on this point and have measured work of breathing or indexes of patient effort during PSV.[11,13,43,45,46,71,72]

MacIntyre was one of the first to study the effects of various levels of PSV in patients.[11] The level of PSV was positively correlated with V_T and negatively correlated with respiratory rate. He suggested that PSV alters the characteristics of work of breathing: the change in the pressure-to-volume ratio of the work of each breath decreased progressively with increasing levels of PSV. In intubated patients recovering from acute respiratory failure, Brochard et al compared breathing characteristics during 10 cm H_2O PSV, spontaneous unassisted breathing through a ventilator, and a continuous flow system without a demand valve.[13] PSV produced significant increases in V_T and partial pressure of arterial oxygen (Pa_{O_2}), and a decrease in respiratory rate, transdiaphragmatic pressure (Pdi) swings, pressure-time index, and electromyographic activity of the diaphragm. Subsequently, Brochard et al compared several levels of PSV in eight patients who were experiencing weaning difficulties, four of whom had COPD.[43] During unassisted breathing, patients breathed with a small V_T and a high rate, a pattern associated with unsuccessful weaning, hypoxemia, and hypercapnia. All patients exhibited intense activity of their sternocleidomastoid muscles and the analysis of the diaphragmatic electromyographic recordings suggested impending high-frequency fatigue during PSV0. All these signs or symptoms disappeared at 10 cm H_2O or 20 cm H_2O of PSV, while activity of the sternocleidomastoid muscles was minimized or no longer present. Work of breathing returned to normal, whereas the respiratory rate remained around 30 breaths/min. These findings were later confirmed by another study also analyzing an index of high-frequency fatigue.[73]

The values of respiratory rate described above emphasize that trying to "normalize" respiratory rate much below the point where a patient is no longer in respiratory distress, such as targeting a threshold of 20 breaths/min or even lower values, may not be desirable; we will see later that it may favor asynchrony. A limit of 30 breaths/min was also found by Jubran et al to be predictive of a inspiratory pressure-time

product of less than 125 cm H_2O.sec/min, representing a desirable level of inspiratory effort.[74] This has important clinical implications for the bedside titration of PSV.

PSV acts with great efficiency in decreasing work of breathing. This is more or less proportional to the level of PSV and is accompanied by changes in breathing pattern measurable at the bedside, together with changes in respiratory muscle recruitment. There is, however, an individual limit of pressure above which work of breathing is not decreased and the patient becomes to be overassisted.[44]

Different indexes have been used to assess respiratory muscle activity. Beck et al compared the crural diaphragmatic electrical activity (Edi) with Pdi during varying levels of PSV in intubated patients.[56] Changes in PSV did not alter neuromechanical coupling of the diaphragm: Edi and Pdi decreased proportionally with the addition of PSV. In contrast, Fauroux et al found that diaphragmatic pressure-time product, often used to quantify loading and unloading of the diaphragm, did not exhibit a linear relationship with the diaphragmatic electromyographic activity during PSV and that flow measurements may be necessary when assessing diaphragmatic unloading during PSV.[75]

Compensation for the Work Caused by Endotracheal Tube and Demand Valve

PSV has been used to predict patient tolerance of unassisted breathing and extubation.[76] The idea is based on selecting a level of PSV just sufficient to overcome the circuit resistance. Thus, spontaneous muscular activity should be similar to what a patient would perform in the absence of an ETT or circuit.[77] The pressure needed to obtain a "adequate" breathing pattern during a spontaneous breathing test can provide insight into a patient's ability to tolerate extubation.

It has long been argued that breathing through an ETT and demand valve increases respiratory muscle work[78] and that PSV can compensate for this increased demand.[77,79,80] Part of the confusion, however, comes from the fact that the resistance posed by an ETT is probably close to upper-airway resistance after extubation. Several clinical studies have compared work of breathing before and immediately after extubation.[80–82] These studies demonstrated that the work of breathing was similar or even often higher after extubation than before extubation (while breathing through an ETT). This indicates that there is no rationale for compensating for the ETT in itself. What needs to be compensated for, however, is the ventilator circuit through which the patient is breathing, including the triggering system.

In intubated subjects breathing with various levels of PSV who were disconnected from the ventilator and finally extubated,[77] the level of PSV that compensated for extra work of breathing through the ETT and ventilator circuit was calculated post hoc. In patients with underlying lung disease, the PSV level that compensated for the additional work ranged from 8 to 14 cm H_2O, while it averaged 5 cm H_2O in patients free of lung disease. Based on various studies,[83,84] it has been argued that a PSV level of 5 to 10 cm H_2O be provided when a patient is breathing through a demand valve.

Despite wide individual variation among patients regarding the best pressure to apply in physiologic studies, a simplified approach, based on the same principle, has been applied in several large clinical trials. These studies showed that a low level of PSV (7 to 10 cm H_2O) is overall as efficient as a T-piece trial in testing whether a patient can be separated from the ventilator and eventually extubated, despite the lack of individual titration of PSV.[8,85–87]

Some studies suggested that this low PSV test may be easier to tolerate than a T-piece trial,[88] and measurements of muscular effort support this impression in cardiac patients.[89] Therefore, a T-piece trial seems to constitute a more challenging test than the low PSV test, at least in cardiac patients.

Effect of Instrumental Dead Space

Instrumental dead space is usually constituted by the flex-tube connector, the Y piece, and the humidification system. Heat and moisture exchangers and heated humidifiers constitute a resistive load,[90] but heat and moisture exchangers also add instrumental dead space, because they are positioned between the Y piece and the ETT. The mechanical characteristics of heat and moisture exchangers can substantially modify breathing pattern, effort to breathe, and gas exchange during PSV. These effects were assessed in several studies during PSV and invasive ventilation,[90–95] and also studies during NIV,[96,97] with consistent results. Adding dead space with the heat and moisture exchanger reproduced well-described effects of addition of CO_2 on breathing pattern. In intubated patients during PSV, for instance, Pelosi et al reported that work of breathing increased from 8.8 ± 9.4 J/min with a heated humidifier to 14.5 ± 10.3 J/min with an heat and moisture exchanger.[92] These investigators suggested that increasing the level of PSV by 5 cm H_2O may be necessary to compensate for the increased work of breathing caused by heat and moisture exchangers dead space. Recently, it was shown, however, that small heat and moisture exchangers have a much lower dead space, and that their impact is therefore limited or negligible.[98]

SLEEP

Mechanical ventilation in the ICU is associated with an abnormal sleep pattern characterized by abnormal circadian distribution of sleep and numerous arousals, similar to the pattern found in sleep apnea patients.[99,100] The exact influence of mechanical ventilation on sleep fragmentation in ICU patients remains poorly understood, but the ventilator mode and its settings, as well as patient–ventilator interactions, can influence the degree of fragmentation and the quality of sleep.[62,99,101–103]

The effects of the ventilator mode and settings were investigated in ICU patients by Parthasarathy and Tobin.[62] Sleep fragmentation was increased with the use of PSV as compared with ACV, mostly because of central apneas caused by the level of PSV. The main mechanism of apnea was a decrease in P_{CO_2}, which could be avoided by adding an external dead space. This illustrated an undesirable effect of PSV, resulting from hyperventilation. During ACV, by contrast, the patient can trigger some or all breaths, and a minimal respiratory rate and the V_T are preset, and this backup setting protects against apnea. Conceivably, however, a similar effect could have been achieved by selecting lower levels of PSV. This important study thus raised relevant clinical questions for the selection of ventilator settings.

The hypothesis that the possible deleterious effect—hyperventilation—could be avoided by a more appropriate level of PSV was confirmed in subsequent studies, both in home-ventilated patients and in ICU patients. A study of outpatients with neuromuscular disease compared two settings for NIV with PSV, one based on clinical parameters and the other based on physiologic requirements as estimated by an assessment of the patient's respiratory effort and mechanics.[103] The physiologic setting was associated with improvements in sleep quantity and quality, as well as with a lower level of PSV. An association was found between reductions of ineffective efforts (a marker of patient–ventilator asynchrony, mainly related to hyperinflation) and a higher proportion of rapid eye movement (REM) sleep, a sleep period with extreme physiologic importance. The smaller number of ineffective efforts with the physiologic settings were ascribed to the lower intrinsic PEEP, possibly related to the lower V_T. The apnea index was also lower at the physiologic setting.

The effects of three ventilatory modes on sleep were compared in nonsedated ICU patients.[102] The three modes were ACV, clinically adjusted PSV, and automatically adjusted PSV. With automatically adjusted PSV, the pressure level is adjusted in real-time based on V_T, respiratory rate, and end-tidal CO_2, as described later in this chapter (Closed loop delivery).[104] The goal of automatically adjusted PSV is to adjust the level of PSV to the patient's ventilatory demand so as to avoid underassistance or overassistance. Sleep was severely altered in the fifteen patients, who exhibited reductions in REM sleep and marked sleep fragmentation. No differences, however, were found in sleep architecture, sleep efficiency, or sleep fragmentation between the three ventilator modes. The absence of significant differences may reflect an adequate adjustment of ventilator settings, as minute ventilation was similar with the three modes. In this study,[102] central apneas and ineffective efforts were relatively uncommon and were similar with the three modes. These results suggest that the mode may be less important than adjustment of the settings of each mode.

Newer modes may provide a more continuous and physiologic assistance. The effects of two assist-ventilation modes on sleep quality have been compared.[101] Patients received proportional-assist ventilation (PAV) during one night and PSV during a second night. PAV involves applying a level of pressure that is proportional to the patient's inspiratory effort; therefore, the level of pressure is variable. The patient triggers all the breaths and V_T changes with every breath, reflecting the natural breath-to-breath variability. PSV, in contrast, applies the same level of pressure independently of the magnitude of a patient's inspiratory effort. The working hypothesis was that PAV would improve patient–ventilator interactions and lessen asynchrony, and therefore reduce sleep fragmentation. The ventilator was set to achieve the same reduction in inspiratory effort. The number of patient–ventilator asynchronies was significantly smaller with PAV than with PSV. In addition, PAV was associated with a lower fragmentation index and with higher percentages of slow-wave sleep and REM sleep. V_T and minute ventilation were lower with PAV, suggesting that this mode ensured better matching of the assistance to the patient's requirements than did PSV, thereby decreasing the number of asynchronies linked to overassistance.

DEGREE OF PATIENT–VENTILATOR SYNCHRONY OR ASYNCHRONY DURING PRESSURE-SUPPORT VENTILATION

The fundamental principle of assisted ventilation is to deliver assistance on a breath-by-breath basis in synchrony with patient effort. As discussed, some patient–ventilator asynchrony often exists with most current assisted modes, which can be aggravated by inappropriate settings, chiefly excessive support. Synchrony has been the subject of several investigations, often not specific to PSV.[28,105–109] Patient–ventilator asynchrony has been described during invasive ventilation[28,109–112] and NIV[113] (Figs. 8-6 to 8-14).

Synchrony between the patient and ventilator can be defined as the adequacy of matching with patient neural inspiratory and expiratory time. PSV has often been viewed as offering good synchrony because it is designed to recognize the beginning and end of each spontaneous effort. As discussed above, this is far from true in all cases. The incidence of asynchrony has been studied in three prospective studies, one in ventilator-dependent patients and two in ICU patients.[105,109,114] These studies suggest a strong association between a high incidence of asynchronies (i.e., more than 10% of the breaths, as quantified by an asynchrony index) and a prolonged duration of mechanical ventilation.[105,114]

During PSV, several forms of asynchrony can be identified by inspecting the airway pressure and flow curves on ventilators and it is often possible to rule out the problem by modifying ventilator settings.[115] Many asynchronies are not specific to PSV.[28,105] Descriptions of these asynchronies may help clinicians understand their mechanisms and thus undertake remedial steps.[116] A parallel can be made with cardiac arrhythmias, where each type of arrhythmia has a specific treatment. We describe here the most frequent, gross, and easily recognized asynchronies encountered during PSV, according to recent descriptions.[105,116] More subtle forms of asynchrony, such as simple delays, are difficult to detect at

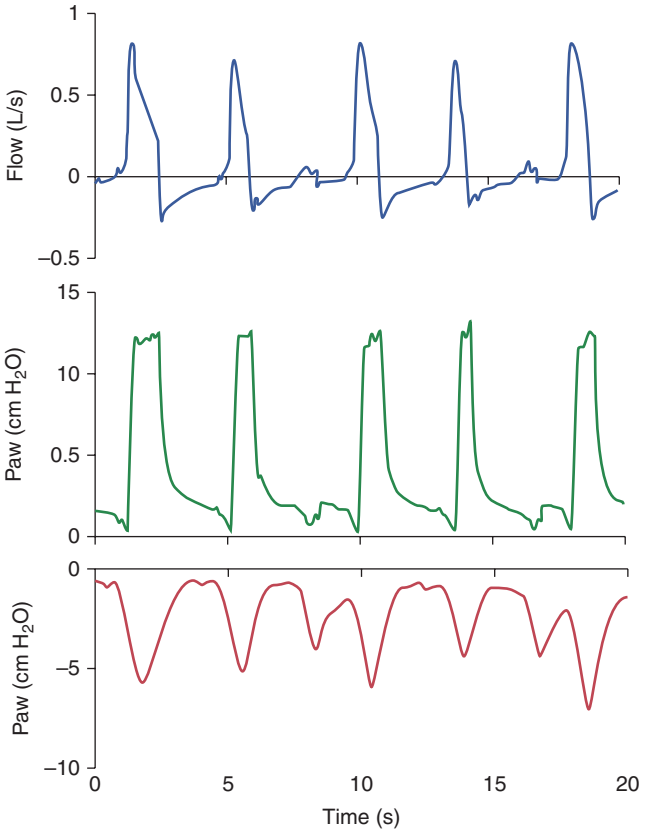

FIGURE 8-6 Ineffective efforts. The third and sixth inspiratory efforts by the patient fail to trigger the ventilator. The efforts by the patient (visible on the esophageal pressure tracing [*Pes*]) are not accompanied by ventilator insufflations. A small and transient increase in flow during expiration and a decrease in airway pressure are visible at the time of the failure-to-trigger events.

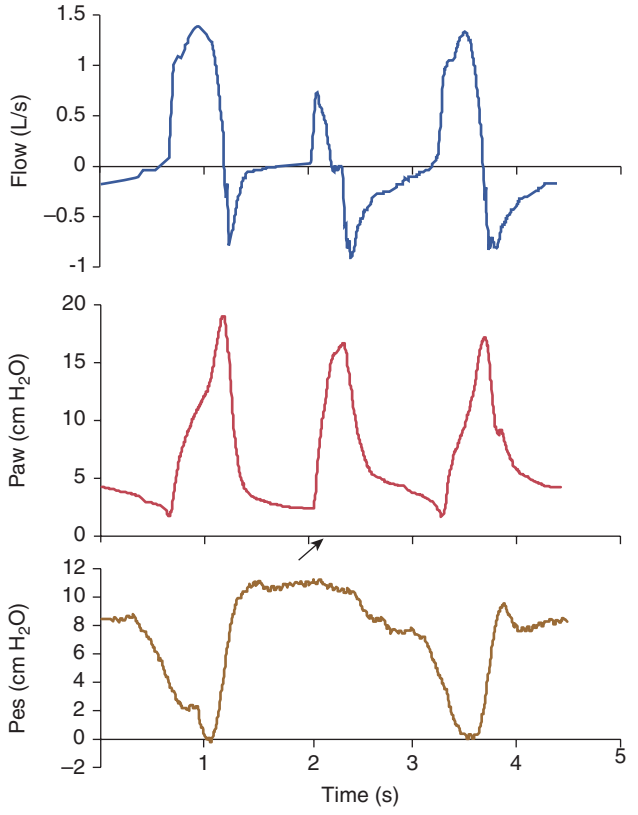

FIGURE 8-7 Autotriggering. This form of asynchrony can occur when the inspiratory trigger is set too sensitive or in the presence of end-expiratory leaks. As on this tracing, a "short cycle" is a frequent result of an autotriggered cycle. The "autotriggered cycle" is accompanied by the absence of an initial airway pressure decay.

the bedside, and need a careful examination of esophageal pressure or diaphragm electromyogram.

At Initiation of the Cycle

Triggering delay, ineffective triggering and autotriggering are all related to lack of synchrony between onset of patient effort and onset of inspiratory assistance but results from different mechanisms (see Figs. 8-6 and 8-7). Short and multiple cycles (see Figs. 8-7 to 8-9) may be related to problems with inspiratory triggering, setting of the pressurization rate, and cycling criteria.

INSPIRATORY TRIGGER DELAY

Trigger delay is almost inevitable with the classical triggering systems and is influenced by the system (pressure versus flow triggering) as discussed previously in the section Differences Among Mechanical Ventilators. Work (or effort) in triggering the ventilator has been evaluated by comparing pressure-triggering and flow-triggering systems.[23,27,117–120] Major delays have also been observed when using the helmet system for NIV.[121] One way to decrease it is to use higher pressure levels with a faster pressurization rate.[122]

INEFFECTIVE TRIGGERING

This asynchrony is illustrated in Fig. 8-6. During invasive ventilation with PSV, asynchrony most often results from ineffective triggering, also called wasted efforts.[28,107–111] The frequency of this asynchrony is directly influenced by the level of PSV and dynamic hyperinflation.[28,54,108,112,123,124] When a patient starts an inspiratory effort, a pressure gradient between the alveoli and mouth necessitates that the respiratory muscles first counteract this gradient before any inspiratory flow can be generated.[27] This constitutes an inspiratory threshold load, which increases breathing effort. The magnitude of positive pressure generated depends on V_T and therefore on set PSV. PSV can worsen hyperinflation by (a) delivering excessive VT, (b) prolonging insufflation time into patient neural expiration, and (c) reducing the respiratory drive. When patient effort is feeble, effort does not reverse expiratory flow or decrease pressure sufficiently to trigger the ventilator. This produces a missed cycle. This

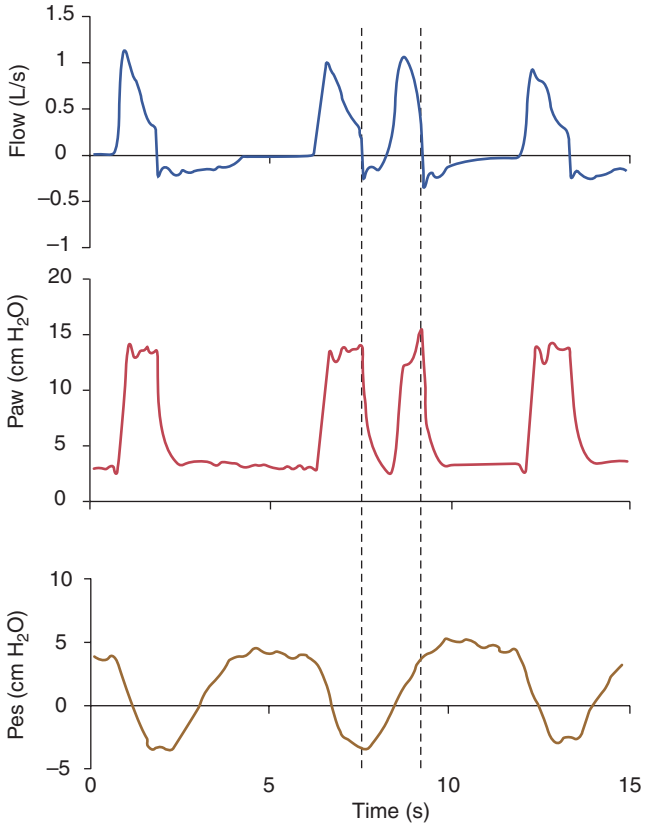

FIGURE 8-8 Double cycles. Two ventilator cycles occur within a single patient's inspiratory effort. Three mechanisms can induce this asynchrony: autotriggering, high pressurization rate (present here with initial overshoot), and early cycling-off (also present in this case).

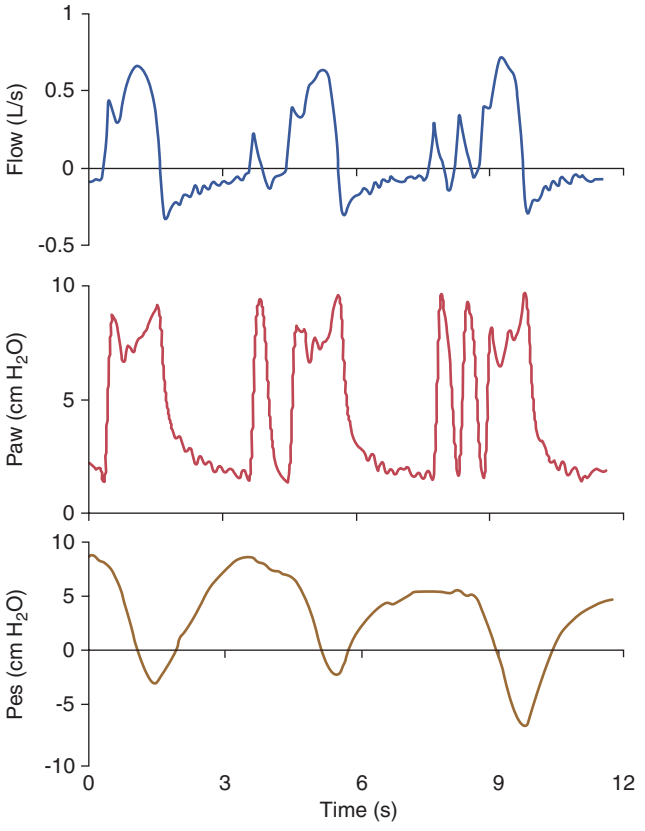

FIGURE 8-9 Multiple cycles. Multiple cycles are frequently associated with autotriggered cycles and frequent "short cycles." A high pressurization rate can favor this form of asynchrony. In this example, both autotriggering and high pressurization rate are present.

type of asynchrony has been described mainly in patients with expiratory flow limitation and intrinsic PEEP.[28,109,111]

In a study where assistance was varied between 0% and 100%, Leung et al found that there was almost no ineffective efforts below 60% of assistance, but they increased gradually when assistance was 60% to 100%.[28] In a cohort of sixty-two intubated patients, Thille et al recently found that ineffective triggering represented almost 90% of all asynchronies during PSV; a quarter of the patients exhibited a high level of asynchrony, that is, more than 10% of their efforts were asynchronous (asynchrony index greater than 10%).[105] COPD was a risk factor for asynchrony, as were a higher V_T, a higher setting of PSV, and progressive alkalosis.[105] In the study by Leung et al, cycles preceding wasted efforts were characterized by higher V_T and lower expiratory time, which lead to greater levels of hyperinflation.[28] Beck et al found that the greater the level of PSV, the longer was the prolongation of insufflation into patient's neural expiration.[56] Therefore, one major reason for ineffective efforts is excessive assistance (PSV), which simultaneously generates dynamic hyperinflation and depresses respiratory drive, both because of high V_T and prolongation of insufflation far beyond the end of patient inspiratory effort.[105]

Ineffective triggering can be detected from irregularities on airway and flow tracings during the expiratory phase (see Fig. 8-6).[27] A respiratory rate lower than 20 breaths/min should also rouse suspicion. Giannouli et al found that ineffective triggering could be detected as accurately on flow and airway tracings as on esophageal pressure tracings.[54] Different approaches are necessary to avoid wasted efforts: check trigger sensitivity, increase PEEP,[108,109,123] lower PSV,[27,28] or decrease instrumental dead space.[92,93] External PEEP decreases the frequency of wasted efforts in some but not all studies.[108,109,115] The two most effective approaches to decrease ineffective efforts are to decrease inspiratory time, achieved by increasing the flow cycling-off criterion or decreasing the level of PSV until the ineffective efforts disappear or the onset of signs of respiratory distress. In patients with COPD, Tassaux et al showed that it was necessary to increase the flow cycling-off criterion to 50% or 75% of the peak flow to reduce ineffective efforts.[125] Thille et al reduced the PSV level in the manner described above, such that VT was around 6 mL/kg. This was associated with a disappearance of ineffective efforts in most, but not all, patients, without significant increase in work of breathing.[115]

Ineffective efforts exist with PSV and with ACV.[105] Thille et al[105] found that a high incidence was significantly

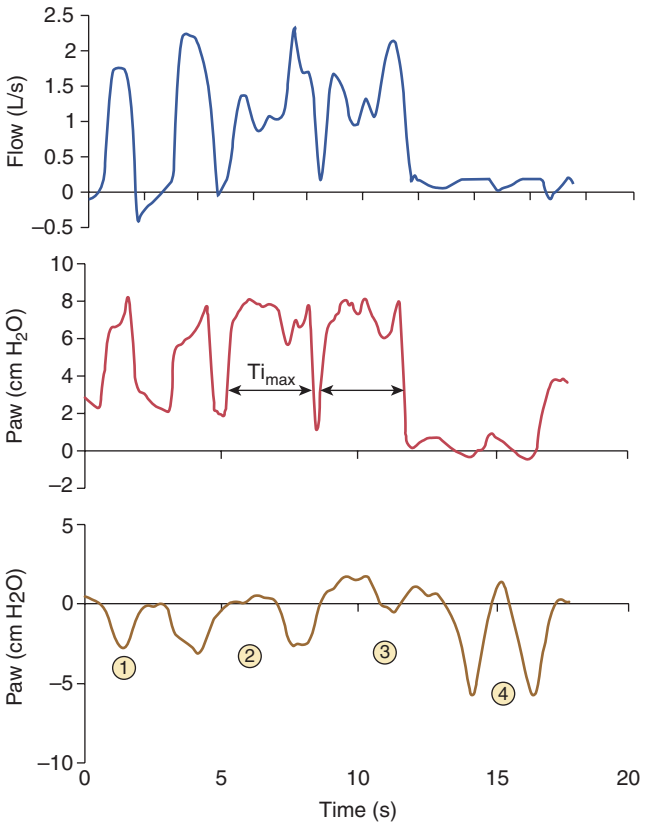

FIGURE 8-10 Prolonged inspiration during noninvasive ventilation. This form of asynchrony during PSV results from a failure to recognize the flow cycling-off criterion. With an end-inspiratory leak, as in this example, the ventilator increases and/or sustains flow to maintain the set airway pressure (here above 2 L/s). This prevents recognition of the decelerating flow threshold and cycling to expiration. Insufflation is stopped only when maximum inspiratory time (Ti_{max}) is reached. Ineffective triggering secondary to hyperinflation may follow the prolonged inspiration, as in this example.

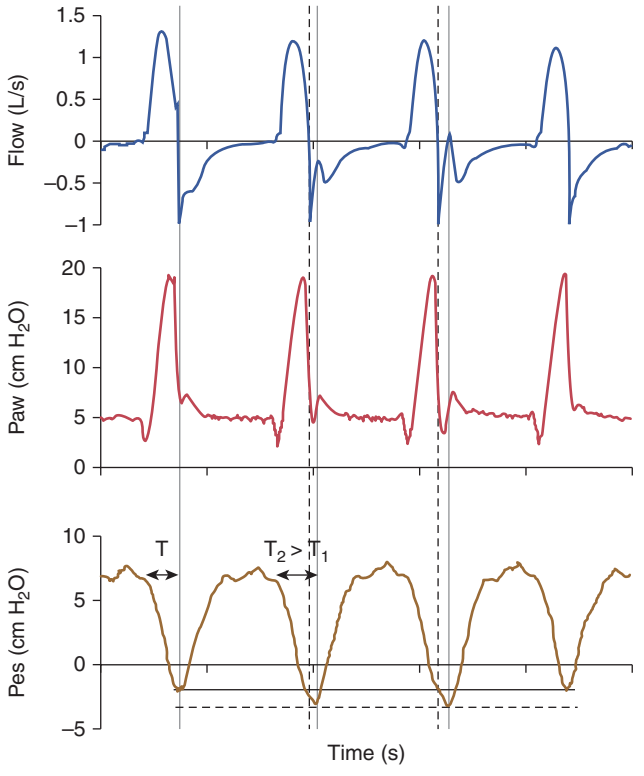

FIGURE 8-11 Early cycling-off. The ventilator ends insufflation (*thick vertical dotted line*) before the patient's inspiratory effort ceases (*second vertical line*). The airway pressure tracing then drops transiently below the baseline end-expiratory pressure level because patient effort is still substantial after ventilator insufflation has ceased. The two cycles with this form of asynchrony are associated with increased effort (*dotted horizontal line*) and prolonged T_I. The duration of T_I on the second cycle (T_2) is longer than T_I on the first cycle (T_1) as reflected with the greater distance between the *arrowheads*. A large T_I favors this form of asynchrony.

associated with prolonged ventilation. The same association was also found by de Wit et al, and was shown to be an independent association by means of multivariate analysis.[114] Because these asynchronies can be avoided by optimized ventilator settings, their treatment and/or prevention may result in a shorter time spent on the ventilator.

AUTOTRIGGERING

Autotriggered cycles (see Fig. 8-7) are falsely triggered by a signal not coming from a patient's inspiratory effort. They can be caused by expiratory leaks around a mask during NIV, or by leaks in the ventilator circuit.[105] It is a special concern when using an ICU ventilator for delivering NIV.[42] An expiratory leak can be misinterpreted by the ventilator as patient effort; an inspiratory cycle is then delivered independently of patient control. Autocycling is also caused by cardiac oscillations,[126] and when the setting trigger is excessively sensitive.

Autotriggering can be difficult to detect on the ventilator tracing. A sudden increase or a persistently high respiratory rate suggest autotriggering. The absence of airway pressure drop at the beginning of an inspiratory cycle is also suggestive (see Fig. 8-7).

Sensitivity of the inspiratory trigger can be reduced, both as a diagnostic test and as a remedy. Triggers based on flow are more sensitive than conventional triggers, and tend to increase of autotriggering.[127] A compromise must be found between triggering that is too sensitive (posing a risk of autotriggering) and too insensitive (with risk of ineffective efforts or increased effort).

MULTIPLE CYCLES

This asynchrony is illustrated in Figs. 8-8 and 8-9. Two or more ventilator insufflations may be delivered within a single patient effort. Auto-triggering can be responsible for multiple cycles (see Fig. 8-9). Ventilator characteristics, such as duration of the refractory period, may

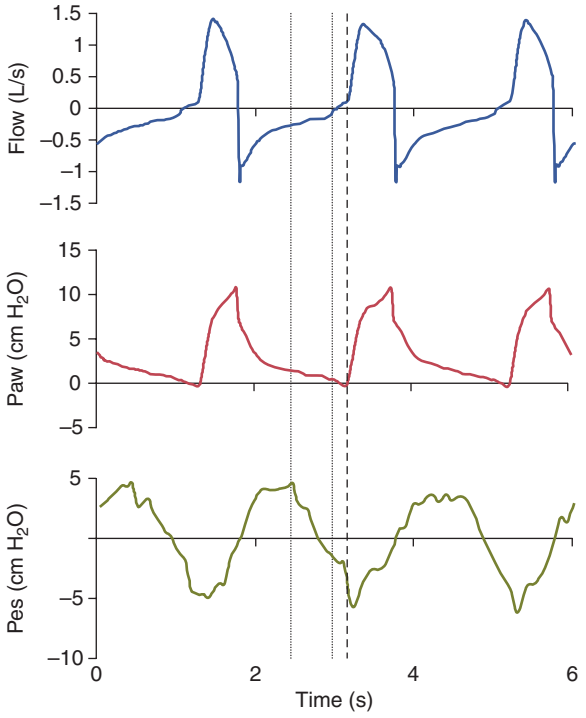

FIGURE 8-12 Inspiratory and expiratory delay. Tracings in an intubated patient with severe COPD receiving PSV. An inspiratory delay secondary to auto-PEEP and triggering delay is evident. The distance between the first and second vertical dotted lines reflects the delay between onset of patient inspiratory effort and positive flow from the ventilator; this delay is caused by auto-PEEP. The delay between the second and third vertical lines is caused by triggering delay (flow triggering). In this patient, mechanical insufflation occurs almost entirely after the patient has terminated inspiratory effort. Consequently, onset of the ventilator's expiratory phase is markedly delayed compared with the patient's neural expiration.

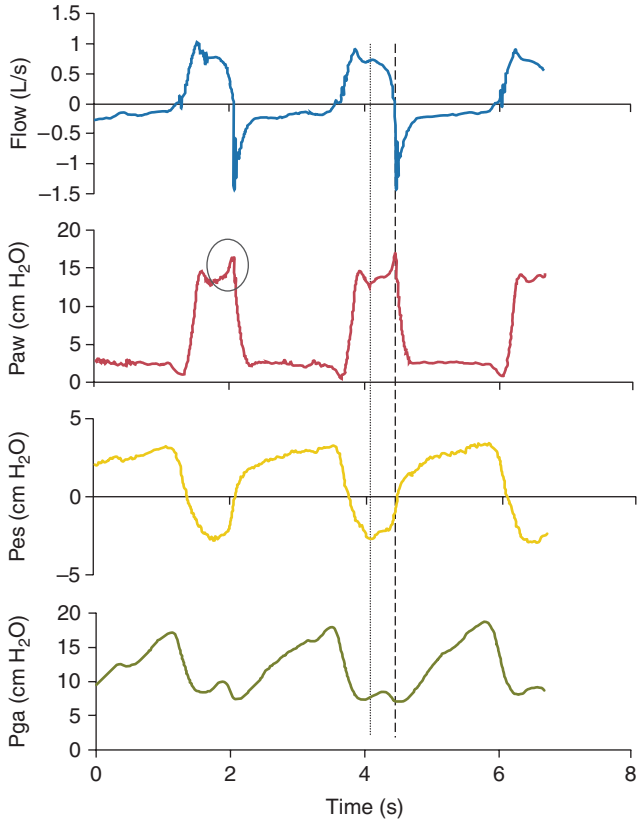

FIGURE 8-13 Expiratory muscle activation. An expiratory increase in gastric pressure (*bottom tracing*) is caused by expiratory muscle activation (at the end of patient inspiration). The apparent "overshoot" on the inspiratory airway pressure tracing (*circle*) indicates, in reality, the abrupt end of patient inspiratory effort. Active expiration is present throughout all of expiration.

also influence this kind of asynchrony. A risk for double-triggering exists with a high inspiratory pressure ramp profile, secondary to a reduction in ventilator T_I relative to neural T_I.[128,129] Tokioka et al described double cycles during PSV in intubated patients with restrictive lung diseases when the cycling-off criteria were high (35% and 45% of maximal inspiratory flow).[130]

Three mechanisms (autotriggering, high pressurization rate, and early cycling-off) should be considered when this asynchrony is detected during PSV.

Pressurization Rate and Inspiratory Flow

The speed of pressurization determines the initial pressure ramp profile and is primarily dependent on the initial peak flow rate. This rate is adjustable on several ventilators. Altering this parameter can directly influence breathing pattern and work of breathing.[131]

Poor matching between patient demand and the provided peak flow may occur as a result of an inadequate rise time during PSV.[32,59,129,132,133] Selecting a low speed of pressurization can cause excessive patient effort, especially when respiratory drive is high and mechanics are poor. Conversely, a very fast rise time may not be optimal[134] and is poorly tolerated by patients.[135] A high speed of pressurization makes it more difficult for the ventilator to properly regulate the pressure throughout inspiration according to its servo-control mechanism.

Patients with the lowest compliance and highest respiratory drive theoretically needed the highest initial flows.[131] In two studies, the longer the time taken to reach the pressure level set on the ventilator, the greater the work of breathing, in patients with obstructive or restrictive lung disease.[59,129] Excessively high pressurization can also lead to an initial overshoot, with possible early termination of the cycle related to high pressure. Chiumello et al found that the relationship between the pressurization rate and dyspnea or work of breathing exhibited a U-shape pattern.[134] During NIV, the highest pressurization rate may increase the amount of leaks and induce double triggering.[135] It can also increase respiratory rate, as previously described with ACV.[136,137]

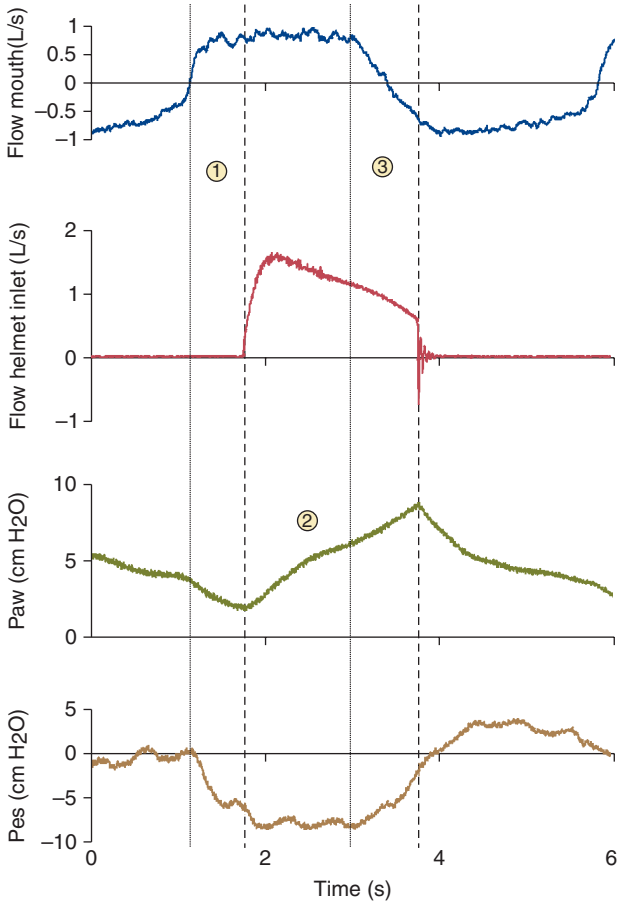

FIGURE 8-14 Inspiratory and expiratory delays and low pressurization during PSV with a helmet system. In this healthy subject, an inspiratory delay is evident between the first vertical dotted line (onset of inspiratory effort) and the second (thicker) vertical line (onset of ventilator assistance) (interval ①). A low rate of pressurization is evident, typical when PSV is delivered via a helmet system (interval ②). Expiratory delay corresponds to the time between the third (end of inspiratory effort) and fourth vertical line (end of insufflation) (interval ③).

Inspiratory Cycling-Off or Cycling to Expiration

DELAYED OCCURRENCE OF EXPIRATION

As with delayed triggering of inspiration, this form of asynchrony is very common and related to the difference between the criterion for inspiration termination on the ventilator and the end of patient neural T_I (see Figs. 8-10, 8-12, and 8-14). Parthasarathy et al[138] studied healthy subjects with simulated airflow obstruction, and found frequent early activation of the expiratory muscles during ventilator insufflation. In intubated patients, Spahija et al compared PSV with neurally adjusted ventilatory assist (NAVA), where ventilator support is driven by the diaphragmatic electromyographic signal. Marked expiratory delays were found with high levels of PSV (1055 ± 1010 milliseconds).[139] These impressive delays may be specific to the ventilator used, Servo 300 (Maquet, Lund, Sweden), which has a low and nonadjustable cycling-off criterion (5% of peak flow).

The inspiratory termination criterion is usually a fixed percentage of peak inspiratory flow rate (12%, 25%, or 30%) and frequently does not correspond to the real end of inspiratory effort.[140] The effect of this setting differs between patients with obstructive and restrictive lung diseases. In general, increasing the flow criterion (expressed as a percentage of peak flow) reduces Ti.[131]

In patients recovering from acute lung injury, Chiumello et al found a low cycling-off criterion (5% of peak flow) was beneficial in terms of breathing pattern (reduction of respiratory rate, increase in V_T), compared with a threshold at 40%.[133] In similar patients Tokioka et al found an increase in V_T and decrease in respiratory rate when the cycling-off criterion was decreased from 45% to 1%.[130] These observations argue for use of a low termination criterion in patients with acute lung injury or restrictive lung disease. Conversely, in patients with COPD, the best cycling-off criterion may be above 50%.[125,141] When the cycling-off criterion is set low (5% with the Servo 300 [Maquet, Lund, Sweden] or 5 L/min with the Puritan Bennett 7200 [Tyco, Carlsbad, CA, USA]), one can expect that insufflation will continue beyond patient neural T_I. Patients may activate their expiratory muscles, and or suffer from increased dynamic hyperinflation.[74,138] The risk of wasted efforts during subsequent respiratory cycles increases.[142]

Some patients exhibit expiratory muscle activity during PSV (see Fig. 8-13).[74,138,143] It has been suggested that an abrupt increase in airway pressure indicates an active expiratory effort from the patient. Although this is indeed possible, a more frequent explanation is the abrupt cessation of patient active inspiratory effort. The release of this effort makes that the airway pressure suddenly reaches the preset level until the end of inspiration.[144]

VERY PROLONGED INSPIRATION DURING NONINVASIVE VENTILATION

This is illustrated in Fig. 8-10. A specific form of the preceding asynchrony may occur in case of large end-inspiratory leaks. Mechanical inflation may be prolonged far beyond the end of patient inspiration, until a limit of maximum T_I has been reached, which is sometimes adjustable. This type of asynchrony can occur during invasive ventilation but is mostly specific to leaks during NIV with ICU ventilators.[113] It occurs because of the impossibility for reaching the cycling-off criterion (e.g., 25% or less of peak inspiratory flow). In the case of end-inspiratory leaks around the mask or in the circuit, the ventilator continues insufflation and flow does not decrease (because of these leaks). The breath does not terminate and is prolonged until a maximum T_I is reached (which can be several seconds). The patient may "fight" against the ventilator and may even attempt additional inspirations. Ineffective

efforts can be observed in this context, either within the same ventilator cycle or in following cycles.

Prolonged inspiration is a common asynchrony in patients receiving NIV for acute respiratory failure with ICU ventilators not having a noninvasive mode.[145] The first step is to reduce leaks and inspiratory pressure by decreasing PEEP or PSV. This asynchrony can also be avoided by adjusting the cycling-off criterion higher. Calderini et al set T_I between 0.8 and 1.2 seconds.[113] This produced better matching between the patient and the ventilator, reducing work of breathing and improving patient comfort.[113] Assist-control pressure ventilation can also be used to deliver pressure with a fixed T_I. Large delays may also result with use of a helmet for NIV (see Fig. 8-14).[146] New ICU ventilators using the NIV mode and dedicated NIV ventilators generally prevent, to a certain extent, the occurrence of these prolonged insufflations.[40,145]

EARLY CYCLING-OFF

This asynchrony is illustrated in Figs. 8-7, 8-8 and 8-11. Very short, aborted cycles can occur during NIV and invasive ventilation. This may indicate either a switch-off mechanism that occurs too early or autotriggering (see Fig. 8-7).[105]

If the cycling-off criterion is reached too early, the ventilator stops insufflation and opens the expiratory valve while patient inspiratory effort continues. This produces an initial drop in airway pressure and flow, followed by an increase related to patient inspiration, resulting in a characteristic contour (see Fig. 8-11).[130] This asynchrony is observed during invasive ventilation and NIV. In patients recovering from acute lung injury,[133] the cycling-off criterion may be set lower to minimize this risk.

Yamada and Du[141] designed a mathematical model to analyze the mechanisms of expiratory asynchrony during PSV.[141] The ratio of flow at the end of patient neural inspiration (neural T_I) to peak inspiratory flow during PSV is determined by the ratio of respiratory time constant (τ) to neural T_I and by the ratio of set PSV to maximal inspiratory muscle pressure. They found that with selected respiratory mechanics, the ratio of flow at the end of neural T_I to peak inspiratory flow ranged from 1 to 85%, and had an excellent linear correlation with the τ-to-neural T_I ratio. The highest values of the cycling-off criterion corresponded to obstructive patients with high resistances and high compliances (resulting in a high time constant). The lowest values corresponded to patients with acute lung injury, who have low resistances and low compliance (resulting in a short time constant).

Hotchkiss et al used linear and nonlinear mathematical models to investigate the dynamic behavior of PSV. Predicted behavior was confirmed with a test lung.[147] In the setting of airflow obstruction, PSV was accompanied by marked variations in V_T and end-expiratory alveolar pressure, even when patient effort was unvarying. Unstable behavior was observed in the simplest plausible linear mathematical model, and it was an inherent consequence of the underlying dynamics of this mode. Because of its complexity and the frequent changes in ventilatory pattern during PSV,[147] automatic adjustment of triggering, based on mathematical models, might be helpful.[148] Du et al proposed an automatic adjustment of the cycling-off criterion based on the measured time constant in a patient.[149,150]

CLINICAL DETECTION

Major asynchronies can be detected at the bedside on the ventilator screen by looking at airway pressure and flow tracings.[116] New ventilators permit clinicians to adjust ventilator settings in order to reduce the frequency of asynchrony.[116] During invasive PSV, a major goal is recognition of ineffective efforts. During noninvasive PSV, an important issue is recognition of prolonged inspirations, caused by leaks, or autocycling.[42] Adjustment of settings (simple decrease of pressure level or change in the cycling-off criterion) avoids or minimizes the problem. This step is likely to improve the efficacy and comfort of PSV.

DIFFERENCES FROM OTHER MODES OF VENTILATION

Intermittent Positive-Pressure Breathing

PSV has some similarities with intermittent positive-pressure breathing (IPPB), an assisted mode used widely in the 1960s for physiotherapy.[151–154] With both IPPB and PSV, cycles are triggered by the patient and limited by pressure, and both can assist patients in acute respiratory failure (with or without endotracheal intubation). They differ in that PSV, but not IPPB, maintains a constant level of pressure during inspiration. The mechanisms that cycle between inspiration and expiration are also different. The end of inspiration is flow-cycled with PSV and is pressure-cycled with IPPB. In normal, nonintubated patients, work of breathing was lower with PSV than with IPPB,[155] a difference considerably exaggerated in the presence of CO_2 stimulation. Expiratory work was also greater and comfort poorer with IPPB devices than with PSV.

Assist-Control Ventilation

Both PSV and volume-controlled ACV can provide full ventilator support but ACV is used more frequently, especially during the early phase of mechanical ventilation because it offers a more stable ventilation with regards to changes in respiratory mechanics.[7] The modes differ in ways that explain their relative advantages and disadvantages. During ACV, V_T is guaranteed and independent of respiratory mechanics, and a minimal frequency and minute ventilation is set. During PSV, by contrast, V_T may change with alterations in respiratory system compliance or resistance.

For any inspiratory effort, addition of PSV augments the pressure difference between the circuit and the alveoli,

leading to a higher inspiratory flow rate and higher V_T than during spontaneous breathing. Until high PSV levels are reached, it increases inspiratory flow rate in a way that remains partially under patient regulation. During ACV, patient inspiratory effort does not modify flow or volume. Therefore, the use of volume ACV is essential when strict control of V_T or transpulmonary pressure is considered important, such as acute respiratory distress syndrome to avoid excessive distension.[156,157] Use of PSV in unstable patients with a high respiratory drive has the major disadvantage of offering no control over V_T, and the pressure level used does not give any indication of what is the real transpulmonary pressure.[158] Conversely, PSV may adapt better to variation in patient demand.

Effects of PSV and ACV on breathing pattern, gas exchange, and indexes of work or effort have rarely been compared. Cinnella et al compared breathing pattern and respiratory muscle effort during ACV and assisted pressure-control ventilation.[159] Although the latter mode differs from PSV in that T_I is preset, this comparison enabled the study of the comparison of a pressure-targeted and a flow-targeted mode. Pressure was adjusted to achieve a similar V_T and T_I as with ACV. With a high V_T (12 mL/kg), the modes did not differ for respiratory muscle effort. At a moderate V_T (8 mL/kg), the decelerating flow pattern of the pressure-targeted mode better matched patient demand than did the constant-flow pattern and work of breathing and pressure-time index were significantly lower with assisted pressure control ventilation. This difference was abolished, however, when inspiratory peak flow rates were increased. Thus, with adequate settings, both modes could adequately unload the muscles. Leung et al also showed that high levels of assistance was equivalent with PSV, ACV, and SIMV.[28]

Synchronized Intermittent Mandatory Ventilation

SIMV combines delivery of assisted breaths with spontaneous unassisted breaths. SIMV differs from PSV, where every breath is supported to the same extent. On a breath-to-breath basis, the effort performed by a patient during SIMV is almost equivalent for assisted and unassisted breathing,[160,161] although differences between assisted and unassisted breaths have been found during SIMV when the mandatory breaths were delivered as pressure-targeted breaths.[27]

MacIntyre compared SIMV (V_T set at 10 to 15 mL/kg), and PSV (set at 13 to 41 cm H_2O) in a crossover study of fifteen patients recovering from acute respiratory failure.[11] Sense of comfort was increased and respiratory rate slower with PSV. In patients ventilated for at least 3 days, Knebel et al compared similar levels of partial support provided by SIMV and PSV in terms of breathing comfort, defined by subjective ratings of dyspnea and anxiety.[162] Preweaning levels of dyspnea and anxiety did not differ significantly between the modes at any level of support. Comfort was not influenced by the level of support, and was similar with the two modes.

Leung et al compared the effects of PSV, SIMV, and their combination at varying levels of support in the same patients.[28] Patient effort was similar with SIMV and PSV at high levels of assistance, but was higher with SIMV than with PSV at lower levels of assistance (20% to 40% of maximal support). The same difference between the two modes was found in animal experiments.[163] The studies suggest that when reducing the level of ventilator support, unloading of the respiratory muscles occurs earlier with SIMV than with PSV.[164] Whether this could explain the different clinical outcomes with the two modes during weaning is unclear.

Proportional-Assist Ventilation

PAV was developed several years after PSV.[165,166] Promising initial results and great physiologic interest has characterized this mode. PAV, however, has essentially remained a physiologic tool, and results of the first clinical comparisons with PSV have been disappointing. Most of physiologic comparisons of PAV and PSV favor PAV in terms of breathing pattern variability, patient–ventilator interaction, and comfort. In clinical trials, mainly during NIV, these physiologic effects did not produce any outcome benefit until recent developments.[167–171]

PAV is designed to deliver assistance in direct proportion to patient effort.[165,166,172]

ADVANTAGES OF PROPORTIONAL-ASSIST VENTILATION COMPARED WITH PRESSURE-SUPPORT VENTILATION

During invasive ventilation and NIV, PAV is consistently superior to PSV on physiologic end points. In response to variable loads (dead space, resistive or restrictive loads), PAV adapts the level of assistance to patient demand. With PSV, in contrast, the level of inspiratory pressure remains constant whatever the load. In response to acute hypercapnia, Ranieri et al showed that PAV adapted more efficiently to ventilatory demand than did PSV.[173] Levels of inspiratory pressure increased during PAV with a relative increase in V_T and no change in respiratory rate, while a small increase in V_T and a large increase in rate were observed with PSV. This resulted in lower work of breathing and better comfort with PAV.[173] In intubated patients, the response to a restrictive load (chest and abdominal binding) resulted in less work and better comfort when compared with PSV.[174] Such adaptations to loads with PAV and PSV were also found in healthy subjects.[175,176]

Several studies found less ineffective triggering with PAV than with PSV in intubated patients.[54,177–179] With PAV, ventilator T_I exactly matches neural T_I, even in patients with a long time constant. Thus, insufflation continues while the patient has begun to exhale with PSV, but not with PAV. Many studies also reveal a greater variability of V_T with PAV than with PSV,[176,180–183] and better patient comfort.[167,168,173,176,181,184–188]

CLINICAL TRIALS

Two prospective randomized controlled studies with clinical end points compared PAV and PSV during NIV.[167,168] The first study enrolled forty-four patients and the second enrolled 117 patients.[168] Intubation and mortality rates were equivalent despite better comfort and less intolerance with PAV. These early clinical trials of PAV are disappointing when contrasted with the promising physiologic studies.

PROPORTIONAL-ASSIST VENTILATION WITH LOAD-ADJUSTABLE GAIN FACTOR

A new method now enables automatic measurement of respiratory mechanics with PAV. The initial results are encouraging.[189,190] In contrast with any other mode (including PSV), greater knowledge of resistive and elastic characteristics of the respiratory system is necessary when setting PAV. It is often difficult to obtain simple and reliable measurements in awake patients triggering the ventilator and the values frequently vary. The setting of PAV is thus complex, and constitutes an obstacle to its wide acceptance. The time needed to set PAV is much longer than for PSV.[182] Also, a major drawback of PAV is the occurrence of a specific asynchrony: flow and pressure runaway.[172] Runaway is mainly related to an excess of volume and elastic assistance because elastance is overestimated.[54,177,184] Methods to automatically and intermittently determine respiratory resistance and elastance were recently described.[189,190] These methods could be incorporated into a closed-loop adjustment of PAV, and possibly constitute a major step forward. A potentially important advance regarding the clinical use of PAV is the possibility to get automated reliable repeated measurements of elastance and resistance of the respiratory system. Few clinical comparisons exist, again mostly with PSV. The effect of modifications in the respiratory loading conditions were compared between PAV with load-adjustable gain factor, referred to as PAV+, against PSV.[191] Adaptation was more physiologic with PAV+, allowing patients to keep the same V_T and minute ventilation, by contrast with PSV. One clinical evaluation of PAV+ randomly compared it to PSV for 48 hours of assistance.[192] In this study, failure to maintain assisted spontaneous ventilation was higher with PSV than with PAV+, and PAV+ was associated with a major reduction of ineffective efforts.

Neurally Adjusted Ventilatory Assist

NAVA is a promising mode of ventilation, although it still lacks clinical data to precisely define its clinical application. Like PAV, it provides assistance in proportion to patient effort but it depends on continuous recording of Edi, which is obtained via a nasogastric catheter incorporating a multiple array esophageal electrode (nine electrodes spaced 10 mm apart). The ventilator thus acts like a muscle under a patient's neural command. Inspiratory airway pressure applied by the ventilator is determined by the following equation:

$$Paw_{(t)} = Edi_{(t)} \times NAVA\ level$$

where $Paw_{(t)}$ is the instantaneous airway pressure (cm H_2O), $Edi_{(t)}$ is the instantaneous diaphragmatic electrical activity signal (μV), and NAVA level (cm H_2O/μV or per arbitrary unit) is a proportionality constant set by the clinician.

The onset and end of assistance and the level of assistance are directly driven by the Edi signal.[193] In theory, NAVA should provide much better patient–ventilator synchrony than achieved with pressure-targeted modes, and both experimental and clinical results support this expectation. Unlike all other modes (including PAV), NAVA should not be influenced by intrinsic PEEP or by the presence of leaks as in the case of standard triggering systems. The initial reports on NAVA revealed advantages compared with PSV in terms of triggering and cycling-off of the ventilator.[193] In a rabbit model of acute lung injury,[194] diaphragmatic unloading was much more efficient with NAVA than with PSV, with an absence of wasted efforts. In intubated patients, Spahija et al compared the trigger delay and cycling-off of inspiration with NAVA and PSV[139] at low and high levels of assistance. Inspiratory trigger delay was around 100 milliseconds with NAVA and around 200 milliseconds with PSV. Cycling-off delays were markedly different: 40 milliseconds (whatever the level of assistance) with NAVA and 500 to 1000 milliseconds with PSV (low and high assistance). The same group also reported an evaluation of an original closed-loop system, using Edi as a target to select the level of PSV: target-drive ventilation.[195] This system was evaluated in eleven healthy subjects, before and during exercise, and without ventilator support. Without target-drive ventilation, Edi increased, as did indexes of effort and end-tidal CO_2 during exercise. With target-drive ventilation, the level of pressure increased during exercise, maintaining the Edi constant.

In the more recent comparisons with PSV, NAVA reproducibly decreased triggering delay by more than 50%, in addition to significantly reducing cycling delay and total asynchrony events.[139,196] Terzi et al showed that beyond a pure proportional assistance, Edi triggering further decreases patient–ventilator asynchrony.[196] These studies also demonstrated that NAVA limits overassistance in contrast to PSV. NAVA prevents overassistance because excessive assist downregulates respiratory center activity (hence Edi) and, thus, inspiratory pressure. NAVA reveals the patient's natural breathing variability that is otherwise masked by constant PSV assist.[197] This finding could be relevant in explaining the oxygenation improvement with NAVA compared to PSV in a 24-hour crossover study of twelve postoperative patients.[198] Thus, the most recent studies have confirmed that NAVA improves patient–ventilator interaction compared to PSV and prevents overassistance. Nevertheless, it remains to be demonstrated that providing control over breathing pattern to a patient will improve clinical outcome.

HEMODYNAMIC CONSEQUENCES OF PRESSURE-SUPPORT VENTILATION

Unique hemodynamic consequences have not been described with PSV.[11,12,45,47,63,76,199] Despite a wide range of pressures, most studies have found little or no deleterious effects of PSV on cardiovascular function in patients after cardiac surgery or in patients with respiratory failure. The negativity of pleural pressure during PSV and the control of airway pressure reduces the risk of negatively influencing venous return or right ventricular afterload. One study found that PSV during NIV may lead to a reduction in cardiac output without change in mixed venous P_{O_2}.[65] Whether this reflects adaptation to a decrease in CO_2 production or a deleterious effect could not be inferred from these data.[200]

In patients with cardiac dysfunction, it was shown that weaning-induced left-ventricular dysfunction appears sooner during T-piece trials than during PSV trials because the workload is higher during the T piece.[89] Whether T piece better predicts postextubation problems in cardiac patients cannot be directly inferred from these data.

ADJUSTMENT OF PRESSURE LEVEL AT BEDSIDE

Precise guidelines for the bedside use of PSV are lacking because the pressure level has been adjusted in various ways in many studies.[11,201,202] Recent data reinforce the notion that targeting a V_T lower than traditionally used and a higher respiratory frequency offers benefit for the patient.[69,115] Assessment of accessory muscle activity, especially the sternocleidomastoid, by inspection and palpation was suggested for deciding optimal assistance.[43] A decrease in respiratory frequency below 30 to 32 breaths/min was also associated with an optimal level of PSV. Respiratory frequency can be used as a simple indicator of the adequacy of PSV[43,76]; and less than 30 breaths/min has been recommended.[74,76,203] As indirectly suggested by weaning trials, targeting a low frequency (25 breaths/min or less) can prolong weaning duration. The latter may also be explained by increased occurrence of asynchrony when a low frequency is displayed on the ventilator.

In early studies, PSV was adjusted to reach a predetermined V_T (8 to 12 mL/kg).[12,47,70] A setting of closer to 6 mL/kg V_T seems more advisable to avoid patient–ventilator dyssynchrony. One study suggested, however, that patients who could be weaned controlled their own V_T and were only mildly influenced by the PSV level.[204]

In patients who display major asynchronies, such as ineffective efforts, reducing the level of pressure support[115] and reducing the insufflation time through an increase in the flow-cycling criterion[125] are recommended. This leads to a smaller V_T than usually recommended, around 6 mL/kg. Interestingly, a recent study using the DL_{CO} technique showed that gas exchange was overall better with a V_T of 6 mL/kg versus 8 mL/kg.[69]

CLOSED-LOOP DELIVERY OF PRESSURE-SUPPORT VENTILATION

Dual Modes

The potential for variation in delivered ventilation has led many manufacturers to develop servo-controlled modalities of PSV. In one ventilator, the PSV level was automatically adjusted to achieve a preset breathing frequency.[205] Several servo-controlled modes have been proposed to adjust the PSV level to keep V_T constant. Pressure can be varied from breath to breath using various algorithms. These options have been designed to provide a better ventilator response to changes in respiratory mechanics.[206,207] An increase in resistance or elastance during PSV normally leads to a drop in V_T if no compensation is made by the patient or the ventilator.

These modes, often called *dual-control modalities*, use closed-loop feedback control systems that enable the ventilator to adapt output based on the difference between measured ventilation and a predefined target. The modes go by different names. Volume-support ventilation (VSV) was introduced in the 1990s on the Servo 300 ventilator (Siemens Elema, Solna, Sweden). VSV is a pressure-limited mode that uses a target V_T and minute ventilation for feedback control. The level of PSV is adjusted continuously to deliver a preset V_T. Two anecdotal reports with VSV[208,209] and one randomized controlled trial[210] have yielded variable results. Several modes are now working on the same principle—volume targeted pressure-regulated mode—and have been extensively developed by manufacturers without clinical validation. Physiologic studies have not assessed the efficacy of VSV in terms of adjustment to spontaneous changes in mechanics. The response of such modes to changes in ventilatory demand can be problematic. Changes in demand frequently occur with different states of, for example, wakefulness, nutrition, episodes of sepsis, pain, and anemia. With a fixed level of VSV, but not of PSV, it was shown that an increase in ventilatory demand resulted in a decrease in the level of support provided by the ventilator, the opposite of a desired response.[211–213] Conceivably, VSV may result in respiratory distress in clinical settings.[211] In general, these modes are not able to cope correctly with changes in ventilator demand. They also make rapid alterations in the level of support, thus potentially interfering with a patient's own response time.[50]

Knowledge-Based Systems

More complex knowledge-based systems have been developed with the aim of providing an automatically performed, patient-adapted ventilator support, which is superimposed on an automated weaning strategy.[104,214–216] Such systems have been implemented in computers that drive a ventilator. These approaches using SIMV plus PSV or PSV alone have

been evaluated in patients. Sophisticated modes have been developed through improvements in computer science.[217,218]

When the physiologic and clinical knowledge needed to manage a well-defined clinical situation is acquired, it can be embedded within a computer program that drives the ventilator using artificial intelligence techniques, such as production rules, fuzzy logic, or neural networks.[219] These techniques allow planning and control. Control is a local task, which consists of determining what the immediate next step is. Planning is a strategic task, aimed at regulating the time-course of the process. For control and planning, numerous techniques have been developed in the fields of control theory and artificial intelligence, respectively. The main difference between these two fields lies in the process models used. It is important to avoid both oversimplification and excessive complexity.[209] Strickland and Hasson tried to develop a controller incorporating an active clinical strategy represented by production rules using SIMV and PSV (IF conditions, THEN actions). Their work did not lead to commercial development.[215,216]

The Smart Care system is an embedded version of the initial NeoGanesh system. The NeoGanesh system drives the ventilator with PSV, keeping a patient within a zone of "respiratory comfort" as defined by respiratory parameters, and superimposing an automated strategy for weaning.[104,214,220] The designers of the knowledge-based NeoGanesh system intended to build a closed-loop system that (a) was efficient for automatically controlling PSV and planning of the weaning process, (b) could be evaluated with the goal of gradually improving its reasoning and planning capabilities, and (c) could be subjected at the bedside to performance measurements at each step of its operation. The NeoGanesh system is based on modeling of the medical expertise required to perform mechanical ventilation in PSV mode. It does not include mathematical equations of a physiologic model. Several types of evaluation have been performed: (a) to determine how well the system adapts the level of assistance to patient needs (evaluation of the control level),[220] (b) to assess the extubation recommendation made by the system (evaluation of the strategic level),[214] and (c) to estimate the impact on clinical outcomes.[221,222] This system reduces periods of excessive respiratory efforts and predicts extubation time with good accuracy.[214,220] It has been used safely during prolonged periods of mechanical ventilation and often predicted earlier than clinicians the time at which patients were ready to be separated from the ventilator.[221] A multicenter study comparing this system of automated weaning to usual weaning was later performed.[222] Five academic centers recruited 144 patients in 1 year; patients were included as soon as they could tolerate PSV. It was compared to usual care, as performed in the various ICUs participating in the study. Weaning duration was reduced by a median of 2 days, which resulted in a shorter duration of mechanical ventilation and ICU stay. These impressive results have not been consistently reproduced. A smaller randomized study showed no difference with a strict weaning approach,[223] whereas other reports a reduction of weaning duration in surgical patients.[224]

Noisy Pressure-Support Ventilation

Introducing a random noise on the distribution of pressure during PSV produces interesting physiologic effects.[225–227] In two animal models of acute lung injury, noisy PSV increased the variability of the respiratory pattern and improved oxygenation by a redistribution of perfusion toward the ventilated nondependent lung regions.[225,226]

Predicting the Effect of Pressure-Support Ventilation Based on Load Estimation

It has been suggested that a noninvasive method allowing load estimation could be used to titrate the level of pressure support.[228] Noninvasive measurement of the power of breathing, and tolerance of these loads, reflected by spontaneous breathing frequency and V_T, could be considered for deciding the level of PSV, so that muscle loads are not too high or too low. Such a computerized PSV advisory system provided recommendations for setting PSV to unload the inspiratory muscles that were essentially the same as the recommendations from experienced, critical care respiratory therapists.[229]

CLINICAL APPLICATIONS

Weaning

The usual weaning methods are once-daily trials of spontaneous breathing, most often with a T piece, resulting in abrupt discontinuation of mechanical ventilation, SIMV, and PSV, with a gradual reduction in the level of assistance. A low PSV level can be used to mimic spontaneous breathing trials, as mentioned earlier (Compensation for the Work Caused by Endotracheal Tube and Demand Valve); the latter trial thus constitutes the final step in the approach of gradual reduction in PSV or as a substitute for a T-piece trial. PSV can also been used in combination with SIMV, although very few data support the use of this combination.[26–28] In a 1998 international survey of the use of mechanical ventilation,[7] PSV was used one way or another in 45% of weaning attempts, indicating that PSV is considered an important weaning technique.

Studies comparing T-piece trials, SIMV, and PSV were rare before the mid-1990s. Studies had included a large percentage of postoperative patients who exhibited no persistent weaning problem; no conclusions were drawn regarding the type of support to use.[230] PSV as a sole mode of ventilation has first been tested in two large prospective, randomized, controlled trials.[201,202] These trials share common conclusions: (a) patients who tolerated 2 hours of breathing on a T-piece constituted 60% to 80% of patients and were easily separated from the ventilator on first attempt; (b) weaning outcome in the remaining patients depended heavily on the

weaning strategy used; and (c) SIMV was consistently the worst weaning method. The two trials, however, differed regarding efficacy of PSV. PSV was found superior to other methods in the study of Brochard et al, but not in the subsequent study of Esteban et al.

At 21 days, a significantly higher percentage of patients had been separated from the ventilator with PSV than with the other two methods in the trial of Brochard et al,[201] and this was accompanied by a shorter duration of weaning with PSV. Esteban et al adjusted the pressure level to achieve a respiratory rate lower than 25 breaths/min, much lower than the 35 breaths/min upper limit in the trial of Brochard et al.[202] PSV was found to be inferior to once-daily T-piece trials and multiple daily T-piece trials in the trial of Esteban et al. This PSV approach seemed to lengthen the weaning process compared with once-daily T-piece trials. In the study of Esteban et al, the final test before extubation was a T-piece trial, during which respiratory rates of up to 35 breaths/min were tolerated. In the same study, the final step with PSV was a level of 5 cm H_2O, during which respiratory rates above 25 breaths/min were considered a sign of poor clinical tolerance. Thus, the use of PSV differed markedly in the two studies and likely explains differences in efficacy. No study has compared the PSV approach in the trial of Brochard et al to the once-daily T-piece method in the study of Esteban et al. Another trial, however, found no difference between T-piece trial and PSV in patients with prolonged weaning difficulties.[231]

PSV and T piece have been compared as a final test before extubation. Use of a low level of PSV has been found equivalent or slightly superior to a T-piece trial both in adults and infants.[85,86,232] A low level of PSV was slightly superior to T piece in terms of short-term success after extubation.[85,232] At 48 hours, the success rate was not significantly different in the largest trial.[85] A small study suggested that patients who do not tolerate a T-piece trial may tolerate a low level of PSV without increasing the risk of reintubation.[88] The study was too small to render definite conclusions, but concurs with recent data showing that the T-piece trial imposes a higher load on the respiratory muscles.[89]

A comparable approach was used in the NeoGanesh closed-loop system that employs automatic adjustment of PSV. Although different from standard clinical use of PSV, the results of computer-driven system constitute a form of validation of PSV weaning, in a system that applies it on a 24-hour-a-day basis.[222,233]

Noninvasive Ventilation

NIV has been used in many patients with acute respiratory failure since the early 1990s.[8,9,36,110,146,234–240] PSV is used preferentially for NIV. Delivered via a face mask, PSV markedly decreases respiratory muscle activity in patients with COPD in acute exacerbation.[235,241] During exercise, which also constitutes a high ventilatory workload, noninvasive PSV improves performance in patients with COPD.[242]

Bi-level ventilation, as PSV is often called when combined with PEEP, is by far the most frequent mode of ventilation. In a large, multicentric French survey of NIV in ICUs, PSV was used in 67%, ACV in 15%, and continuous positive airway pressure in 18% of patients.[243] PSV is often considered better tolerated than ACV during NIV.[244]

Determinants of the success of NIV have been described in several studies. They relate to patient characteristics (severity scores, etiology of the respiratory failure, nutritional status)[111,241,243] and immediate outcome variables (evolution of arterial blood gases over 2 hours, comfort, level of leaks).[111,243,245–248] These determinants are in part related to technical aspects: ventilator performance, modes,[110,244] settings,[20,31,110,113,123,249] interfaces,[146,250,251] and patient–ventilator asynchrony.[113,145]

Use of Noninvasive Ventilation with Pressure-Support Ventilation for Weaning

In patients with acute exacerbations of COPD, prolonged mechanical ventilation is associated with complications. In this setting, Nava et al suggested that deliberate extubation followed by a switch to NIV might improve weaning outcome.[239] Using PSV for such a goal achieved greater weaning success and higher survival rate. A subsequent study did not confirm these results; patients switched to noninvasive PSV experienced a longer time of ventilator support.[252] In patients with stable chronic respiratory disorders who were unable to sustain spontaneous breathing, Vitacca et al found that invasive PSV, delivered while patients were still intubated, and noninvasive PSV were equally effective in reducing respiratory muscle work and improving arterial blood gases.[253] In addition, noninvasive PSV was slightly better tolerated.

The best indication for NIV with PSV after extubation seems to be the prevention of subsequent respiratory failure in patients at risk of reintubation, as shown in several randomized clinical trials.[254,255] By contrast, applying NIV at the time of postextubation respiratory distress has not proved efficient and can even delay reintubation.[256,257]

CONCLUSION

PSV is a mode of partial ventilator assistance that has proved very efficient in reducing work of breathing and can offer often acceptable synchrony with patient effort. As such, PSV has constituted an enormous change in the way patients have been ventilated over the last 15 years, and has also provided a model to increase understanding of patient–ventilator interaction. Its place has been first assessed during weaning and NIV but is by now largely increasing. It can be used early in the course of ventilation, enabling the patient to be ventilated without need for sedation and in preparation for weaning. In the early phase, its use was limited by lack of control over the volume delivered and the lack of knowledge of the transpulmonary pressure generated. One of its main drawbacks,

however, is the possibility of overassisting patients, causing dyssynchrony between a patient's rhythm and that of the ventilator, inducing hyperventilation, episodes of apneas and potentially sleep fragmentation, especially in patients with obstructive lung disease. For clinical use, lower tidal volumes than usually recommended and relatively higher frequencies should be targeted together with clinical assessment of patient comfort.

PRESSURE-CONTROLLED AND INVERSE-RATIO VENTILATION

Marcelo B. P. Amato
John J. Marini

The use of pressure-controlled ventilation (PCV) increased substantially after 1995, when intensivists became increasingly aware of ventilator-induced lung injury (VILI) and the risks of high inspiratory pressures. Familiarity with the concept of permissive hypercapnia contributed to this change, helping physicians to overcome the old and stringent mindset on arterial blood gases.[1–4] Tidal volume or minute ventilation requirements were increasingly regarded as secondary goals during mechanical ventilation and the apparent security provided by PCV, keeping airway pressures under strict limits, gained broader acceptance. Recent surveys in intensive care units demonstrate that PCV is now used in up to 25% of ventilated patients, usually in the most severe cases[5,6] (including pediatric patients[7]). Studies, describing the implications of PCV on the cardiovascular system, work of breathing, regional mechanics, risks of VILI, and recruitment maneuvers are now available. These studies increase physician comfort in moving away from volume-controlled ventilation.

In contrast to the increasing acceptance of PCV, the use of inverse-ratio ventilation (IRV)—that is, the prolongation of inspiratory time to the point of inverting the conventional inspiratory-to-expiratory (I:E) ratio—is now very rare. This decline was caused by recent progress in our understanding on the pathophysiology of lung collapse, and demonstration of unnecessary hemodynamic compromise. The original benefits in terms of oxygenation ascribed to IRV,[8–14] and the apparent reduction of peak inspiratory alveolar pressures[11,12] are now supplanted by more consistent effects of recruiting maneuvers followed by optimization of positive end-expiratory pressure (PEEP),[15–20] especially during controlled mechanical ventilation. It is only in the more specific context of airway pressure release ventilation (APRV) that the use of IRV has still survived, although surrounded by great skepticism and controversy.[21,22]

In this chapter, we do not revitalize IRV. We believe there are always safer, more predictable, and more efficient ventilatory solutions to be implemented at the bedside. IRV was extensively discussed in the second edition of this book. At the end of the present chapter, we present a few aspects of IRV that still offer great insights about the pathophysiology of acute respiratory failure.

TYPES OF CONTROLLED VENTILATION AND SELECTION OF THE "CONTROLLED" PARAMETER

Ventilators regulate the pressure profile applied to the airways or the pattern of flow delivery. Somewhat imprecisely, flow-controlled ventilation has been designated

"volume-controlled" ventilation (VCV). We avoid this convention because the criterion by which the ventilator ceases to pressurize the airway (initiates deflation) may be a specified value of delivered volume, pressure, elapsed time, or flow. The variable, however, actively controlled by the ventilator during "volume-controlled" breaths is in reality inspiratory flow. Therefore, the modes of ventilation currently used in medical practice should be classified as *pressure-controlled* or *flow-controlled* and as *time-cycled, volume-cycled, flow-cycled,* or *pressure-cycled.* Pressure-support ventilation (PSV) is an example of a pressure-controlled, *flow-cycled* mode, whereas PCV is an example of pressure-controlled, *time-cycled* mode.

In flow-controlled modes, the waveform theoretically can be of any desired contour; in practice, however, the flow waveforms usually are rectilinear (square), linearly decelerating, and sinusoidal. Setting tidal volume as the "off switch" criterion (*volume-cycled*) means that the pressure applied to the airway opening can rise to any value required by impedance to inflation that does not exceed the pressure-limit alarm. For instance, very high absolute airway pressures can develop during acute airway obstruction, acute lung edema or expulsive efforts or bouts of coughing, without consequences to delivered tidal-volume (except if the alarm is activated).

Although once used extensively, *pressure-cycled* ventilation is now considered obsolete for continuous support, and its application in intermittent positive-pressure breathing has been restricted greatly as a backup cycling-off criterion during flow-controlled, *volume-cycled* ventilation (when airway pressures reach a preset alarm threshold), or as a backup for flow-cycling during pressure support ventilation.

To improve safety or decrease the need for repeated adjustments at the bedside, flow-controlled and pressure-controlled algorithms have been combined recently to form new modes (*dual modes*, such as "volume-assured pressure support" and "pressure-regulated volume control"), incorporating the desirable characteristics of each category.[23,24]

The equation of motion of the respiratory system confines the clinician to setting independently the inspiratory flow and tidal volume or just the applied pressure profile. Flow and pressure cannot be selected independently at the same time because their relationship is intrinsically defined by the mechanical properties of the respiratory system. Because modern ventilators can provide online feedback information about output variables (airway pressures during flow-controlled ventilation or flow and tidal volume during pressure-controlled ventilation), either flow-controlled, *volume-cycled* ventilation or pressure-controlled, *time-cycled* ventilation (PCV) can be used interchangeably during specific conditions. For instance, instead of using the original pressure-control algorithms during IRV, some investigators proposed the equivalent use of IRV through flow-controlled, *volume-cycled* breaths,[13] although doing so requires careful monitoring and frequent readjustments. Depending on particular combinations of compliance and resistance in the respiratory system, the pressure profile generated in the airways can be similar in both modes.

The major differences between *flow-controlled* and *pressure-controlled* breaths appear during prolonged use, after unpredictable changes in respiratory system characteristics. By using the traditional flow-controlled, *volume-cycled* mode, minute ventilation is guaranteed safely over prolonged periods of time, although airway pressures may rise significantly when respiratory system impedance increases. Conversely, during prolonged use of pressure-controlled, *time-cycled* ventilation, airway pressure limits are guaranteed, although minute ventilation is at risk whenever lung impedance changes.

Independent of selection of the controlled parameter, inspiration can be triggered by elapsed time or by small perturbations in pressure and flow in the airways (usually indicative of patient effort). Elapsed time defines a totally controlled breath, whereas small perturbations in pressure and flow define an assisted (patient-triggered) breath. In recent years, modern ventilators have incorporated algorithms providing pressure-controlled breaths triggered by either elapsed expiratory time, characterizing traditional PCV, or patient effort (*assisted* pressure-controlled ventilation), analogous to the traditional flow-controlled assist-control ventilation.

During *assisted* PCV, some important and relevant differences between VCV and PCV may appear. For instance, in the presence of a sustained inspiratory effort, extending from the beginning until end-inspiration, the *pressure*-controller will respond with an increased delivery of flow and tidal volume so as to keep airway pressures close to target. The result is an increased transpulmonary effective pressure (which is the sum of the positive airway pressure generated by the ventilator plus the modulus of the negative perturbation in pleural pressure driven by inspiratory muscles). In contrast, the *flow*-controller keeps inspiratory flow close to the target, while peak airway pressures decreases in proportion to the negative perturbation in pleural pressures. The result is a near constant transpulmonary effective pressure (Fig. 9-1, which shows that the modulus of positive airway pressure from the ventilator decreases in direct proportion to the modulus of the negative perturbation in pleural pressures; thus, the sum of the two is almost constant). This is why some investigators believe that VCV is safer during acute lung injury in the presence of strong patient effort and a persisting need for lung protection.[25,26] The drawback of this "forced" maintenance of transpulmonary pressures by VCV, however, is the increased workload to inspiratory muscles and the promotion of a regimen of more negative pleural pressures, which, when excessive, may promote lung edema.[27]

SPECIFIC CHARACTERISTICS OF PRESSURE-CONTROLLED VENTILATION

Many recently introduced ventilator modes can be considered as variants of pressure-controlled or *pressure-preset* ventilation. This includes traditional PCV,[8,27] PSV,[28,29]

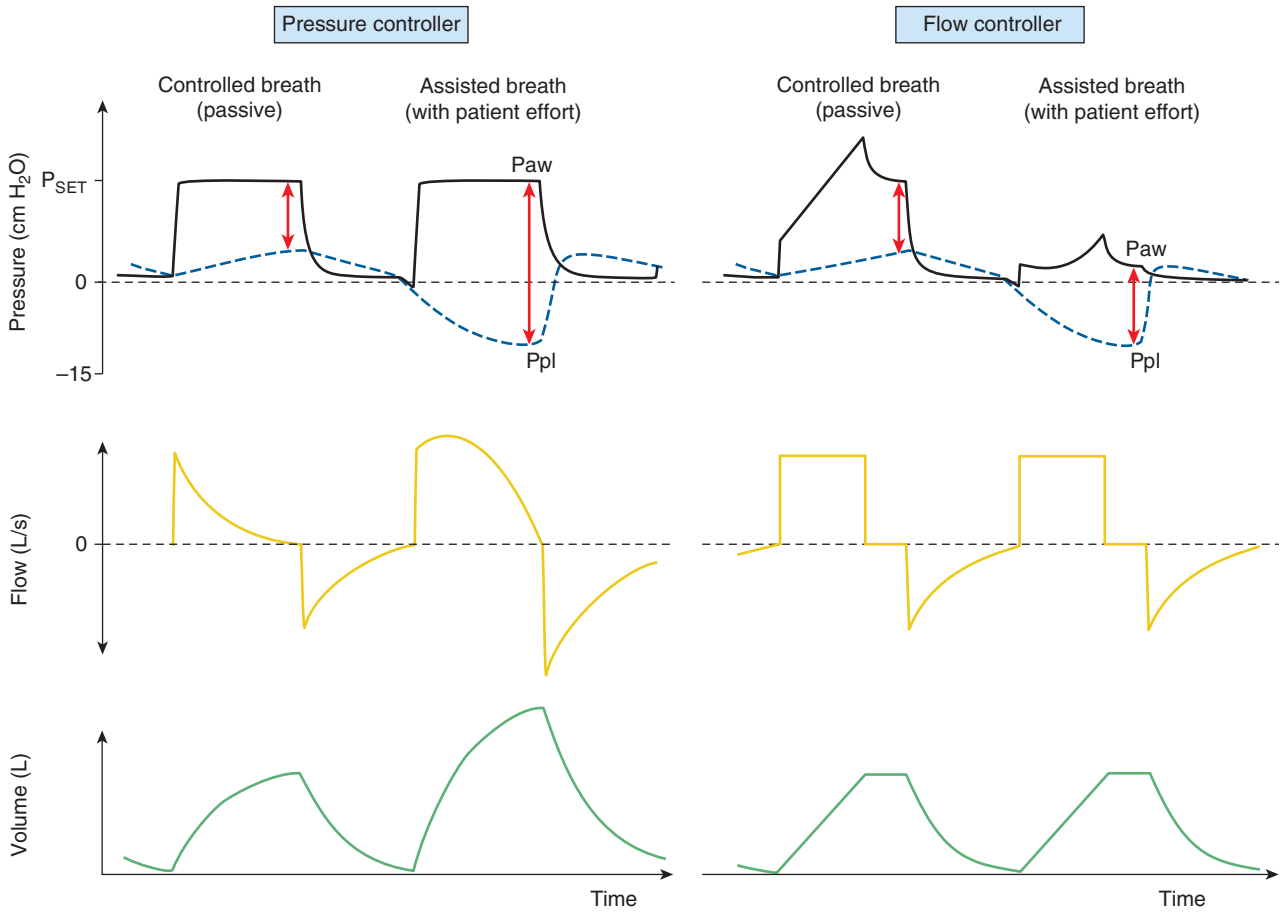

FIGURE 9-1 Airway opening pressure (Paw), pleural pressure (Ppl—*blue dashed lines*), flow and volume tracings during pressure-controlled ventilation (PCV, *left panel of curves*) and during flow-controlled ventilation (VCV, *right panel of curves*). In this simulation, pleural pressures are +1 cm H_2O at relaxed end expiration, which corresponds to the midpleural pressure in a supine patient under anesthesia. In the second cycle of each panel, a patient effort is simulated (muscle pressure = –15 cm H_2O). *Red arrows* at end-inspiration represent the total amplitude of effective transpulmonary pressure at end-inspiration. Note that transpulmonary pressures may increase during assisted PCV, in conjunction with increases in inspiratory flow and tidal volume (second breath in the left panel). In contrast, the assisted-VCV breath (*second breath in the right panel*) is associated with a drop in airway pressures, and with sustained inspiratory flow and tidal volume. The result is a near-constant transpulmonary pressure at end-inspiration. Because of safety concerns, some modern ventilators do not operate as pure flow controllers during VCV if airway pressure drops to below baseline pressure (PEEP); they may provide an extra demand flow to compensate excessive drops in Paw. In this case, the effective transpulmonary pressure might also increase during VCV, although to a lesser degree.

biphasic continuous positive airway pressure, and variants of APRV.[30,31] In some modes, spontaneous respiratory efforts continue. In others, none occur. These modes vary both in their intended objectives and in their criteria for initiating and terminating the machine's inspiratory cycle. Yet all can be viewed as modes in which the machine applies approximately square waves of pressure to the airway opening. In concept, any pressure profile can be regulated. In current practice, however, most *pressure-controlled* modes build pressure rapidly, toward a preset value, attempting to maintain pressure nearly constant throughout the remainder of the higher-pressure phase. During exhalation, pressure is released abruptly, allowing passive deflation to occur unimpeded or against a set PEEP level. By fixing the level of applied pressure during inspiration, the physician imposes an upper limit to the machine's energy transferred to lung tissue.

The specifics of the new pressure-controlled modes are discussed in other chapters. The physical principles governing pressure-controlled, *time-cycled* ventilation—which serves as the prototype for this group—and its major "outcome" variables, such as tidal volume, minute ventilation, and intrinsic PEEP, are addressed here. Some discussion of the concepts of mean airway pressure ($\overline{P}_{aw}$) and mean alveolar pressure ($\overline{P}_{\phi A}$) also are presented because these concepts are essential tools for understanding the physiologic implications of all pressure-controlled modes.

Input Parameters of Pressure-Controlled Ventilation

Apart from the external PEEP, the clinician sets only three parameters during PCV: the applied inspiratory pressure, backup or mandatory frequency, and fractional inspiratory time (duty cycle, T_I/T_{TOT}). The most salient feature of PCV is that maximal airway and alveolar pressures are restricted by the cap of preset pressure, whereas tidal volume, flow, minute volume, and alveolar ventilation depend on the impedance of the respiratory system in conjunction with the three input variables just described. Once the impedance (resistance and compliance) of the respiratory system is known, the machine's contributions to ventilation and alveolar pressure can be characterized completely from knowledge of just those three input parameters.

Machines vary in the rapidity (*rise time* or *inspiratory slope*) with which airway pressure builds toward the preset maximum value. Faster rates of pressurization are needed in certain situations when flow demands are high (during assisted *pressure-controlled* ventilation) so as to achieve high peak inspiratory flows that exceed patient demands. Because of limitations in the controlling system of most ventilators, however, a faster (shorter) *rise time* has to be selected during low-impedance conditions (in large patients), whereas a slower one has to be selected during high-impedance conditions (to avoid overshoots in airway pressure at the beginning of inspiration). Some newer machines allow the clinician to adjust rise time to suit the situation at hand, whereas others adjust it automatically.

With most machines today, physicians set the pressure increment above external PEEP to be applied during inspiration. This means that absolute inspiratory pressures increase as external PEEP increases. With a few machines, the physician has to set the absolute inspiratory pressure, which is independent of external PEEP.

Mean Airway and Alveolar Pressures

When considering a plot of airway-opening pressure (Paw) over time, mean airway pressure is the integral of Paw over time divided by the time span of the breath. Two input parameters that the clinician sets during PCV bear direct relationships to mean airway pressure ($\bar{P}_{aw}$): preset inspiratory pressure and T_I/T_{TOT}. Because of the square waveform of pressure during PCV, $\bar{P}_{aw}$ can be expressed simply as

$$\bar{P}_{aw} = P_{SET} \times T_I / T_{TOT} + PEEP_E \times (1 - T_I / T_{TOT}) \qquad (1)$$

where $PEEP_E$ is external PEEP. Therefore, variations in either set pressure (P_{SET}) or T_I/T_{TOT} influence $\bar{P}_{aw}$ predictably. Frequency variations leave $\bar{P}_{aw}$ unaffected.[28,29]

Under passive conditions, airway pressure represents the total pressure applied across the respiratory system. Under this circumstance, it can be demonstrated mathematically that mean alveolar pressure $\bar{P}_A$ bears a close relationship with $\bar{P}_{aw}$, and its bedside estimation requires only some previous assessment of inspiratory and expiratory resistances

$$\bar{P}_A = \bar{P}_{aw} + \dot{V}_E \times (R_E - R_I) \qquad (2)$$

where R_E and R_I are mean expiratory and mean inspiratory resistances, respectively, and $\dot{V}_E$ is the minute ventilation.

Some practical conclusions can be drawn from this simple formulation. First, changing frequency alters mean alveolar pressure very little if inspiratory and expiratory resistances are similar. In this particular situation, mean airway pressures will reflect alveolar pressures consistently. Conversely, when expiratory resistance exceeds inspiratory resistance, a frequent condition in chronic obstructive lung disease, mean airway pressures can seriously underestimate mean alveolar pressures, especially when minute ventilation is high. Under such conditions, variations in frequency do influence mean alveolar pressure, and physicians easily could overlook the hemodynamic consequences of a ventilator setting.

Figure 9-2 illustrates some additional features related to alveolar and airway pressures during PCV. Alveolar pressure (P_A) can rise no higher than P_{SET}, the pressure to which it equilibrates at end inspiration when sufficient inspiratory time is provided (in Fig. 9-2 there is no equilibrium). Peak P_A falls rather than rises with increasing frequency. One also can grasp from the figure that intrinsic PEEP increases with increasing frequency, reducing the *effective* ventilating pressure (P_{SET}–total PEEP) and consequently reducing tidal volume. As frequency increases further, P_A oscillations decline to the point that $\bar{P}_A$ sets the upper bounding value for intrinsic PEEP.

Under conditions of passive inflation, mean airway pressure reflects the average distending pressure of the respiratory system. Understandably, therefore, mean airway pressure has been associated with two beneficial physiologic effects (ventilation and oxygenation) and three potentially noxious effects (hemodynamic compromise, fluid retention, and barotrauma). These effects, however, are nonlinear, and there are exceptions. For instance, as discussed later, the relationship between $\bar{P}_{aw}$ and oxygenation is very dependent on the extent of pressure-volume hysteresis of the lung, which is greatly affected by lung disease. The greater the hysteresis, the greater is the dependency of oxygenation on PEEP and previous lung history (i.e., the maximum alveolar pressure achieved in previous breaths), and the looser is the correlation between the current $\bar{P}_{aw}$ and oxygenation. In situations of negligible lung hysteresis, for instance, during partial liquid ventilation, the correlation between $\bar{P}_{aw}$ and oxygenation is straight forward.[30] The complex relationship between $\bar{P}_{aw}$ and oxygenation is further elaborated in the short discussion of IRV below.

Mean airway pressure is also a measurable correlate of the back pressure for venous return. Raising $\bar{P}_{aw}$ during passive ventilation increases both lung and chest volumes by similar amounts. Lung expansion tends to increase right-ventricular afterload, which is already high in many patients

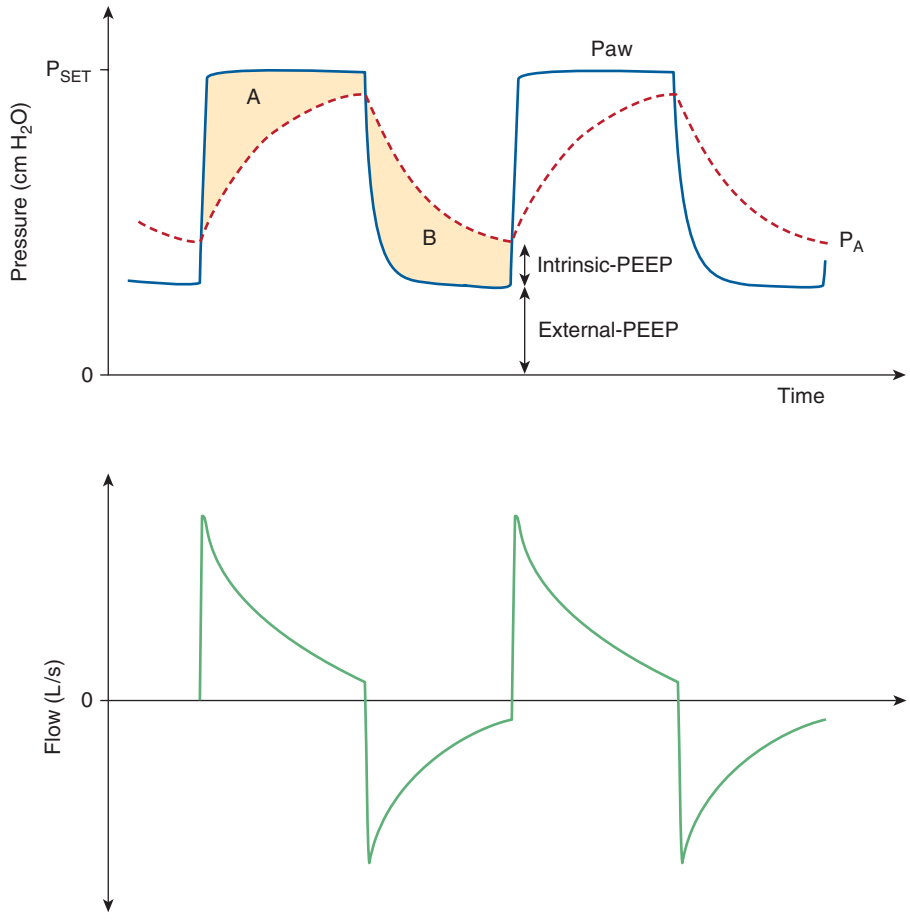

FIGURE 9-2 Airway opening pressure (Paw), alveolar pressure (P_A, red *dashed line*) and flow during pressure-controlled ventilation. Intrinsic-PEEP presents a backpressure that opposes the applied pressure (P_{SET}) and reduces the effective ventilating pressure, which is equal to P_{SET}–total-PEEP (total-PEEP = intrinsic-PEEP + extrinsic-PEEP). Areas *A* and *B* represent the pressure-time product dissipated during inspiration and exhalation, respectively. These areas are proportional to mean inspiratory and expiratory resistances.

with acute respiratory failure. More important, the increase in intrapleural pressure may raise right-atrial pressure, often impeding venous return. Rising back pressure can have clinical consequences in patients with impaired systemic venous tone and reduced tissue turgor (e.g., consequent to sedation or paralysis). Sodium and water retention also tends to correlate with the magnitude of $\bar{P}_{aw}$. Although high $\bar{P}_{aw}$ may not be directly implicated in the *generation* of barotrauma (barotrauma seems to be mainly associated with high inspiratory plateau pressures or high inspiratory driving pressures[31]), a high level of $\bar{P}_{aw}$ may *exacerbate* damage or *accentuate* gas leakage through rents in the alveolar tissues, thereby bringing barotrauma to clinical attention.

Output Variables of Pressure-Controlled Ventilation

As discussed earlier, the major "output" variables of PCV are tidal volume, intrinsic PEEP, minute ventilation, alveolar ventilation, and inspiratory flow.

TIDAL VOLUME

When maximal airway pressure is preset, the tidal volume actually delivered varies with several key variables: the pressure gradient existing between the airway opening and the alveolus at the onset of inflation, the resistance to airflow, the compliance of the respiratory system, and the time available for inspiration. Theoretically, inspiratory time should be longer than the three time constants of the respiratory system to allow near-complete (>95%) lung filling, thus maximizing delivered tidal volume. This scenario would guarantee that alveolar pressures are in equilibrium with airway pressures at the end of inspiration. In adult patients with orotracheal intubation, equilibration usually requires 1.0 to 1.5 seconds of inspiration. In the presence of severe obstructive disease, this value can be as high as 2 to 4 seconds, whereas in patients with reduced compliance (acute respiratory distress syndrome [ARDS]) this value can be as short as 0.8 to 1.0 second. To improve synchrony during *assisted* PCV, sometimes it is necessary to match the spontaneous inspiratory time of the patient. In this case, inspiratory time rarely should exceed 1.2 seconds, usually resulting in incomplete lung filling but promoting comfort.

Any residual end-expiratory pressure (intrinsic PEEP) detracts from the total pressure difference available to accomplish ventilation (*driving pressure*). Therefore, incomplete lung emptying is also an important factor affecting the delivered tidal volume. To allow near-complete lung emptying, expiratory time should be longer than three expiratory time constants. The aggravating factor is that expiratory resistance is usually higher than inspiratory resistance, implying that the expiratory time constants are longer. An expiratory time shorter than 1.5 seconds in an adult patient should be considered a potential source of intrinsic PEEP, reducing the potential for tidal volume delivery.

Such relationships are also valid during low tidal ventilation (used for lung protection, often combined with tidal volumes of approximately 6 mL/kg or lower), which means that incomplete lung filling or emptying are common at respiratory rates above 25 to 30 breaths/min. Because the *absolute* values of intrinsic PEEP, however, in this setting tend to be negligible (from a clinical perspective),[32] clinicians have used PCV with respiratory rates up to 40 breaths/min without great concern about intrinsic PEEP.

INTRINSIC PEEP

Intrinsic PEEP (auto-PEEP) that results from dynamic hyperinflation is a complex function of the input parameters of PCV in conjunction with the impedance characteristics of the respiratory system.[33] The general principles affecting it can be summarized as follows: (a) higher-frequency, longer T_I/T_{TOT} ratio, and higher P_{SET} tend to increase intrinsic PEEP; (b) increments in T_I/T_{TOT} cause a monotonic increase in intrinsic PEEP from external PEEP up to P_{SET}; (c) pure increments in frequency also cause an increase in intrinsic PEEP but with a saturation effect that limits intrinsic PEEP to half (approximately) the range between external PEEP and P_{SET}, which arises because as frequency rises, inspiratory time is curtailed, preventing equilibration between applied airway and alveolar pressures, keeping maximum P_A well below P_{SET} (Fig. 9-3); and (d) the higher the compliance and the higher the expiratory resistance, the higher is the intrinsic PEEP for the same input parameters. Figure 9-3 illustrates some of these relationships.

MINUTE VENTILATION

The relationships just described are responsible for important and nonintuitive effects on minute ventilation (Figs. 9-4 and 9-5). When frequency increases at constant values for P_{SET} and T_I/T_{TOT}, the durations of inspiration and expiration both decrease, and intrinsic PEEP rises. As tidal volume falls, minute ventilation exponentially approaches an upper bound mainly determined by resistance.[33] In obstructed adult patients breathing at respiratory rates above 40 breaths/min, changes in compliance have a minor influence on minute ventilation generation, because most of the *driving pressure* is spent in overcoming resistive losses. For instance, a decrease in compliance from 100 to 50 mL/cm H_2O will produce a maximum fall in minute ventilation of 10%. This

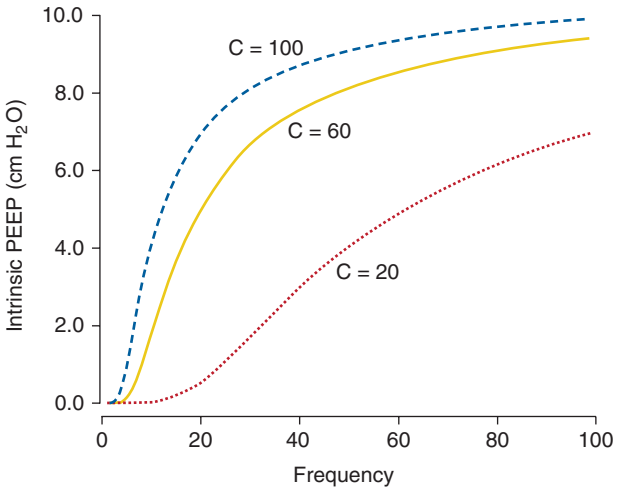

FIGURE 9-3 Effect of frequency on intrinsic-PEEP generation during PCV. Three impedance combinations with moderate airflow obstruction and varying respiratory system compliance (expressed in mL/cm H_2O). A decrease in compliance causes both a reduction in intrinsic PEEP and alteration in the curvature of the intrinsic PEEP-to-frequency relationship. Note that curves converge to an asymptote at 10 cm H_2O, which corresponds to approximately half P_{SET}. *Simulated conditions:* P_{SET} = 20 cm H_2O above PEEP; T_I/T_{TOT} = 0.4; R_E = 25 cm H_2O/L/s. (Adapted from Marini JJ, Crooke PS 3rd. A general mathematical model for respiratory dynamics relevant to the clinical setting. *Am Rev Respir Dis.* 1993;147(1):14–24).

situation resembles a condition commonly observed during high-frequency oscillation,[34,35] when the distribution of ventilation is mainly driven by the distribution of regional resistances, rather than regional compliances.

Figure 9-4 suggests that in patients with moderate to severe airway obstruction (resistance ≥25 cm H_2O/L/s), the benefits of increasing respiratory rate above 12 breaths/min is negligible (this is an important hint when ventilating patients with asthma). The situation changes considerably, however, under conditions of low compliance (≤25 mL/cm H_2O): any increase in frequency becomes an effective mechanism to increase minute ventilation (see Fig. 9-4, *top*).

Important differences between obstructed and restricted patients also can be seen in the relationship between minute ventilation and duty cycle. Minute ventilation becomes very sensitive to changes in duty cycle for obstructed patients but not for restrictive patients. As shown in Figure 9-5, if one wants to maximize minute ventilation for a given P_{SET} (a common target during intensive care of patients with asthma), T_I/T_{TOT} has to be titrated according to the ratio between inspiratory and expiratory resistances. For patients with fixed obstruction and equivalent values for inspiratory and expiratory resistances (as sometimes occurs in asthmatic patients), the ideal T_I/T_{TOT} for maximizing minute ventilation is 0.5.

ALVEOLAR VENTILATION

Over the lower frequency range, increasing frequency tends to improve alveolar as well as total ventilation, decreasing partial pressure of arterial carbon dioxide (Pa_{CO_2}); however,

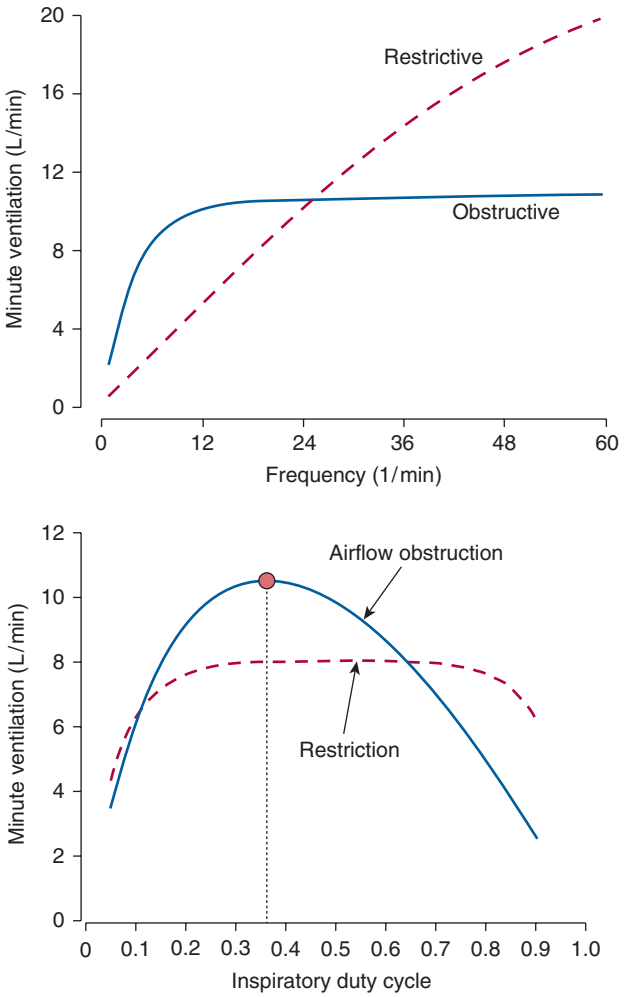

FIGURE 9-4 *Upper plot.* Effect of frequency on minute ventilation during PCV. An increase in frequency causes tidal volume to fall so that minute ventilation approaches a mathematically defined plateau value mainly determined by the applied pressure and resistance. The approach is more gradual for a restrictive ventilatory defect with low compliance. *Bottom plot.* Unlike minute ventilation in the obstructed condition, for which a distinctly optimal T_I/T_{TOT} is evident (*red dot*), minute ventilation in the restricted condition remains essentially unaffected by changes in this parameter. *Simulated conditions:* P_{SET} = 20 cm H_2O above PEEP; T_I/T_{TOT} = 0.4; restrictive, C = 20 mL/cm H_2O, R_I = R_E = 10 cm H_2O/L/sec; obstructed, C = 100 mL/cm H_2O, R_I = 15, R_E = 45 cm H_2O/L/sec. (Adapted from Marini JJ, Crooke PS 3rd. A general mathematical model for respiratory dynamics relevant to the clinical setting. *Am Rev Respir Dis.* 1993;147(1):14–24.)

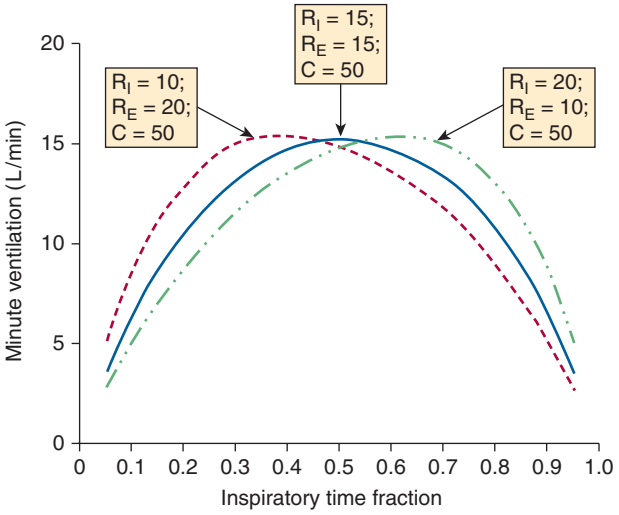

FIGURE 9-5 Effect of inspiratory time fraction(T_I/T_{TOT}) on minute ventilation according to the balance between inspiratory and expiratory resistances (R_I and R_E, respectively). As is true for tidal volume, the apogee of the curve is reached at T_I/T_{TOT} = 0.5, provided that R_I = R_E. Note that optimum T_I/T_{TOT} is shifted leftward, when $R_E > R_I$, exemplifying a common situation in clinical practice. (Adapted from Marini JJ, Crooke PS, 3rd, Truwit JD. Determinants and limits of pressure-preset ventilation: a mathematical model of pressure control. *J Appl Physiol.* 1989;67(3):1081–1092.)

the same is not necessarily true when high frequencies are used. As frequency rises at a fixed, noninverse T_I/T_{TOT}, inspiratory time is curtailed, preventing equilibration between applied airway and alveolar pressures.

From a practical standpoint, the ventilator itself becomes less able to generate the nominal pressure waveform, especially when flow impedance is low and *rising-time* is not optimal. As tidal volume declines, the wasted fraction of each breath (dead-space-to-tidal-volume ratio [V_D/V_T]) increases owing to the predominance of the series ("anatomic") dead-space component. Under certain conditions, this increase in dead space actually may cause Pa_{CO_2} to rise rather than fall with increasing frequency.[36] In practical terms, there is an important message for the bedside: For a given P_{SET} and T_I/T_{TOT}, increments in frequency may cause a decrease in Pa_{CO_2} up to the point that tidal volume decreases by 25% to 30%. Beyond this limit, even when minute ventilation increases with frequency, it is likely that further increments in frequency will be counterproductive because of excessive amounts of dead space.

Because the principles just outlined are rooted in physics and mathematics, hypercapnia can be an unavoidable consequence of a pressure-targeted strategy for managing acute lung injury.

INSPIRATORY FLOW

Decelerating inspiratory flow necessarily is observed during pressure-controlled breaths with rectilinear pressure waveforms—provided that there is no patient effort. Under such conditions, the theoretical maximum of flow associated with a square wave of pressure (P_{SET}) depends on inspiratory resistance (R_I) and end-expiratory alveolar pressure ($PEEP_{TOT}$), and is achieved at inflation onset:

$$Peak\ flow = \frac{P_{SET} - PEEP_{TOT}}{R_I} \quad (3)$$

where $PEEP_{TOT}$ = intrinsic PEEP + external PEEP.

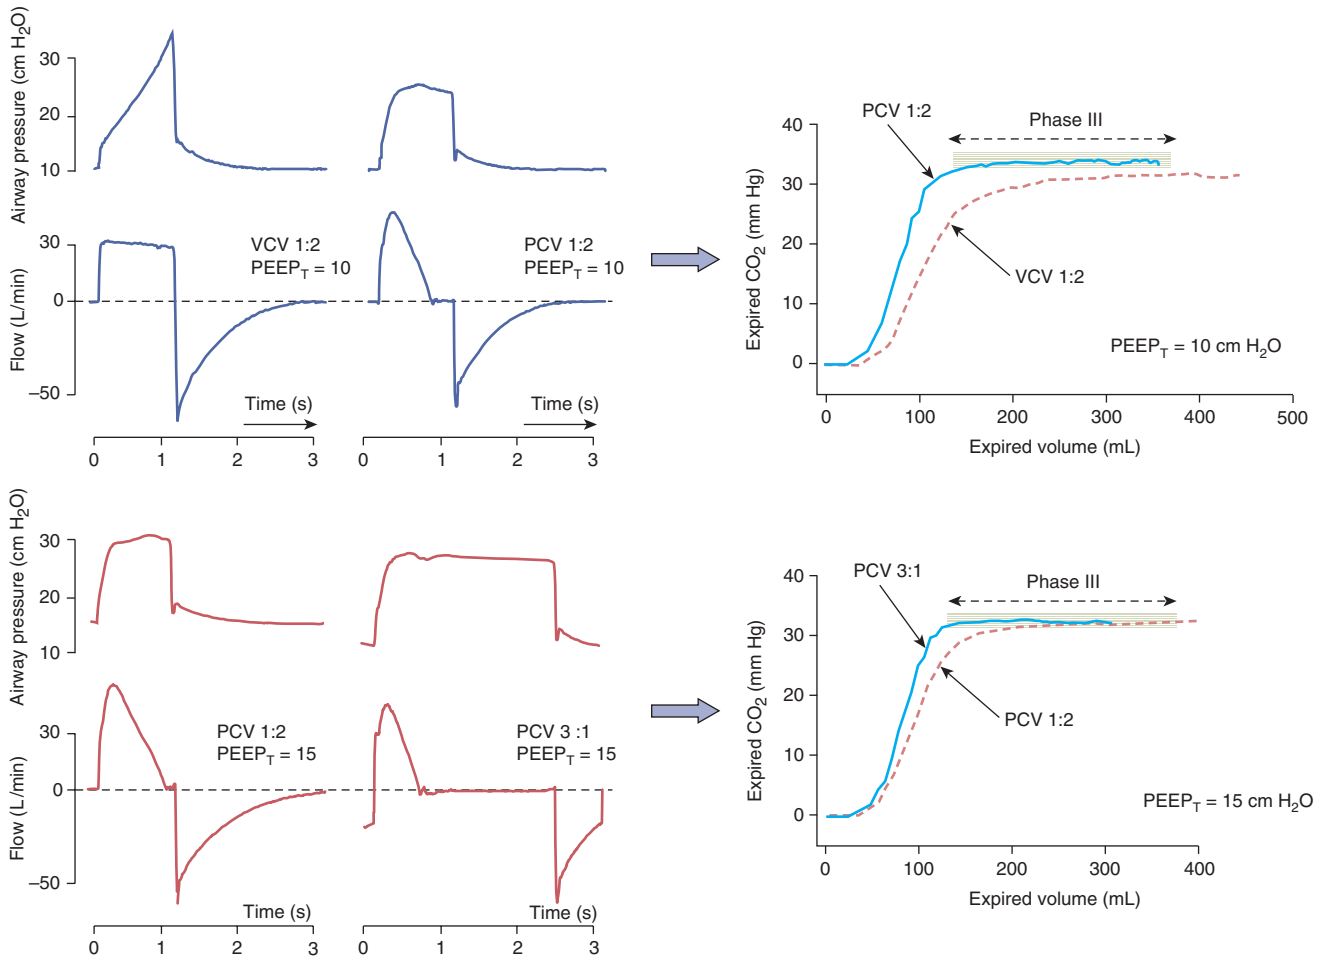

FIGURE 9-6 Effects of inspiratory flow profile on CO_2 elimination per breath (CO_2 single-breath tests obtained in a mainstream volumetric capnograph). *Top.* The change from *flow-controlled, volume-cycled* ventilation (VCV) to PCV, while keeping the same inspiratory time, resulted in more efficient elimination of CO_2 per breath, reflected by the large area under the curve of CO_2 versus exhaled-volume (especially in the first 200 mL, and consequently reflecting a lower dead space). Note that inspiratory flow decayed to zero before exhalation and that the phase III slope is almost flat during PCV, reflecting less heterogeneity among lung units. Arterial P_{CO2} was the same (38 mm Hg) in both conditions, despite the lower tidal volume during PCV. *Bottom.* Changing PCV with an I:E ratio = 1:2 to PCV with an I:E ratio = 3:1 (when part of external PEEP was replaced by intrinsic PEEP) resulted in a further increase in the area under the curve of CO_2 versus exhaled volume. The benefit, however, was much less evident than in the *top panel.*

In practice, however, the abruptness of the rise to the nominal peak value is a set characteristic of the particular ventilator, which may be modulated by the *slope* or inspiratory *rise-time* adjustment. Under conditions of quiet breathing, a precipitous buildup to peak flow often is associated with some pressure overshoot, which may be annoying for monitoring purposes because of alarm triggering. Because most of this pressure overshoot represents pressure dissipation as frictional work across the endotracheal tube, it does not cause elevation of peak alveolar pressure and probably is *not* associated with any harm.

Conversely, under high flow demands (especially in large patients, or in patients using the helmet for noninvasive ventilation), a slow "attack rate" up to peak flow can cause some pressure undershoot or a slow ramp of pressure at the initial phase of the breath, forcing the patient to expend considerable effort and causing delaying filling of the lung.[37,38] Because of limitations in the hardware controlling system, the flow performance of most ventilators, especially at the first 300 milliseconds of inspiration, tends to be poor when P_{SET} is less than 10 cm H_2O. Under such conditions, maximizing rise time or slightly increasing P_{SET} (in association with some procedure to avoid too prolonged T_I, such as shortening the set T_I during assisted PCV, or increasing the cycling-off criterion during PSV[39]) can be very helpful.

The decelerating-flow pattern found in PCV usually improves the distribution of ventilation and limits the end-inspiratory gradient of regional pressures among units with heterogeneous time constants. When inspiratory time is long enough, inspiratory flow may decrease down to zero before exhalation, a phenomenon that further favors redistribution of air or pressure among heterogeneous units and collateral ventilation.[40,41] The consequences of such a flow profile are reflected mainly in the CO_2 eliminated per breath (Fig. 9-6).[42]

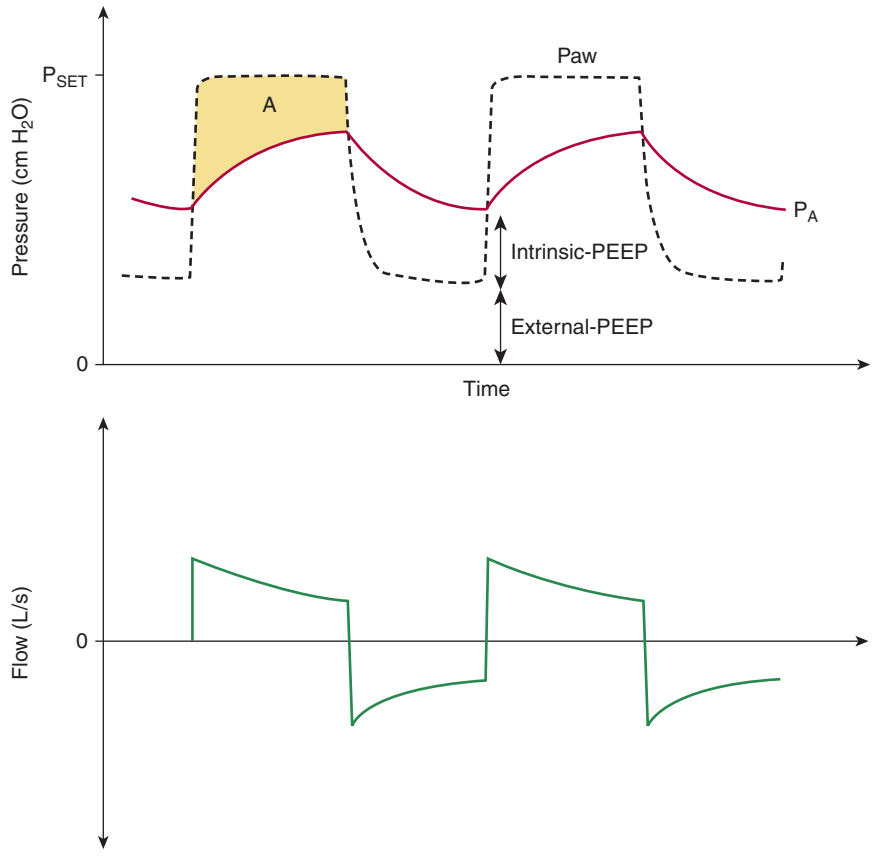

FIGURE 9-7 Typical tracings in an obstructed patient receiving PCV. Note that the flow pattern resembles a square waveform, mimicking *flow-controlled, volume-cycled* ventilation. Intrinsic PEEP is evident and end-inspiratory alveolar pressures (in *red*) are much lower than end-inspiratory airway pressures (*black dashed line*).

The longer the inspiratory time, the more effective is the clearance of CO_2, although most of the benefit may be seen already when T_I slightly exceeds the point of zero flow (Fig. 9-6). This topic is discussed further in "The Controversy on Optimal Distribution of Ventilation" below.

Figures 9-7 and 9-8 illustrate the effects of resistance and compliance on flow profile. Because of the consequent increase in time constant, increments in resistance tend to produce a less decelerating flow pattern (presenting reduced peak flow, with more squared appearance) and rendering tidal volume very sensitive to reductions in inspiratory time. In contrast, decrements in compliance tend to accelerate flow decay. It is obvious, therefore, that restrictive patients tolerate a shorter inspiratory time without marked consequences to their tidal volume.

PHYSIOLOGIC EFFECTS OF PRESSURE-CONTROLLED VENTILATION

Advantages of Controlling Airway Pressures

A major feature of PCV is that peak alveolar pressure cannot rise any higher than P_{SET}. In critical situations, when one attempts to minimize ventilator-induced lung injury, this aspect of PCV may be convenient. Specifying the maximum achievable alveolar pressure, however, does not cap the upper limit for *transalveolar* pressure (equivalent to transpulmonary pressure during an end-inspiratory pause) unless the patient's own breathing efforts also have been silenced (see Fig. 9-1). As suggested by many studies, transalveolar pressure, rather than alveolar pressure, is the key determinant of ventilator-induced lung injury and barotrauma.[43,44]

In the absence of patient efforts, keeping peak alveolar pressures within a safe range makes sense. Under these circumstances, controlling airway pressure effectively controls maximal alveolar pressure. Obviously, the same peak alveolar pressure always can be achieved by flow-controlled, volume-cycled ventilation, although more bedside adjustments are necessary. The subtle difference here is that by selecting *pressure* as the controlling parameter, the physician better defines the priority of his or her strategy (i.e., to minimize peak alveolar pressure at the expense of minute ventilation and possible hypercapnia) and probably minimizes violations to the target during ongoing tidal ventilation (see the section The Controversy on Optimal Distribution of Ventilation).

When thinking in peak alveolar pressures as opposed to peak airway pressures, it is important to stress some important aspects of PCV. When inspiratory time is brief,

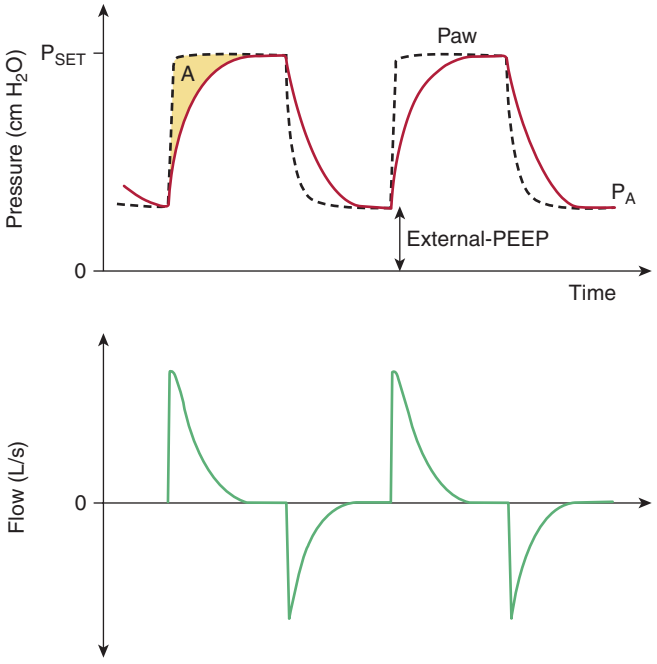

FIGURE 9-8 Typical tracings observed in a restricted patient receiving PCV. Note that inspiratory flow decelerates quickly, achieving zero-flow conditions well before the end of inspiration (generating a small area *A*; compare with Fig. 9-7). There is no intrinsic PEEP and end-inspiratory alveolar pressures (in *red*) equilibrate with end-inspiratory airway pressures (*black dashed line*).

end-inspiratory airway and alveolar pressures fail to equilibrate, so the maximal alveolar pressure is considerably *less* than the set value. This is reflected by persistent end-inspiratory flow, which frequently occurs in obstructed patients.

For a given inspiratory time and peak airway pressure, however, PCV is the waveform that applies the greatest cumulative pressure to the respiratory system.[45] Therefore, for the *same* peak airway pressure—and provided that inspiratory time is long enough—PCV generates a higher peak alveolar pressure and a higher tidal volume than VCV (flow-controlled, volume-cycled breaths delivered with a square-wave profile). Such characteristics of PCV are advantageous during laryngeal mask ventilation: for the same delivered tidal volume, PCV generates lower peak laryngeal pressures during inspiration (approximately 3 to 4 cm H_2O lower than during VCV), resulting in less inadvertent gastric insufflation,[46] and keeps peak airway pressures at a safer distance from the threshold leak pressures.[47]

The consequences of PCV on $\bar{P}_{aw}$ were discussed earlier. It is an important parameter for evaluating the hemodynamic consequences of PCV. Unlike in flow-controlled VCV, $\bar{P}_{aw}$ relates linearly to P_{SET} and T_I/T_{TOT} (see Eq. 1). As its defining equation indicates, $\bar{P}_{aw}$ is unaffected by changes of respiratory system impedance and frequency. Provided that changes in inspiratory and expiratory resistance are roughly balanced, mean alveolar pressures follow mean airway pressures very consistently. Consequently, the impact of adjustments in $\bar{P}_{aw}$ on $\bar{P}_A$ can be predicted much more easily during PCV than during VCV.

Such a straightforward relationship between $\bar{P}_{aw}$ and the input parameters of PCV may be convenient during short-term procedures such as recruiting maneuvers. By adjusting PEEP, P_{SET}, and T_I/T_{TOT}, one can easily predict the generated $\bar{P}_{aw}$ (or $\bar{P}_A$) and hence the hemodynamic consequences. Recent studies demonstrate the relative safety of recruitment maneuvers using PCV for 1 to 2 minutes,[15–17] which achieved equivalent or superior efficacy as sustained pressure maneuvers (continuous positive airway pressure [CPAP]) adjusted to equivalent P_{SET}.[15,48–51] Because the motor of effective recruitment is the surpassing of threshold opening pressures of terminal airspaces,[52] applied long enough to overcome the forces of viscosity and adhesion,[53] cyclic pressurizations with PCV provide an interesting alternative. At the same time that repeated waves of inspiratory pressure promote progressive recruitment, repeated relief of pressure during exhalation minimizes impairment of venous return. Theoretically, one should adjust P_{SET} above the threshold opening pressures, adjust PEEP above the closing pressures, and ensure that inspiratory time is long enough to favor slow, sequential stepwise recruitment of clumps of alveolar units.[52] As suggested by Neumann et al,[54] inspiratory times exceeding 0.6 second (ideally closer to 3 seconds)—for instance, obtained during PCV with a frequency of 8 to 10 breaths/min and an I:E ratio of 1:1—would be enough to maximize the potential for recruitment at a certain P_{SET}. The great appeal of such PCV maneuvers is their reasonable hemodynamic tolerance: because the $\bar{P}_{aw}$ generated during a PCV maneuver is substantially less than the $\bar{P}_{aw}$ generated during a CPAP maneuver (at equivalent P_{SET}), the hemodynamic consequences are less pronounced.[48,50,51,55] Preceding volume expansion with colloids further improves hemodynamic tolerance of the maneuver.[50]

Some investigators, such as Schreiter et al,[56] have applied PCV recruiting maneuvers over much shorter periods (approximately 10 to 15 seconds) but reached higher inspiratory pressures (50 to 80 cm H_2O) and reported good success in patients with severe chest trauma. Comparative data of the relative efficacy and safety of shorter, more intensive application of recruiting pressures[57–60] versus longer (1 to 2 minutes) application of less intensive (45 to 60 cm H_2O) recruiting pressures[15,17,61–63] do not yet exist.

When some active patient effort is present during PCV, the primary control of airway pressures (instead of flow) might offer the potential benefit of introducing some variability in the flow or tidal volume profiles among breaths. By design, an assisted PCV breath provides more freedom (lower machine impedance) for the intrinsic variability of a patient's respiratory motor output to manifest. Besides the likely improvement in comfort, recent research suggest that some random variation (within certain limits) in the effective driving pressure applied to the respiratory system may bring additional benefits in terms of oxygenation, mechanics, and surfactant function.[64–69] The benefits of such extra freedom, however, have to be tempered in conditions where lung protection is a priority, especially when patient effort becomes too vigorous (see Fig. 9-1).

As with any time-cycled mode of ventilation, PCV invites dyssynchrony when the patient breathes spontaneously. The implications of slow *rising-time* settings were discussed earlier. It is important to think about the other end of the inflation period, however, when the airway continues to be pressurized to the nominal value until the set inspiratory time has elapsed. As with flow-controlled VCV, the patient may attempt to cycle to expiration before the ventilator completes its pressurization cycle. One could imagine, however, that unlike the situation with flow-controlled ventilation, patient effort never could force airway pressure higher than the preset value during PCV. Unfortunately, this is not always true (see the section Activation of Exhalation Valve During Pressure-Controlled Ventilation: Airway Pressure Release Ventilation) because of hardware limitations in some ventilators.

Another feature related to dyssynchrony is the fact that by fixing T_I, as required with many commercial ventilators, one allows T_I/T_{TOT} to vary with frequency whenever the patient retains control of the cycling rhythm. As frequency increases, T_{TOT} decreases and T_I/T_{TOT} tends to increase, often provoking dynamic overinflation and generation of intrinsic PEEP. Even with ventilators in which the direct input is "duty cycle," most of them calculate the inspiratory time based on the *set* frequency rather than on *measured* frequency. Therefore, the resulting T_I/T_{TOT} can be very different from the originally set T_I/T_{TOT}.

The Controversy on Optimal Distribution of Ventilation

Several studies have attempted to demonstrate a definitive advantage of PCV over VCV (squared flow pattern) in terms of ventilation distribution, oxygenation, hemodynamics, lung injury, and patient outcome. At first glance, results seem inconclusive. By separating the studies according to key ventilator parameters measured, however, some consistency emerges.

First, it is important to distinguish studies that compare PCV-IRV from studies comparing PCV with normal I:E ratio against other modes. As discussed within this section, the effects of IRV are complex and depend on intrinsic PEEP generation. Thus, during IRV, the choice of the controller (*flow* versus *pressure*) is just a minor issue inside a complex and broader picture. Second, it is important to observe whether all the remaining variables (I:E ratio, tidal volume, intrinsic PEEP, total PEEP, frequency, and O_2 fraction) were kept constant during the comparison and whether they were consistent. For example, studies displaying different plateau pressures or tidal volumes during PCV and VCV can hardly be considered to be perfectly matched if one is interested in the effects on oxygenation[70] or lung overdistension.[71] Thus, they should not be used to draw important conclusions on this controversy.

Keeping such boundaries in mind and by considering only the effects of a pure change in the type of controller (from squared *flow control* to squared *pressure control*, while keeping similar values of I:E ratio, tidal volume, frequency, total PEEP, and plateau pressure), most studies have demonstrated that:

- The resulting decelerating flow during PCV decreases peak airway pressures but increases $\bar{P}_{aw}$.[71–79] Such reduction is helpful during laryngeal mask ventilation,[46] avoiding high peak pressures at the esophageal entrance and avoiding gastric insufflation.[80]
- Pa_{CO_2} and V_D/V_T decrease slightly (ΔPa_{CO_2} approximately 2 to 4 mm Hg), with modest clinical significance,[72,75–77,79] in accordance with the example shown in Figure 9-6. PCV seems to favor ventilation of units with slow time constants, increasing also the *mean distribution time* (defined as the time available for gas distribution and diffusion during inspiration[41,42]). The fast delivery of flow during early inspiration is probably responsible for this effect.
- Such selective benefit in terms of ventilation distribution has been explored theoretically and clinically in obstructed patients.[81–83] PCV is certainly an interesting option in conditions of severe CO_2 retention. Theoretically, however, if obstruction is too severe, the decelerating flow waveform of PCV may become relatively "squared" (see Fig. 9-7), and some benefits reported for decelerating *flow-controlled* VCV[84] (which necessarily achieves zero flow at end-inspiration) may not be directly translated to PCV.
- Minor, if any, changes in dynamic (within the breath) or static lung aeration (end-expiratory or end-inspiratory pause) are observed by computed tomography.[71,74,78] or by mathematical modeling.[85] Regional lung strain measured by computed tomography was also equivalent.[86] Peak alveolar pressure distribution across lung units, however, seems to be more favorable during PCV, guaranteeing a lower exposure to high pressures in more diseased areas of the lung.[85]
- Minor changes are seen in the partial pressure of arterial oxygen (Pa_{O_2}),[72,74,84] slightly favoring PCV.[75,79,87,88] Numerous studies have evaluated the advantages of PCV during anesthesia and one-lung ventilation (during thoracic surgery)[89,90] or during laparoscopic exploration of abdominal cavity,[91–93] including in morbidly obese patients.[94–96] All showed equivalence or minor advantages of questionable clinical relevance.
- No hemodynamic impairment is seen on switching from VCV to PCV, provided that the increments in $\bar{P}_{aw}$ are moderate (usually the case when using I:E<1:1).
- No differences are seen in barotrauma or patient outcome. Studies suggesting benefit of PCV had imbalanced randomization,[88] whereas some studies suggesting benefit of VCV were poorly controlled (including crossovers and rescue procedures).[97–99]

Taken together, the evidence suggests a clear physiologic difference between the two modes of flow delivery, although the clinical implications are modest. At the bedside, the most consistent effects are a reduction of peak inspiratory airway

pressures, increase in $\overline{P}_{aw}$, and small reduction in Pa_{CO_2}. Because of the increment in $\overline{P}_{aw}$, Pa_{O_2} tends to increase with PCV, but this depends on PEEP and plateau pressure in the particular case.

Some concerns are raised repeatedly about the potential generation of greater shear forces at the beginning of inspiration during decelerating-flow patterns. It is suggested that the squared-flow waveform might distribute stress more evenly throughout inspiration, theoretically decreasing VILI. This notion, however, is just theoretical speculation, valid in only extreme conditions. The isolated effects of high inspiratory flow rates on VILI[100–109] have been investigated in recent years. Most studies suggest a deleterious effect,[100,104,106–109] although a few suggest a neutral or protective effect.[102,103,105] The deleterious effects, however, could be demonstrated only in association with tidal volumes above 20 mL/kg, and in conditions where PCV caused an approximate three fold increment in inspiratory flow, as compared to VCV.

In the context of protective ventilation, the peak flow rates observed during PCV are much lower, usually within the same range as those achieved during VCV.[25] When the driving pressure set on the ventilator is within the 15 to 20 cm H_2O range, the resistance across the endotracheal tube and connectors is usually enough to avoid peak flow rates above 1.5 L/s. Thus, consistent differences in VILI will hardly be linked to PCV as opposed to VCV, at least during controlled ventilation and during ventilation with small tidal volume (≤6 mL/kg). Isolated short-term changes in the controller, from flow to pressure control, could probably induce mild perturbations in the effective stress applied on the parenchyma.[85,86] But when compared with the potential for iatrogenic damage associated with other parameters set on the ventilator, such as the choice of tidal volumes or resulting driving pressures (plateau pressure minus PEEP during controlled ventilation), the controller option is most likely insignificant.

As discussed earlier, with adequate feedback it is usually possible to obtain the same ventilator output with either a *flow controller* or a *pressure controller* under specific conditions. For instance, a flow-controlled breath with a decelerating-flow waveform can be generated by modern ventilators, mimicking the flow and airway pressure waveforms commonly observed during PCV[79,110] and producing some of its physiologic effects. Because it is practically impossible to match the degree of deceleration with the impedance characteristics of different patients (e.g., more obstructed patients would present a less accentuated deceleration during PCV), peak airway pressures are frequently higher during such pressure-control "imitations."[110,111]

Considering the evidence presented above, we again suggest that the choice for PCV should be decided in terms of a global bedside strategy and not based on subtle physiologic differences. Minor differences between PCV and VCV may have an impact only when considering the associated clinical problems. For instance, in a patient requiring high PEEP levels, in whom Pa_{CO2} and alveolar dead space are also increased, and who thus requires high plateau pressure to achieve satisfactory ventilation, a change from VCV to PCV might be appropriate because (a) plateau pressures will rarely exceed the physician-adjusted P_{SET}; (b) any decrease in dead space afforded by decelerating flow may allow further reduction in tidal volumes and, thus, in P_{SET}; (c) an eventual rise in respiratory rate triggered by the patient will not be translated into increased plateau pressures despite the possible generation of intrinsic PEEP; and (d) paralyzing agents and sedation may thus be reduced.

Paradoxically, however, such advantages may be quickly nullified if spontaneous efforts become too strong. By decreasing pleural pressures, diaphragmatic activity may cause transpulmonary pressures to be excessive, despite rigid control of maximum alveolar pressures (capped at P_{SET}, see Fig. 9-1). In fact, during strong patient efforts, a *flow controller* avoids excessive transpulmonary pressure more efficiently than a *pressure controller*, because airway pressures follow changes in pleural pressure more closely, being transiently reduced during patient effort (there is no extra "demand" flow to maintain airway pressure). The result is an almost constant transpulmonary pressure. This important physiologic difference may explain some evidences pointing to a better outcome in neonates during *flow-controlled* VCV[112] versus pressure-limited ventilation (which is essentially similar to PCV working with an open exhalation valve; see below the section "Variants of Pressure-Controlled Ventilation and Activation of Exhalation Valve"). Irregular breathing patterns and strong spontaneous efforts are especially common in neonates; the eventual coupling of such efforts with a *pressure-controlled* breath can transiently promote excessive transpulmonary pressures.

This is why we strongly recommend the close monitoring of the extra tidal volume generated by a patient during assisted PCV. Even when P_{SET} is relatively low, it is important to infer the effective driving pressures applied to the respiratory system by observing the resulting tidal volume during synchronous efforts. The simple division of tidal volume by respiratory compliance provides a good estimate of the effective driving pressure (the driving pressure applied across the respiratory system [the lung plus chest wall in series]). It is common to observe patients with ARDS submitted to PCV with P_{SET} at 10 cm H_2O, and producing tidal volumes of 500 mL during synchronous efforts. If respiratory system compliance is 20 mL/cm H_2O, such a presentation means that the effective inspiratory driving pressure is equivalent to 25 cm H_2O. Failure to adhere to these principles can make PCV more dangerous than VCV.

Another point considered here is that peak-flow rates during PCV at low levels of P_{SET} may be equal to lower than during VCV, increasing work of breathing.[25,113] This might appear quite surprising, considering the previous rationale that the *free* inspiratory demand-flow during assisted PCV is an effective tool to reduce the work of breathing.[114] One should note, however, that this rationale was developed in an era when high levels of P_{SET} were common in clinical practice. This topic is discussed in the section Assisted Pressure-Controlled Ventilation.

Assisted versus Controlled (Time-Triggered) Ventilation

Most reasons to control ventilation can be classified as needs to regulate the ventilatory pattern, reverse life-threatening abnormalities in blood gases, reduce agitation and the O_2 cost of breathing, or prevent excessive excursions of the injured lung. Perhaps the most common indication is to provide ventilator support to a patient with marginal cardiorespiratory reserve in whom breathing efforts compromise comfort, gas exchange, or cardiac function. Reducing O_2 consumption in a patient with critical coronary ischemia, for example, may prove lifesaving, especially in the setting of circulatory shock or acute pulmonary edema. Silencing ventilatory effort also can improve arterial oxygenation and lung volume recruitment in agitated patients with ARDS,[115–119] probably by reducing expiratory efforts that may reduce end-expiratory transpulmonary pressures. The silencing of vigorous patient efforts during the first few hours of protective ventilation may also help by decreasing lung inflammation,[119,120] and reducing double triggering ("breath stacking").[121] The active control of minute volume to achieve normocapnia or to achieve transient hypocapnia, when reductions in cerebral blood volume and intracranial pressure are urgent priorities, are also common indications for controlled ventilation. Controlling ventilation greatly facilitates the monitoring of respiratory mechanics but in itself is seldom sufficient reason to undertake deep sedation or pharmacologic paralysis.

Apart from reducing O_2 consumption and preventing spontaneous efforts from interfering with intended patterns of *conventional* ventilation, establishing ventilatory control facilitates the therapeutic application of "nonphysiologic" breathing patterns. Interventions such as IRV,[9,13] independent lung ventilation,[122] continuous-flow ventilation,[123] and permissive hypercapnia[1,3,4,124] usually require cessation of patient effort. In patients with acute lung injury, use of small tidal-volume ventilation is a priority, but this pattern is not easily tolerated by patients unless deep sedation, ventilator overriding,[125,126] or complete paralysis is applied.[120] This is especially true when tidal volume is set at 4 to 6 mL/kg.[125,127]

Sedation is commonly used to enhance comfort or inhibit excessive respiratory drive. Muscle relaxants, however, should be used sparingly because of their injurious potential. A better understanding of the sequelae of prolonged paralysis, especially when combined with sepsis and systemic inflammation,[128] high-dose corticosteroids and hyperglycemia,[129–131] has forced physicians to minimize the magnitude and duration of paralysis in ventilated patients. Recent work suggests that severe diaphragmatic dysfunction occurs after only 2 to 3 days of controlled mechanical ventilation,[132–134] independent of the use of paralyzing agents, with loss of more than 40% of power generation. It is likely that paralyzing agents magnify or trigger such effects[135] by blocking protective mechanism against atrophy. Independent of its precise mechanism, critical illness polyneuropathy increases the duration of mechanical ventilation significantly.[136]

Recent evidence suggests that calm assisted ventilation, with efforts just sufficient to trigger the ventilator, can avoid excessive muscle wasting.[133] Because spontaneous efforts also can improve oxygenation during pressure-controlled breaths,[65,137–139] probably secondary to redistribution of blood flow to nondependent, well-ventilated lung areas, it is tempting to conclude that some level of spontaneous effort always should be promoted in patients receiving PCV. Such approach consistently reduces sedation requirements.[139] An anticipated drawback of such a strategy, however, is an undesirable increase in I:E ratio when the patient respiratory rate is much higher than the set respiratory rate. Another problem is the generation of unpredictably high transpulmonary pressures during strong and synchronous effort by the patient (see Fig. 9-1). In both circumstances, however, deeper sedation or partial paralysis could control the situation easily. By keeping the spontaneous respiratory rate close to the set rate, one easily can avoid changes in the I:E ratio. Also, by keeping the exhaled tidal volume close to a value associated to low driving pressures during totally controlled breaths (see the section The Controversy on Optimal Distribution of Ventilation), one may ensure that a patient's spontaneous effort does not cause significant increments in inspiratory transpulmonary pressures.

VARIANTS OF PRESSURE-CONTROLLED VENTILATION AND ACTIVATION OF EXHALATION VALVE

As discussed earlier, the variants of traditional PCV[10,75] include assisted PCV,[25,114,140] PSV,[141,142] and variants of APRV.[143–147]

Assisted Pressure-Controlled Ventilation

Assisted PCV is similar to PSV in that the breaths can be triggered by the patient (physicians set the sensitivity and triggering mechanism). The difference is that cycling off is determined by time instead of flow. Another obvious difference is that assisted PCV possesses the same backup mechanism available with traditional assisted flow-controlled breaths: breaths can be triggered by patient effort or by elapsed expiratory time, whichever occurs first.

Compared with assisted VCV at equivalent tidal volumes, assisted PCV decreases peak airway pressures. Although irrelevant during invasive ventilation, this characteristic is relevant during noninvasive ventilation, minimizing leaks through the mask[80,148] and avoiding uncomfortably high pressures in the upper airways.[46,149] When comparing the level of patient assistance during invasive ventilation, the characteristic decelerating flow (*on demand*) provided by PCV seems to reduce workload more efficiently than most flow-controlled, volume-cycled breaths.[114,140] The reduction in inspiratory muscle

load is especially prominent during moderate to high tidal volume (8 to 10 mL/kg) ventilation or use of a low inspiratory flow during VCV (<0.7 L/s). It is important to stress, however, that with use of low tidal volume (≤6 mL/kg), this assumption is not always valid.[25,113,125] Because physicians have to set low values of P_{SET} during *pressure-controlled* breaths (to keep tidal volume in a safe range), peak inspiratory flow rates are commonly at lower during PCV than during *flow-controlled* VCV. To circumvent this problem, it is tempting to use higher levels of P_{SET}, guaranteeing a high peak flow at the beginning of a breath, but keeping inspiratory time short enough so that a high tidal volume is not delivered.[39] This maneuver, however, must be used under close monitoring, or combined with some inspiratory pause so as to avoid double triggering and "breath stacking."

The algorithm configured for assisted PCV also may carry some advantages over PSV. First, in patients with unstable respiratory drive, the backup rate works as a safety and stabilizing mechanism, avoiding central apneas and sleep fragmentation, especially in patients with cardiac failure or in those receiving heavy sedation.[150] Second, although PSV is popular during noninvasive ventilation, serious concerns have been raised about potential dyssynchrony at end inspiration. During PSV, transition from inspiration to expiration is triggered by flow (i.e., when inspiratory flow decays below a certain threshold). Hence the presence of mask leaks or severe airway obstruction can render this mechanism inefficient—both conditions cause a relatively high inspiratory flow at end inspiration. Leaks simply mislead the inspiratory flow regulator of the ventilator, which cannot detect that inspiratory flow is not being delivered to patient. Conversely, severe obstruction changes the shape of inspiratory flow (see Fig. 9-7), making it less decelerating and pushing end-inspiratory flows closer to peak flow. With both conditions, the default expiratory triggering threshold for PSV (usually 25% of peak inspiratory flow) may never be reached, causing excessive prolongation of inspiratory time and patient overinflation.[39,151–153] Under such conditions, pressure-controlled, *time-cycled* ventilation could be convenient: The intensivist needs only to adjust inspiratory time to match the patient's spontaneous inspiratory time, usually 0.6 to 1.2 seconds.[39,151,152] By changing from PSV to PCV, the intensivist necessarily decreases the freedom of ventilation pattern (restraining, for instance, the possibility of a spontaneous sigh and potentially increasing discomfort) but also avoids dangerous prolongation of inspiratory time. This is a difficult balance that has to be judged at the bedside.

During assisted PCV, especially under high flow demands, a fast "attack rate" to peak flow (at the initial phase) of the breath is desirable and decreases the work of breathing.[37] Thus, when changing from totally controlled (time-triggered) PCV to assisted PCV, it is advisable to increase the speed of pressurization (i.e., to decrease the *rise time* or to increase the inspiratory *pressure slope*).

Activation of Exhalation Valve During Pressure-Controlled Ventilation: Airway Pressure Release Ventilation

OPENING OF THE EXHALATION VALVE

In theory, any pressure-controlled breath should limit airway pressures to P_{SET} independent of patient demand, dyssynchrony, premature expiratory efforts, or cough. In practice, however, hardware and software limitations of most ventilators preclude such ideal configuration. Usually, ventilators can overcome an increase in inspiratory-flow demands efficiently during PCV (caused by leaks or strong inspiratory efforts) by boosting flow through the demand valve. Airway pressures are raised quickly back to P_{SET}. Additionally, during the period in which the demand valve is still open, any sudden increment in alveolar pressure (cough) can be counterbalanced promptly by a sudden decrease in demand flow, attenuating the potential raise in airway pressures. Once the demand valve is already closed, however—because alveolar pressures have equalized airway pressures—the ventilator is no longer able to control airway pressures. Because most ventilators do not actively control the exhalation valve during inspiration (they just close it tightly until the end of inspiratory time), any unexpected increment in airway pressures can only be counterbalanced by total closure of the demand valve, but this is already at its minimum position. The end result is a steep increment in airway pressures, as in *flow-controlled* breaths.

Physicians have to keep this limitation of PCV in mind because it may be responsible for undesirable increments in airway pressures above P_{SET} in most ventilators. This situation has been observed during continuous tracheal gas insufflation,[154] during cough, and during strong efforts in assisted PCV breaths. In the latter circumstance, marked elevations of airway pressures can be found even in the absence of active expiratory efforts. This is so because the patient effort can increase effective driving pressures in early inspiration, increasing tidal volume and, consequently, the elastic recoil pressure at end inspiration (when diaphragmatic contraction already has ceased). An inactive exhalation valve could not release this extra tidal volume before the beginning of next exhalation, thus increasing airway pressures.

To overcome such limitations, some modern ventilators have incorporated improved hardware in their exhalation system that allows the simultaneous control of both valves (the inspiratory demand-flow valve and the exhalation valve) during the inspiratory phase of PCV. The end result is a smoother control of airway pressures during cough or during continuous tracheal gas insufflation.[155] Whenever available, such active control of the exhalation valve enhances ventilator operation.

The opening of the exhalation valve and its active control during inspiration are the technological basis for incorporation of APRV in microprocessed ventilators.

AIRWAY PRESSURE RELEASE VENTILATION AND ITS VARIANTS

APRV is a form of partial ventilatory support intended originally to offload a portion of the work required to ventilate during a primary crisis of oxygenation.[143,144] In its original conception, APRV elevated mean airway pressure by maintaining a moderately high level of CPAP, delivered through a specially designed high-flow CPAP system linked to a release valve operated by a time controller. The system was design to work independently of any commercial ventilator. Spontaneous breaths were planned to occur around this pressure baseline. Periodically, the airway was depressurized rapidly during one of the patient's deflation cycles, exhausting waste gas from the expiratory reserve before replacing it with fresh gas as CPAP rebuilt to the baseline level. Total time for both phases of the release cycle generally was brief, ideally occupying only a single breath of the patient's rhythm. The release pattern was repeated at a clinician-selected frequency. As predicated by the mathematics of pressure-preset ventilation,[33] ventilator support (achieved by the machine) was necessarily a function of the number of release cycles, the magnitude of the pressure drop during release, the duration of the release period, and the impedance to inflation and deflation. Synchronization between the patient's own exhalation and airway depressurization also affects the effectiveness of ventilation. Ineffectual inspiratory efforts during the deflation phase could impair the released volume. Despite such concerns, the original system was not designed to be synchronous.

Subsequently, different names were used for similar systems and arrangements, *biphasic positive airway pressure*, *intermittent mandatory pressure-release ventilation,* or simply *PCV+* (this latter mostly used in the United States). Despite the similarity, the term *bilevel airway pressure,* commercially known as *biphasic continuous positive airway pressure,* represents something different, being simply a combination of pressure-supported ventilation and CPAP; this product is designed for noninvasive use. The basic difference among these systems is the duration of each phase, although all the systems can be approximated to periodic alternation between two CPAP levels according to a time controller. A longer period at the lower CPAP level, enough to allow one or more spontaneous breaths, is characteristic of biphasic positive airway pressure ventilation. This definition, however, is not consistent in the literature, with considerable ambiguity in the use of terms.[21] Commercial ventilator branding further add to confusion. The specific transition from low to high CPAP levels differs among these variants, whether it is synchronized or not.

Adjustment of all these features is now possible in modern ventilators, and this does not represent any important conceptual modification. Accordingly, we believe that the confusing proliferation of names should be simplified under a single acronym: *APRV*.

In modern ventilators, provided that the ventilator works with an *active* (open) exhalation valve during inspiration, APRV can be perfectly imitated by PCV breaths with a single difference. During APRV, if the expiratory time is set long enough to allow the patient to complete one or more spontaneous breaths during the low-pressure phase, the spontaneous breath will be assisted by an efficient CPAP system (equivalent to PSV set at zero driving pressure). Conversely, during the exhalation phase of PCV, the spontaneous effort cannot be well assisted in most ventilators, because the bias-flow systems responsible for PEEP maintenance are not designed to support strong efforts. The end result may be some drop in PEEP unless sensitivity is adjusted to allow triggered inspirations (this latter, however, will result in an *assisted* PCV breath, which will necessarily cause an increase in the I:E ratio).

During the inspiratory phase, the opening of the exhalation valve during PCV assures that both systems perform identically, allowing spontaneous breaths to occur around highly sustained airway pressures. When spontaneous breaths are abolished by paralysis, APRV is not different from PCV.

It is important to remember that spontaneous cycles and ventilator cycles are completely uncoupled in the most frequent usage of APRV. This means that spontaneous breathing can occur at any phase of the ventilator cycle without any synchronization mechanism. Switching between the two CPAP levels obeys a timed-cycled mechanism, and patient inspiratory work is mechanically supported only when it coincides with the restoration of the high CPAP phase. In view of such inherent dyssynchrony, more sophisticated APRV algorithms have been introduced in recent years, although without a clear rationale or clinical benefit. These include triggered transitions between low and high CPAP levels and use of PSV during one or both phases, on top of the corresponding baseline pressures.

Regarding the synchronized transition, it is important to remember that whenever commercial ventilators allow the patient to trigger the CPAP transition, usually during a time-window that spans the last 25% of the preset low-pressure phase, the actual time intervals at high and low pressures (equivalent to I:E ratio) may vary according to the respiratory drive of the patient.[156] Furthermore, even when some synchronization with CPAP transitions is attempted, most spontaneous breaths during APRV are still nonsynchronous because of the long duration of both phases. Under such conditions, the real advantage of synchronized systems is questionable. *From a workload perspective, APRV is an inefficient way of assisting the patient, imposing a higher workload and greater discomfort as compared with equivalent levels of PSV or assisted PCV*.[65,139,157,158] The benefit, if any, of providing some synchronization has to be balanced against the loss of control over T_I/T_{TOT}. Synchronization would only make sense if applied to most spontaneous efforts, meaning that APRV should be set at higher frequencies and shorter inspiratory times, as with assisted PCV. Another potential disadvantage of synchronization is the creation of high driving pressures

during this upward transition, caused by the coupling of muscle effort with the positive-pressure wave from the ventilator. The high inspiratory volume generated, however, will not be evident when looking at the next exhalation, because the release will occur against a higher PEEP level. To compute this hidden, large, inspired volume, one should carefully look at the next downward transition, a few breaths ahead, when most of the insufflated volume will be finally released.

Whenever APRV is applied in its common configuration, with long time intervals set for both phases, the intermittent mechanical assistance (applied only when the spontaneous effort coincides with transition from low to high pressures) shares some similarities with intermittent mandatory ventilation. As with synchronized intermittent mandatory ventilation, the presence of alternating levels of assistance probably impairs smooth accommodation of patient drive,[159] potentially causing some distress in patients when sedation is removed. Therefore, it is still an open question as to whether APRV will prove helpful during weaning or for patients with extreme weakness, very high workloads, or conditions in which release cycles are relatively inefficient in achieving ventilation (e.g., severe airflow obstruction).

For the sake of simplicity, whenever the patient gets too distressed during APRV and sedation is contraindicated, it is preferable to change to PSV or assisted PCV, assisting the patient in a more predictable way. The combination of PSV with APRV introduces unnecessary complexity, making little sense in terms of physiologic benefit or as an attempt to minimize driving pressures and ventilator-induced lung injury.

By extending the higher CPAP level further, APRV gets closer to inverse-ratio PCV. The shorter the time at low CPAP levels, the lower is the ventilator contribution to minute ventilation,[156] and the higher is the Pa_{CO2}. On the other hand, Pa_{O2} tends to increase because intrinsic PEEP increases. The full consequences of the duty-cycle settings on oxygenation are discussed in the section Intrinsic Positive End-Expiratory Pressure versus Extrinsic Positive End-Expiratory Pressure.

Comparison of APRV associated *with* spontaneous breaths versus APRV *without* spontaneous efforts (identical to conventional PCV), when both modes are set at *equivalent end-expiratory* and *end-inspiratory* airway pressures, showed that the former achieved better oxygenation,[147] higher cardiac output,[147,160] higher renal blood flow,[161] higher lung aeration, and higher functional residual capacity.[145] Whereas the hemodynamic benefits seem to be related to lower intrathoracic pressures generated during spontaneous efforts,[146] the benefits in lung function seem to be mostly related to higher transpulmonary pressures.[145,162] When equivalent transpulmonary pressures are accomplished by controlled PCV without any patient effort (with P_{SET} adjusted at higher levels, matching the transpulmonary pressures observed during APRV), the oxygenation benefits are no longer observed.[162]

It is also important to stress that equivalent physiologic benefits can be achieved during simple CPAP application (matched to the high-pressure phase of APRV), in fact, with better outcomes in terms of oxygenation.[163] These findings demonstrate that *most of the benefits attributed to APRV relate to the replacement of mechanically applied driving pressures by patient-generated driving pressures.*

When considering the overall implications on hemodynamics, lung injury, and muscle function, APRV still poses a well-defined set of potential problems. Central vascular congestion and exacerbated pulmonary edema are natural consequences of lower intrathoracic pressures and increased cardiac workload. Interstitial pressures are expected to be lower in this setting, potentially increasing transcapillary pressures and interstitial edema.[26] Thus, in patients with cardiac failure, APRV should be used with caution. Conversely, to unload inspiratory muscles significantly, the high-pressure CPAP in APRV first must be raised to a considerable degree, obscuring the major advantage of APRV, which is the use of lower airway pressures. Moreover, inspiratory muscles will be disadvantaged by the resulting hyperinflation, promoting a sense of dyspnea that APRV is designed to relieve.

Finally, the intrinsic design of APRV raises important concerns about VILI. Because relaxation of inspiratory muscles is common during end-exhalation, even during spontaneous effort, we should not expect any significant advantage of APRV in terms cyclic lung collapse and its related damage.[164–167] Also, because inspiratory transpulmonary pressures are unpredictable, probably higher than during passive PCV breaths (supposing a situation where P_{SET} matches the high CPAP level of APRV) we should not expect much improvements in terms of overdistension.[18,43,168–170] Conceptually, the same principles of protective ventilation should be respected during APRV: the need to reduce effective driving pressures, whatever their source of generation, and the need to avoid cyclic collapse and tidal recruitment. The practical implications are that the releasing pressures of APRV should be titrated carefully (as during any PEEP titration), and, similarly, driving pressures should be estimated carefully and minimized (as during any attempt to reduce plateau pressures during controlled ventilation). Unfortunately, the general use of APRV rarely follows such protective principles.[21]

In conclusion, the important message provided by studies of APRV is that the preservation of spontaneous efforts is an important aspect of mechanical ventilation that should be employed prudently. Often, the simple use of assisted PCV, instead of fully controlled PCV, is the required change to promote profound benefits in hemodynamics, lung recruitment and oxygenation.

COMBINED MODES

In recent years, attempts have been made to combine the desirable features of both *flow*-controlled, volume-cycled and *pressure*-controlled, time-cycled ventilation. These modes include *pressure-regulated volume-control, volume-assured pressure-support ventilation*,[24] and *autoflow* among others; they guarantee any tidal volume compatible with the physician-set upper pressure limit. Some modes accomplish

a dual target over a few breaths, whereas others, like volume-assured pressure-support ventilation, guarantee a dual target within the same breath. Despite limited research, the original rationale for theses modes was the desire to combine the benefits of *pressure* and *flow* controllers while avoiding their problems.

A major advantage of such modes is their use in patients in whom some level of spontaneous ventilation is desirable, but in whom some control over transpulmonary pressures is necessary. Provided that the patient is not extremely agitated, a volume-cycled target promotes a decrease in inspiratory airway pressures in proportion to the magnitude of patient effort, still allowing the patient to choose inspiratory flow pattern. Such feedback limits transpulmonary pressures and, theoretically, would be a convenient strategy to avoid ventilator-induced lung injury. Also, such feedback usually provides a smooth transition from *ventilator-imposed* driving pressures to *patient-generated* driving pressures. The drawback of such strategy is the increase in the work of breathing, especially when the volume target is set below 6 mL/kg.[125,127]

INVERSE-RATIO VENTILATION

After the tremendous enthusiasm that followed Reynolds' original publication in 1971,[8] especially over the subsequent two decades,[9–13,171–175] IRV has today become an almost extinct mode, with the exception of its incorporation into APRV (see the section Activation of Exhalation Valve during Pressure-Controlled Ventilation: Airway Pressure Release Ventilation). Most studies on IRV used duty cycles (T_I/T_{TOT}) between 0.5 (the lower limit consistent with its definition) and 0.8. The original concept behind IRV was the attempt to increase $\overline{P}_{aw}$ and $\overline{P}_A$ without violating the desired upper limits for airway and alveolar pressures.

In initial studies, IRV was implemented either with *pressure-controlled*, time-cycled forms of ventilation or with *flow-controlled*, volume-cycled ventilation. Over time, the pressure-controlled application gained wider acceptance because of its better performance in terms of gas exchange[28,176] and the lower risks of over inflation when paralysis was not total. Specific details and advantages of those earlier implementations can be found in Chapter 10 of the second edition of this book.

The enthusiasm associated with IRV was driven by the original report of three main physiologic advantages: (a) oxygenation improvement despite the use of low external PEEP,[9–12,171] (b) apparently lower peak inspiratory pressures for equivalent tidal-volumes,[177–179] and (c) very low levels of dead space and efficient CO_2 removal.[72,76,176,177,179–183] Over time, it became clear that these advantages had a high price, and that we have better alternatives while maintaining conventional I:E ratios (<1:1).

The oxygenation benefits of IRV were shown to be the result of two basic mechanisms: (a) higher $\overline{P}_{aw}$ and $\overline{P}_A$ (when compared to conventional I:E ratio at same levels of external PEEP and plateau inspiratory pressures), and (b) higher intrinsic PEEP, promoted by the shorter exhalation time. Other mechanisms, like better gas distribution, were initially proposed and later found to be irrelevant. The relative efficacy of these two basic mechanisms was shown to be related to lung history and the degree of lung *hysteresis*. Some of the intricate relationships between the two mechanisms are shown in Figures 9-9 and 9-10, which can be used as a guide to understand most studies on IRV(even those suggesting an apparent controversy).

The major lesson to be learned from the studies on IRV is that lung hysteresis plays a greater role in the oxygenation response, irrespective of the I:E ratio, than was initially thought. Irrespective of its basic mechanism—which is linked to a complex sequence of lung opening and closing at the microscopic level—hysteresis can be generally understood as a lung *parenchymal memory* to pressure challenges. As schematized in Figures 9-9 and 9-10, one can regard hysteresis as representing an asymmetry of lung status or configuration according to the direction (in time) of pressure variations across the lung. Hysteresis means that there is a transitional state (representing a corresponding window of pressures) in the parenchyma that keeps "memory" of the previous state; if many lungs units were closed in the previous state, it is likely that the system will stay partially or totally closed during subsequent increments in pressure. It is only when pressures reach a certain limit (*opening pressures*), defined by the transitional window of pressures, that we can see a change in status. And the opposite is also true: a previously opened lung state will favor an open lung state during subsequent application of airway pressures, even if airway pressures are brought down to below the opening pressures.

The range of such a transitional window of pressures depends on the distribution of opening and closing pressures of lung units. The higher the mean threshold opening pressure and the lower the mean threshold closing pressure, the larger is this transitional range, and the more the entire system depends on lung history. If we assume, for the sake of simplification, that the blood flow through a lung unit does not change much from inspiration to exhalation, we can grasp the consequences of a large hysteresis on pulmonary shunt and, consequently, on oxygenation.

If hysteresis is large, with a wide transitional window, it is likely that inspiratory plateau pressures will remain below *opening pressures* in a large portion of the lung. In this scenario, a single recruitment maneuver might have a profound impact on those units and, consequently, on oxygenation. Symmetrically, the subsequent use of a proper PEEP, by keeping (or not) alveolar pressures above the threshold closing pressures, would also have a profound impact on oxygenation, preserving (or not) the new status achieved by the recruitment maneuver. In clinical practice, the range of this transitional window of pressures (representing hysteresis) exceeded 30 to 40 cm H_2O in patients with severe ARDS or trauma.[15,56] Such a large hysteresis explains the apparent discrepancy in oxygenation responses across many studies on IRV. A careful match of previous pressure challenges, as well

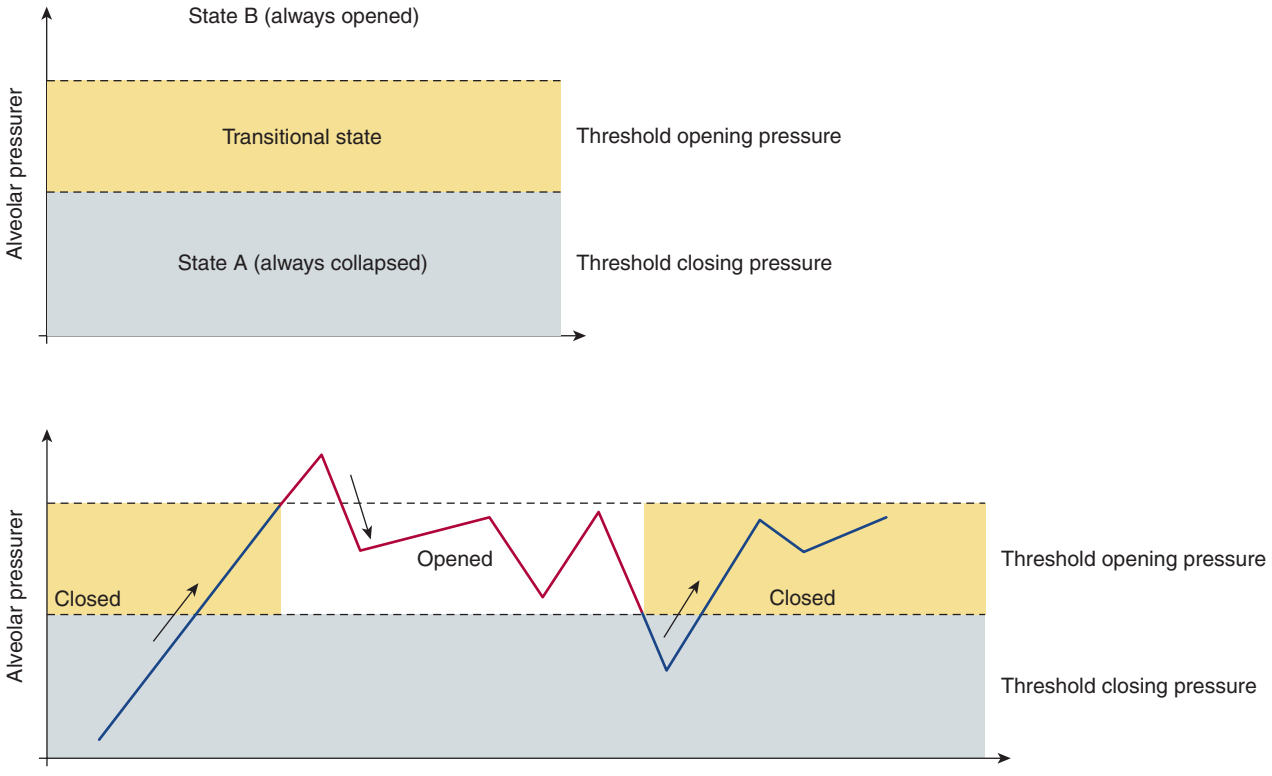

FIGURE 9-9 Representation of lung hysteresis according to the pressures applied on the system (for simplicity, we considered alveolar pressures as roughly representing transpulmonary pressures). The system changes its status according to the direction (in time) of the transition. The transitional state keeps some "memory" of the previous state, behaving like in *state A* when coming from lower pressures, or behaving like in *state B* when coming from higher pressures. Once inside the transitional state, the situation can be stable for a long period, provided that pressures do not trespass the boundaries, that is, the threshold opening/closing pressures. The *red color* illustrates an alveolar condition producing low pulmonary shunt (perfusion of alveoli in an open condition), whereas the *blue line* illustrates a condition associated with high pulmonary shunt (perfusion of closed alveoli).

as a careful match of subsequent total PEEP application, is a prerequisite for any fair comparison. The same principles must be applied today in our understanding about the effects of recruiting maneuvers and external PEEP.[15,184,185]

Conversely, if hysteresis is small, and by using the same rationale, it is also possible to explain why changes in $\overline{P}_{aw}$ (as achieved through prolongation of inspiratory time) are linearly related to oxygenation in particular settings. In fact, a small hysteresis favors the occurrence of tidal recruitment, because it is easier for alveolar pressures to exceed *opening pressures* during inspiration and, similarly, to reach *closing pressures* during exhalation (in the absence of hysteresis, *opening* pressures would equal *closing* pressures). Under this circumstance, any prolongation of inspiration would prolong blood flow through open lung units, decreasing shunt fraction. Using ultrafast intraarterial partial pressure of oxygen (Po_2) sensors, Baumgardner et al[186] showed that arterial Po_2 can oscillate by more than 400 mm Hg along the respiratory cycle, demonstrating the importance of the intricate relationships between *opening and closing* pressures and its direct influence on oxygenation.

Nonetheless, as explained in Figure 9-10, it is often possible to achieve the same oxygenation with conventional I:E ratios, while generating a much lower $\overline{P}_{aw}$ and, consequently, milder hemodynamic consequences.[72,73,176,181,182,187] The latter observation means that IRV represents a waste of $\overline{P}_{aw}$ application: it is always possible to achieve the some oxygenation benefits at a lower hemodynamic cost while using a shorter inspiratory time. More than a waste of airway pressures, some experimental reports have shown greater lung injury and edema linked with longer distending stress during inspiration.[101,187]

The lower peak inspiratory pressures achieved during IRV[177–179] were never proved to be consistent. Many studies show a decrease in peak airway pressures,[72,76,176,181–183,187] but not in peak alveolar pressures. In the few studies in which a true reduction in plateau inspiratory pressures was achieved by IRV (associated with lower levels of total PEEP), the oxygenation benefits could no longer be demonstrated.[177–180]

Finally, the better CO_2 removal by IRV[72,76,176,177,179–183] was shown to be of minor importance and related to the decelerating flow pattern, which increases the *mean distribution time* of the inspired gas.[41,42] As explained in the section The Controversy on Optimal Distribution of Ventilation, however, most of this effect is already observed when T_I slightly exceeds the point of zero flow (see Fig. 9-6), which means that prolonging inspiration beyond this point is of questionable benefit.

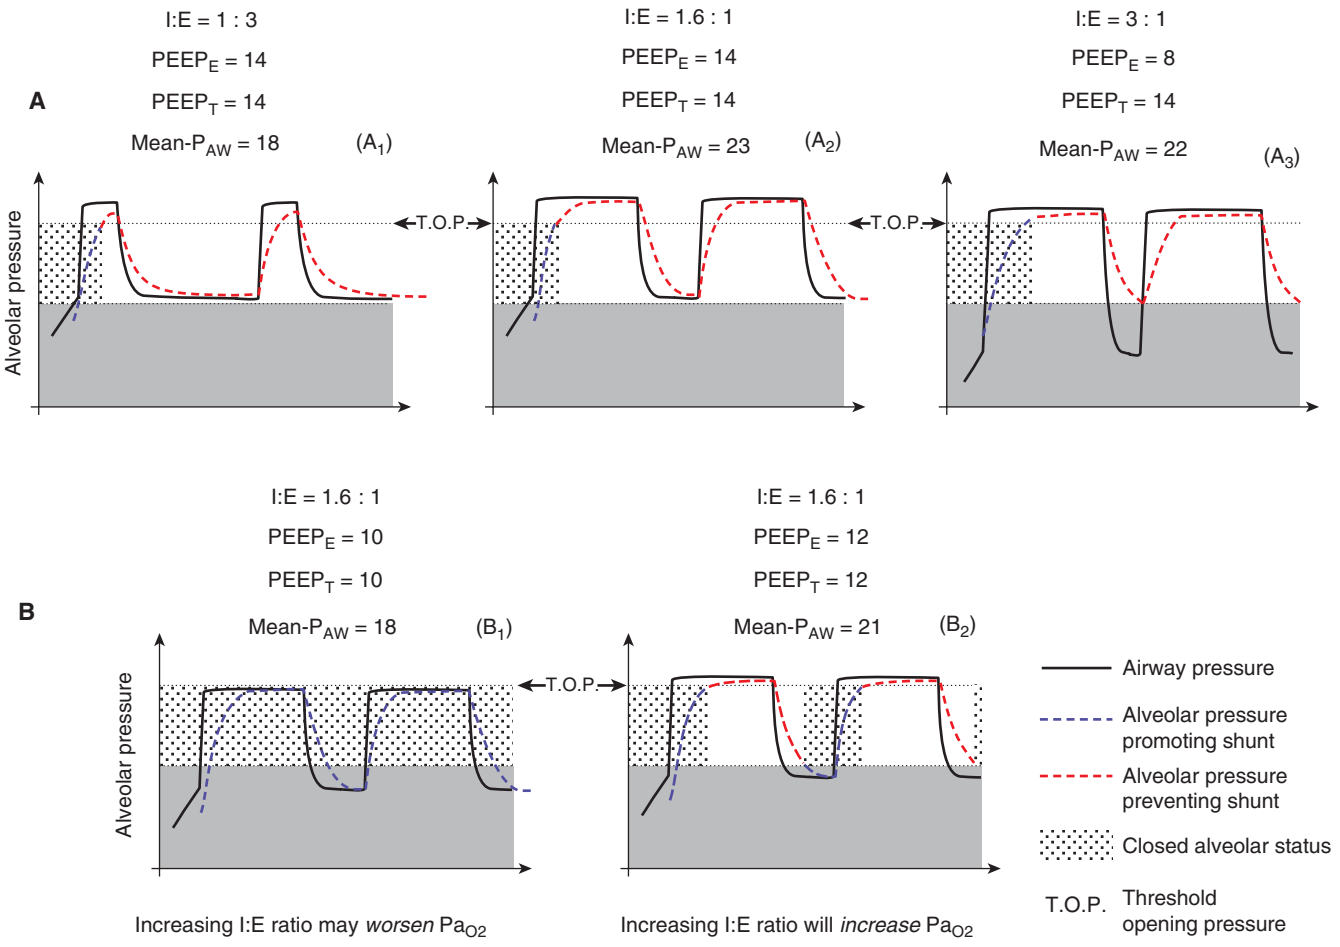

FIGURE 9-10 **A.** Low-shunt situations. Three ventilator settings producing the same effect on Pa_{O2}. In each, alveolar pressures exceeded the threshold opening pressure after the first breath *and* were kept above the threshold closing pressures (defined by the *gray zone*) for the rest of cycles. Provided that a major part of lung units is adequately represented by the boundaries of threshold pressures indicated, the three settings will result in very low and equivalent shunt levels. Under such conditions, increments in mean airway pressure (produced by increased I:E ratios, as in the examples A_2 and A_3) will only put hemodynamics at risk. **B.** High-shunt situations. Because *end-expiratory* alveolar pressures are now trespassing on the closing pressures, the situation changes dramatically. The effect of increased mean airway pressure differs according to *end-inspiratory* pressures developed. In B_1, because P_{SET} is below the threshold-opening pressures, prolongation of inspiratory time can only impair hemodynamics, but the lung stays closed and producing high shunt levels. Conversely, if P_{SET} and alveolar pressures trespass threshold opening pressures during inspiration (B_2), Pa_{O2} becomes dependent on mean airway pressure. The longer the inspiratory phase, the longer the open status and the higher the Pa_{O2}. This situation is commonly observed when lung hysteresis is low or, alternatively, when driving pressures are relatively high, producing tidal recruitment/derecruitment. Alveolar pressures are represented in *blue* or *red dashed lines*, whenever they are promoting or preventing pulmonary shunt, respectively.

Intrinsic Positive End-Expiratory Pressure versus Extrinsic Positive End-Expiratory Pressure

The research on IRV has fostered great controversy on the role of intrinsic PEEP, as opposed to extrinsic PEEP, in patients with alveolar instability. According to some initial proponents of IRV, intrinsic PEEP (intentionally promoted by IRV) should be considered as a "selective" form of PEEP that preferentially ventilates parts of the lung with short time constants, placing at rest parts with prolonged time constants.[188] In a theoretical exercise, if respiratory rate approaches infinity, alveolar pressures would remain practically constant in the *slow* units, equilibrating at an intermediate value between PEEP and P_{SET}. Because healthier units tend to have slower time constants and to be located in nondependent regions in patients with ARDS, intrinsic PEEP is expected to produce less cyclic overdistension of the nondependent parenchyma, increasing ventilation in dependent and more perfused lung regions. Consequently, such selective improvement of ventilation at low $\dot{V}/\dot{Q}$ areas would eliminate CO_2 more efficiently.[189] Another way of formulating such rationale has been to propose a strategy in which "the absolute time of the expiratory phase is so short that the stiffest parts of the lung have no time for collapse."[188] Thus, external PEEP could be reduced, with desirable benefits in terms of hemodynamics.

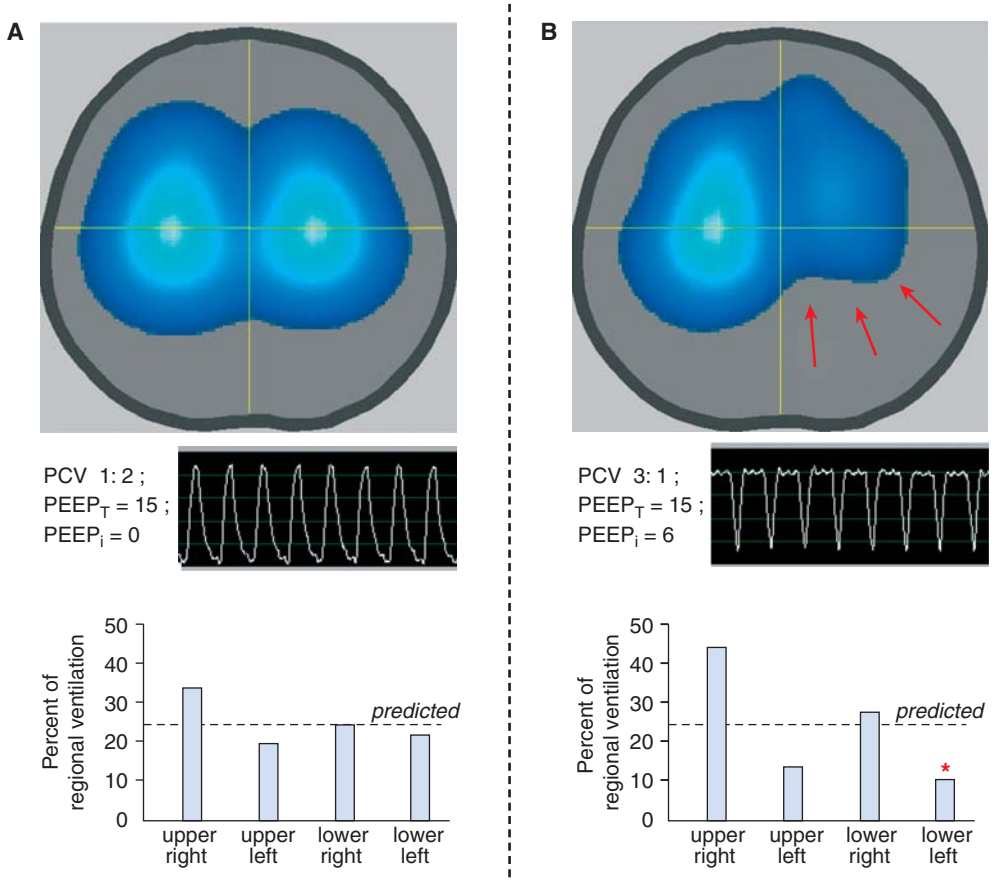

FIGURE 9-11 Regional ventilation distribution measured by electrical impedance tomography (EIT) in an animal model (pig) of acute lung injury. There was preferential injury of the left lung. The functional images display the amplitude of cyclic changes in aeration for each pixel during tidal ventilation. Bright colors represent regions with higher swings in aeration and hence higher regional ventilation. Perfusion perturbations were subtracted by temporal filtering. Although total PEEP in both conditions was the same (15 cm H_2O; checked by end-expiratory occlusion), the left image was obtained during ventilation with external PEEP equaling 15 cm H_2O and PCV with I:E ratio equaling 1:2, whereas the right image was obtained during 9 cm H_2O of external PEEP added to 6 cm H_2O of intrinsic PEEP (PCV with I:E ratio = 3:1). This latter pattern resulted in more heterogeneous ventilation, with preferential ventilation of the right lung and marked hypoventilation of the left lower lung (*red arrows* and *asterisk*). The black midpanel represents the temporal changes in total impedance of the thoracic slice monitored by EIT, which roughly illustrates the cyclic lung volume changes associated to each condition. The graph with bars at the bottom shows that external PEEP produced more even pattern of regional ventilation.

Recent evidence does not support this view but demonstrates the opposite.[54,76,190–194] Because different time constants in individual lung regions are crucial for a "selective effect" of intrinsic PEEP, intrinsic PEEP may allow the "selective collapse" of regions with short time constants, especially the edematous regions. When comparing intrinsic PEEP with matching levels of external PEEP in patients with ARDS, Zavala et al[76] demonstrated that shunt levels increased by 6% with intrinsic PEEP. There was some increase in the efficiency of CO_2 removal, but this could be ascribed to better inspiratory flow distribution during IRV rather than to intrinsic PEEP. Animal experiments in dogs[191] reproduced the same results. Other clinical studies came to similar conclusions,[193] including studies in patients with obstructive disease,[194] suggesting that partial or complete substitution of intrinsic PEEP by external PEEP improves gas exchange without any impairment in CO_2 removal.

The original perspective of considering absolute time for collapse[188]—instead of end-expiratory pressures—also carries some problems. Computed tomographic studies demonstrate that the time window to prevent end-expiratory lung collapse without external PEEP is extremely short (<0.6 second) and might not be feasible during mechanical ventilation of many patients with ARDS.[54,192] To avoid unnecessary confusion, it is also important to prove that time per se, independent of local alveolar pressure, is an important variable affecting lung collapse. To our knowledge, this has never been demonstrated.

After reviewing available evidence, we conclude that there is no rationale supporting the preferential use of intrinsic PEEP. In terms of oxygenation, it seems inferior to external PEEP, slightly increasing the risk of collapse in unstable units.[195] In lung models with different time constants, it is clear that fast (more disease) units are at a disadvantage during intrinsic PEEP generation.[190] Figure 9-11 provides further insight: regional ventilation becomes more

heterogeneous with intrinsic PEEP, with evident collapse in the left lower lung, and ventilation is increased in nondependent regions. A computed tomographic study revealed more hyperinflation with intrinsic PEEP than with equivalent external PEEP.[74]

In terms of CO_2 removal, it is impossible to draw any conclusion because the concomitant use of IRV and decelerating flow in most studies precludes any estimation of the isolated impact of intrinsic PEEP. In clinical practice, one also has to consider that a combination of IRV plus intrinsic PEEP usually results in a higher $\bar{P}_{aw}$ than conventional I:E ratios plus external PEEP and thus greater hemodynamic compromise. Another major drawback of the intrinsic PEEP approach is its complexity. Much closer monitoring and more frequent adjustments of ventilator settings are required, even with a computerized protocol.[196] Consequently, external PEEP in association with conventional I:E ratio is preferable.

If CO_2 removal is a clinical problem, an increased frequency—even if associated with low tidal volumes—may solve the problem, especially when using high PEEP levels. By increasing functional residual capacity, external PEEP usually causes a decrease in airway resistance and lung compliance, both factors contributing to a very short time constant. Under such conditions, respiratory rates up to 40 to 50 cycles per minute could increase minute ventilation considerably (see Fig. 9-3), improving CO_2 removal.

THE FUTURE OF PRESSURE-CONTROLLED VENTILATION

During controlled ventilation, there is little doubt that PCV is advantageous in terms of lung protection, helping physicians better define the targets for lung protection. This is especially true during recruitment maneuvers or in any situation where lung tissue is close to its limits of rupture. In this context, we believe that the growing acceptance of PCV over VCV represents a consistent trend. In the presence of spontaneous efforts, however, the future of assisted PCV is still uncertain and we need more studies to solve important physiologic questions. For instance, during protective, low tidal-volume ventilation, the assisted-PCV option commonly result in higher transpulmonary pressures and higher work of breathing than occurs with optimally adjusted assisted VCV.[25] This is not a limitation of the mode per se, but a problem in the way we employ it. This is also true when we have to choose between assisted PCV and PSV to improve synchrony. Research that addresses deeper questions about priorities in such situations will help us to better define the future of assisted-PCV.

SUMMARY AND CONCLUSION

Contrasted with the growing acceptance of PCV, use of IRV is almost extinct. Safer, more predictable, and more efficient ventilator solutions can be implemented at the bedside. Physicians were initially enthusiastic about IRV because internal PEEP and peak pressures were hidden. Later, physicians realized that total PEEP and peak alveolar pressures were not that different, yet IRV necessarily imposed higher levels of $\bar{P}_{aw}$ and greater hemodynamic consequences for similar clinical benefits. Whereas concepts such as VILI and permissive hypercapnia have boosted the use of PCV, the better understanding of the dynamics of alveolar collapse have dampened enthusiasm for use of IRV.

POSITIVE END-EXPIRATORY PRESSURE

Paolo Navalesi
Salvatore Maurizio Maggiore

Positive end-expiratory pressure (PEEP) is not a ventilator mode itself, but rather an adjunctive treatment that can be combined with all forms of mechanical ventilation, both controlled and assisted,[1–7] or applied to spontaneous breathing throughout the entire respiratory cycle, so-called continuous positive airway pressure (CPAP).[8–10] Following the pioneering work of Poulton and Oxon[11] and Barach and associates[12] who demonstrated in the mid-1930s that application of positive pressure to the airway can effectively treat patients with pulmonary edema, several pathological conditions were proved to benefit from PEEP, which is today considered by intensive care unit physicians as one of the most powerful treatments available for acute respiratory failure (ARF).[13]

Since publication of the second edition of this book in 2006, several relevant studies have been published on PEEP and CPAP, primarily concerning lung injury and cardiogenic pulmonary edema. To update the chapter with this new information, we have condensed material that was covered in greater depth in the second edition.

OVERVIEW OF PERTINENT PATHOPHYSIOLOGY

The reversal of hypoxemia caused by intrapulmonary shunt and venous admixture requires interventions that recruit more aerated lung units for ventilation. In patients with an acute reduction of lung volume secondary to lung edema and/or atelectasis, PEEP can improve arterial oxygenation[1,8] by increasing functional residual capacity (FRC),[14–19] reducing venous admixture,[20–24] shifting tidal volume (V_T) to a more compliant portion of the pressure–volume curve,[25] preventing the loss of compliance during mechanical ventilation,[5,26] reducing intratidal alveolar opening and closing[27] and the work of breathing.[28] Figure 10-1A summarizes the

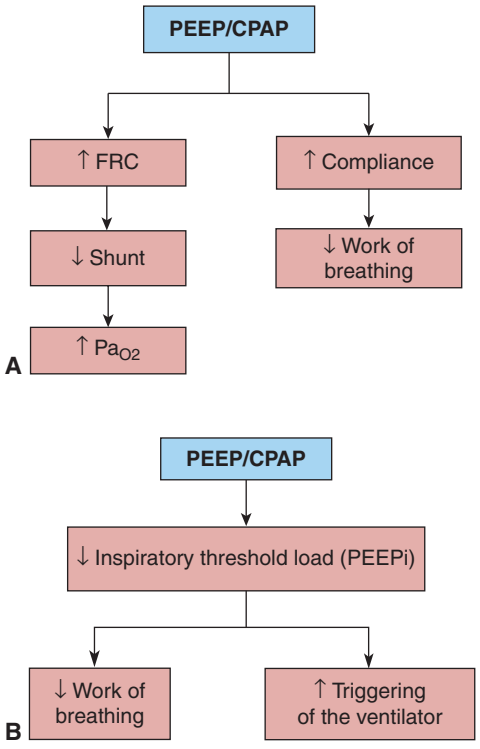

FIGURE 10-1 Respiratory effects of PEEP/CPAP in acute respiratory failure secondary to (**A**) lung volume reduction caused by edema and/or atelectasis and (**B**) airway obstruction and expiratory flow limitation. *FRC*, functional residual capacity; Pa_{O_2}, partial pressure of arterial oxygen; *PEEP*, positive end-expiratory pressure.

rationale for PEEP in patients with ARF secondary to acute lung volume reduction.

Although there is general consensus about the potential of PEEP in treating patients with hypoxemic ARF secondary to lung edema and/or atelectasis, several aspects are controversial. For many years, it has been recognized that the actions of PEEP on gas exchange and pulmonary mechanics are variable,[29,30] depending on the type and severity of lung injury, which may be sustained by different pathways[31,32] and pathophysiologic mechanisms.[31,33] As with any treatment, PEEP is not free of side effects.[34] In patients with acute respiratory distress syndrome (ARDS), PEEP may recruit nonaerated regions, but also distend normally aerated regions,[35,36] contributing to barotrauma through increase in end-inspiratory plateau pressure.[22,37–40] High levels of PEEP also have been shown to augment the physiologic dead space,[24,41,42] and worsen gas exchange[35] and tissue perfusion.[43–45] Potential extrapulmonary side effects of PEEP include decreased cardiac output,[46–51] increased intracranial pressure,[52,53] renal dysfunction,[54,55] and decreased splanchnic perfusion[56–58] and oxygenation.[43,44] Although the benefits and detriments of PEEP in patients with ARDS have been variously weighted for many years, debate as to optimal PEEP and the best method for detecting it is still ongoing.

In the presence of airflow obstruction, the lungs may fail to deflate to FRC at end-expiration and alveolar pressure remain positive to an extent that depends on the volume of trapped air, a phenomenon referred to as *auto* or *intrinsic PEEP (PEEPi)*.[59] In this setting, application of external PEEP may be beneficial. Benefit is evident during spontaneous breathing: CPAP reduces dyspnea[9,60] and work of breathing.[9,60] Benefit is also evident with any patient-triggered mode of ventilation:[2,61–63] PEEP enhances triggering function,[2,61–63] reduces patient's respiratory drive,[62] reduces inspiratory muscle effort,[2,61–63] and improves patient–ventilator interaction.[63,64] PEEP replaces the amount of pressure that must be generated by the inspiratory muscles to offset PEEPi (necessary to initiate inspiratory flow or trigger the ventilator).[2,62] Figure 10-1B summarizes the principal effects of PEEP in patients with chronic obstructive pulmonary disease (COPD).

PEEP has substantial effects on hemodynamics. When left-ventricular function is normal, an increase in intrathoracic pressure causes a fall in cardiac output, largely secondary to decrease in venous return (i.e., preload).[47,65,66] In patients with poor left-ventricular function, when filling pressure and left-ventricular diastolic volume are elevated, cardiac output is relatively insensitive to decline in venous return.[67] In this condition, the dominant effect of an increase in intrathoracic pressure is to decrease left-ventricular transmural pressure (i.e., afterload), which improves left-ventricular performance.[68–71] These effects (Fig. 10-2C) are also observed with relatively moderate levels of CPAP; the impact on afterload is likely to result primarily from a reduction in the inspiratory negative swings of intrathoracic pressure,[72] consequent to improvement in respiratory mechanics.[72] Application of CPAP in patients with severe cardiogenic pulmonary edema may accelerate the physiologic improvement and reduce the need for endotracheal intubation.[10,73–75]

Several investigators have studied the use of CPAP in the treatment of the obstructive sleep apnea syndrome, which is characterized by reduction or cessation of breathing secondary to periodic narrowing and/or collapse of the upper airway. Detailed discussion of this topic is beyond the scope of this chapter. Likewise, we do not provide detailed discussion of positive expiratory pressure, a physiotherapeutic technique aimed at clearance of secretions.

PHYSIOLOGIC RATIONALE FOR POSITIVE END-EXPIRATORY PRESSURE

Effect of Positive End-Expiratory Pressure on Gas Exchange

The role of PEEP in correcting hypoxemia in patients with pulmonary edema and ARF has long been recognized[11,12] and extensively documented.[24,42,76–79] The chief mechanism by which PEEP improves arterial oxygenation is through an increase in the amount of alveoli reached by the air. By decreasing cardiac output, however, PEEP may negatively

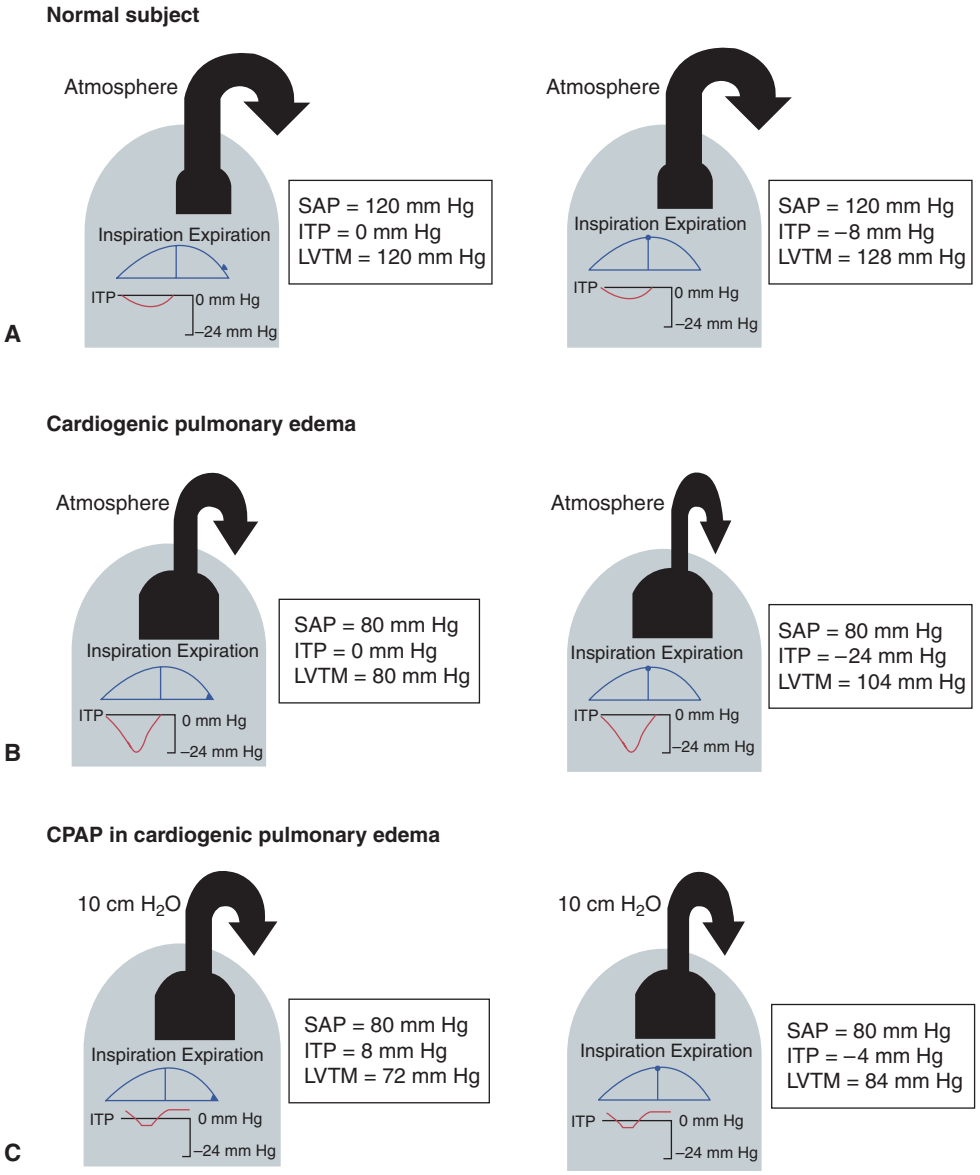

FIGURE 10-2 Heart–lung interactions during spontaneous breathing in a normal subject (**A**), and in a patient with cardiogenic pulmonary edema resulting from a low cardiac output in the absence (**B**) and presence (**C**) of CPAP. The effects of variations in intrathoracic pressure (ITP) on left-ventricular systolic function are shown at end-expiration (*left panels*) and end-inspiration (*right panels*). LVTM, left-ventricular transmural pressure (SAP – ITP); SAP, systolic arterial (intraventricular) pressure. In a normal subject (A), tidal excursions in ITP have little effect on left-ventricular systolic function. With pulmonary edema (B), more negative swings in ITP are needed to achieve the same tidal volume. As a result, LVTM (afterload) is increased independently of systemic vascular resistance. The rise in ITP produced by CPAP 10 cm H_2O (C) produces a slight reduction in LVTM during expiration. CPAP remarkably decreases LVTM during inspiration by decreasing negative swings in ITP, because of improved lung mechanics.

affect mixed venous O_2 tension, which, in turn, decreases the partial pressure of arterial oxygen (Pa_{O_2}) to an extent that depends on alveolar ventilation–perfusion ($\dot{V}_A/\dot{Q}$) mismatch.[80–83]

EFFECT IN ANESTHETIZED SUBJECTS

Arterial oxygenation is often impaired during anesthesia[84,85] as a result of the intrapulmonary shunt[86–90] caused by atelectasis, predominantly in the dependent zones.[85,91–97] Areas of collapsed parenchyma occur in 90% of all intubated anesthetized subjects, both during spontaneous breathing and muscle paralysis.[90,98–100] Other mechanisms, such as regional distribution of ventilation,[101] airway closure,[102–112] and pharmacologic inhibition of hypoxic vasoconstriction[113–116] may also contribute. Application of PEEP during anesthesia can prevent or reverse closing of peripheral airways,[105] decrease atelectasis,[90,100,117,118] and improve regional $\dot{V}_A/\dot{Q}$ ratios and oxygenation,[118–120] although shunt may only be partially improved.[90] In normal anesthetized dogs, however,

Dueck et al found that PEEP ≥10 cm H_2O produced a reduction in Pa_{O_2} and increases in dead space ventilation and partial pressure of arterial carbon dioxide (Pa_{CO_2}). This was mainly caused by a drop in cardiac output associated with an increase in alveolar ventilation of both high $\dot{V}_A/\dot{Q}$ and unperfused lung regions, suggesting overdistension of nondependent lung regions.[121] Similarly, Pelosi et al showed that PEEP values up to 10 cm H_2O decreased, although not significantly, Pa_{O_2} during general anesthesia in normal subjects.[122]

Alterations in diaphragmatic position and mechanics during anesthesia also contribute to impaired gas exchange by inducing ventilation abnormalities in the dependent and caudal zones.[123,124] This phenomenon has been elegantly studied in anesthetized rabbits by Heneghan et al who compared PEEP and phrenic nerve stimulation, adjusted to produce the same increase in lung volume. Phrenic stimulation caused a greater caudal movement of the diaphragm, particularly in the dependent regions, and produced greater improvement in gas exchange than did PEEP.[123]

Beneficial effects of PEEP on oxygenation have been reported in obese patients, who are at greater risk to develop caudal atelectasis during anesthesia, and during pneumoperitoneum induced for laparoscopic surgery causing cephalad displacement of the diaphragm.[122,125,126] Pelosi et al found that PEEP induced an increase in Pa_{O_2} in obese patients; this increase was correlated with recruitment of atelectatic lung regions.[122] Other authors found that the sole application of 10 cm H_2O PEEP was able to reduce atelectasis but not to improve oxygenation in these patients.[125,127,128] Oxygenation improved and atelectasis was further decreased, however, when PEEP application was preceded by a recruitment maneuver or associated with vertical positioning both in obese patients and healthy subjects undergoing laparoscopic surgery. In the former case, use of high airway pressures opened atelectatic lung areas subsequently kept open by PEEP, while in the latter case vertical positioning decreased the negative effect of abdominal pressure on diaphragmatic displacement. In morbidly obese patients, PEEP has also been found beneficial during induction of general anesthesia. Gander et al showed that applying 10 cm H_2O PEEP during induction of anesthesia increased the duration of apnea without hypoxia by approximately 50%.[129]

Conflicting data on the effect of PEEP have been obtained in postoperative patients who had developed respiratory failure. In two studies, PEEP up to 10 cm H_2O did not significantly modify Pa_{O_2} during the early postoperative course of patients who underwent cardiac or vascular surgery.[130,131] Conversely, other investigators found that PEEP, combined with bilevel positive airway pressure ventilation administered via a nasal mask, improved oxygenation in the vast majority of patients who exhibited respiratory distress after various types of surgery.[132–135] A recent randomized, clinical trial found that the use of noninvasive positive-pressure ventilation with low PEEP (approximately 4 cm H_2O) increased Pa_{O_2}, reduced the need for intubation, and improved survival of patients who developed ARF after lung resection.[136]

In summary, use of PEEP to improve oxygenation during and after anesthesia in normal subjects has generated contradictory results, probably because of the deleterious effects of PEEP on hemodynamics and lung overdistension. PEEP, however, can be effective in improving gas exchange in selected patients.

EFFECT IN HYPOXEMIC RESPIRATORY FAILURE

Most forms of hypoxemic respiratory failure, such as cardiogenic pulmonary edema, ARDS, and unilateral pneumonia, are characterized by a decrease in lung volume caused by atelectasis, interstitial and alveolar edema, and small airway closure. The pivotal mechanism for hypoxemia in these conditions is intrapulmonary shunt as demonstrated by the small increase in Pa_{O_2} when pure O_2 is administered,[137] and, to a lesser extent, $\dot{V}_A/\dot{Q}$ mismatch.[138,139] Moreover, the high fractional inspired oxygen concentration (FI_{O_2}) frequently used in these patients, may decrease lung volume by promoting alveolar denitrogenation and reabsorption atelectasis.[137,140,141] In ARDS, the altered blood flow distribution, resulting from widespread involvement of the pulmonary vasculature[142] and impaired hypoxic vasoconstriction, contributes to worsening of gas exchange.[140]

PEEP has long been recognized as an effective means of increasing lung volume and improving gas exchange.[1] In cardiogenic pulmonary edema, CPAP (alone or in association with an inspiratory assistance) improves gas exchange[10,73,143–154] by increasing aerated lung volume,[155] and improving cardiac output[73,143,148] and $\dot{V}_A/\dot{Q}$ distribution.[155,156] A decrease in extravascular lung water is another possible mechanism whereby PEEP reduces intrapulmonary shunt.[157] Yet, PEEP does not decrease, and sometimes increases, extravascular lung water when microvascular hydrostatic pressure is high.[158] Malo et al[156] clarified this issue. They showed that PEEP 13 cm H_2O decreased shunt and alveolar flooding without modifying extravascular lung water; indeed, perivascular cuff edema increased.[156] These findings indicate that PEEP redistributes the excess alveolar water into the compliant perivascular space, thus reinflating previously flooded and collapsed air spaces, without decreasing the overall amount of lung edema.[159]

Unilateral pneumonia and ARDS are characterized by severe impairment of gas exchange because of increased intrapulmonary shunt,[138,140] resulting mainly from flooded and/or collapsed alveoli.[160–163] This observation is corroborated by the correlation between the extent of lung densities mainly found in the dependent regions on a computed tomography (CT) scan and deterioration in arterial blood-gases.[18,78] In fact, the edema increases the total mass of the lung (up to more than twice that of normal lungs); consequently, the dependent zones progressively collapse under the weight of the superimposed lung (compression atelectasis), and aerated lung decreases ("baby lung" concept).[164–166]

Atelectasis in the lower lobes and in dependent lung regions may be caused by other mechanisms, such as

external compression by the heart[167,168] and the abdominal compartment.[93,169–172] The severity of intrapulmonary shunt may also be affected by surfactant abnormalities,[173] increased airway resistance,[174–187] hyaline membranes, and inflammatory proteins and cells accumulating within the alveoli. Interstitial edema and the deposition of cells and connective tissue in the interalveolar septa may further contribute to gas exchange impairment in ARDS. The amount of nonaerated lung volume may also be increased by the combined effects of reabsorption atelectasis[89,138,140,188] and ventilation occurring at low lung volumes.[141,189,190] Hypoxic pulmonary vasoconstriction appears greatly impaired in most patients with ARDS.[140,191] In some patients with diffuse lung injury, however, hypoxic pulmonary vasoconstriction is partially preserved, explaining a lack of hypoxemia despite diffuse loss of aeration. Conversely, hypoxic pulmonary vasoconstriction is constantly impaired in some patients with localized lung injury, explaining severe hypoxemia despite well-preserved lung aeration.[191]

Use of PEEP to correct gas exchange impairment in ARDS was initially proposed by Asbaugh et al.[1] It remains the cornerstone of ventilatory management of these patients. Extensive literature supports the use of PEEP for improving oxygenation in hypoxemic respiratory failure, alone or combined with various ventilator modes, during both invasive[5,18,42,76,78,184,192–209] and noninvasive ventilation.[210–213] Several mechanisms may explain the effect of PEEP on gas exchange. PEEP promotes alveolar recruitment and increases aerated lung volume, therefore decreasing intrapulmonary shunt.[214,215] PEEP-induced recruitment of aerated lung volume is strongly correlated with arterial oxygenation (Table 10-1).[18,197,200,215,216] Prevention of atelectasis consequent to pure O_2 breathing helps explain the beneficial effect of PEEP on oxygenation.[141] In addition, a redistribution of alveolar edema to the interstitial spaces may also explain the benefit of PEEP on gas exchange.[156] Following the pioneering work of Webb and Tierney,[217] PEEP has been shown to decrease pulmonary edema,[218–220] partly because of a concomitant reduction in cardiac output.[219] By recruiting nonaerated alveoli and stabilizing airways, PEEP also affects the regional distribution of tidal ventilation.[169,199,221,222] When the predominant effect of PEEP is recruitment, alveolar ventilation is expected to become more homogeneous, particularly in the dependent zones. Although an increase in lung volume is the main mechanism for PEEP-induced changes in oxygenation, a small decrease in cardiac output also reduces intrapulmonary shunt and improves Pa_{O_2}.[48] Finally, different pathophysiologic mechanisms of ARDS influences the response to PEEP,[31,33,198] although understanding is far from being conclusive.[223]

Improved efficiency of alveolar ventilation and an expected decrease in alveolar dead space should produce a reduction in Pa_{CO_2}. Several authors, however, have failed to find any significant relationship between Pa_{CO_2} and PEEP. The lack of response probably arises because PEEP both favors lung recruitment, which theoretically reduces Pa_{CO_2}, and promotes pulmonary overdistension, which theoretically increases Pa_{CO_2}.[33,169,224]

The benefit of PEEP on gas exchange might also be expected in unilateral pneumonia and localized lung injuries. In these conditions, however, high PEEP is more likely to produce overdistension of normally aerated regions, because of the coexistence of areas with normal, low, and very low compliances.[169,199] The net effect of PEEP on gas exchange depends on the balance between overdistension of already aerated alveolar units and recruitment of collapsed (nonaerated) alveoli, and is also influenced by the level of PEEP.[169,225] In patients with unilateral lung disease, PEEP may be detrimental whenever it hyperinflates the normal lung, thus directing the blood flow to the diseased lung and increasing intrapulmonary shunt.[226–230] To limit this risk, unilateral delivery of PEEP to the injured lung has been proposed;[231] the technical complexity of this approach greatly limits its feasibility in the clinical practice.

In summary, PEEP improves gas exchange in hypoxemic ARF, mainly through recruitment of previously nonaerated lung areas and the homogenization of regional distribution of tidal ventilation. PEEP remains the cornerstone of ventilator treatment of most forms of hypoxemic ARF. Debate continues about the optimal level of PEEP, not about its usefulness.

EFFECT IN OBSTRUCTIVE LUNG DISEASE

Impaired gas exchange in obstructive lung diseases is caused by complex disturbances of regional $\dot{V}_A/\dot{Q}$ relationships associated with alveolar hypoventilation; diffusion impairment is not a major factor.[232] During an acute exacerbation of COPD, high $\dot{V}_A/\dot{Q}$ areas predominate in patients who mostly have the emphysematous variant with loss of blood flow consequent to alveolar wall destruction.[232–234] Conversely, low $\dot{V}_A/\dot{Q}$ regions are mostly seen in patients with a predominant obstructive component.[232–234] In general, application of PEEP does not affect gas exchange.[2,235–238] Nevertheless, Rossi and coworkers reported that low PEEP (50% of PEEPi) induced a moderate increase in Pa_{O_2} and slight decrease in Pa_{CO_2} secondary to improved $\dot{V}_A/\dot{Q}$ distribution without alteration in respiratory mechanics or hemodynamics.[239] Further increases in PEEP (up to 100% of PEEPi) did not produce further improvement in gas exchange.[239] In other small studies, low to moderate PEEP (5 to 9 cm H_2O) produced similar improvements in Pa_{CO_2} and Pa_{O_2}.[240–243] Other authors, however, reported little or no change in arterial oxygenation with PEEP[2,60,237,238] unless high levels were applied;[237,238] Pa_{CO_2} did not change with up to 15 cm H_2O PEEP.[2,60,236–238]

PEEP may have some benefit on gas exchange. Unless hypoxemia is caused by a large intrapulmonary shunt, the benefit is small and of little clinical importance and PEEP may have negative hemodynamic effects that worsen oxygen delivery.[236–238] The balance between positive and negative effects depends to some extent on the level of applied

Abbreviations: *CT*, computed tomography; Δ*EELV*, change in end-expiratory lung volume; *FRC*, functional residual capacity; ΔPa_{O_2}, change in arterial oxygen tension compared to PEEP 0 cm H_2O; *P-V*, pressure-volume; *SD*, standard deviation; *Voverdist*, volume of lung overdistension; *Vrec*, recruited volume.

* Compared to PEEP 5 cm H_2O; † compared to PEEP 10 cm H_2O.

PEEP; nevertheless, the chief reason for using PEEP in COPD is not to improve gas exchange.

Effect of Positive End-Expiratory Pressure on Respiratory Mechanics

ASSESSMENT OF RESPIRATORY MECHANICS

The static behavior of the respiratory system is described by the pressure–volume curve.[244–246] In healthy subjects, the pressure–volume curve, from residual volume to total lung capacity, has a sigmoidal shape.[246] Above FRC, however, the curve is linear. Thus, the tangential slope of the curve (i.e., the linear or chord compliance, reflecting the elasticity of the respiratory system) is constant over the range of tidal ventilation. FRC is the volume of gas in the lungs at the end of a passive expiration. It corresponds to the point of equilibrium between lung and chest-wall elastic recoil.

The shape of the pressure–volume curve reveals two important features: stiffening of the lungs at high lung volumes, and closure of peripheral airways and lung units at low lung volumes.[247] At volumes above 75% to 80% of total lung capacity, the slope of the pressure–volume curve varies, with a sharp decrease in compliance, indicating that the lungs are close to their maximum stretch limit, although the chest wall is normally not stiffer. Further increases in pressure beyond this point, the so-called *upper inflection point* (UIP), have progressively less effect on lung volume. When lung volume falls below FRC and approaches residual volume, the smallest airways tend to collapse under the influence of surface tension of alveolar lining fluid.[248–251] During the subsequent inflation, these structures remain closed until a much higher pressure is applied. From this point on, compliance rapidly increases during inflation, as the closed lung units progressively pop open. This action produces a knee on the pressure–volume curve, termed the *lower inflection point* (LIP).

During constant-flow controlled ventilation, the elastic and resistive properties of the respiratory system can be assessed using the occlusion technique, which consists of occluding the airway at end-inspiration for 3 to 5 seconds.[252–258] As soon as flow is interrupted, there is a rapid drop in airway pressure from the peak (P_{PEAK}) to a lower value (P_1), followed by a gradual decay to an apparent pressure plateau (P_{PLAT}) (Fig. 10-3). Ohmic (flow-dependent) resistance (R_{max}) is calculated as the initial drop in airway pressure ($P_{PEAK} - P_1$) divided by inspiratory flow. The slower pressure change ($P_1 - P_{PLAT}$) divided by the inspiratory flow preceding the occlusion yields the additional tissue resistance (ΔR). The sum of airflow and tissue resistances provides the total respiratory resistance ($R_{TOT} = (P_{PEAK} - P_{PLAT})/\dot{V}$). By occluding the airway at end-expiration, it is possible to determine the total PEEP ($PEEP_{TOT}$), which is the sum of the externally applied PEEP and PEEPi (Fig. 10-4). The difference between P_{PLAT} and $PEEP_{TOT}$ is the recoil pressure. It is then possible to compute the static compliance (Cst) of the respiratory system according to the equation $Cst = V_T/(P_{PLAT} - PEEP_{TOT})$. The failure to take into account PEEPi may result in a substantial underestimation of Cst, especially when low or no PEEP is used.[259,260]

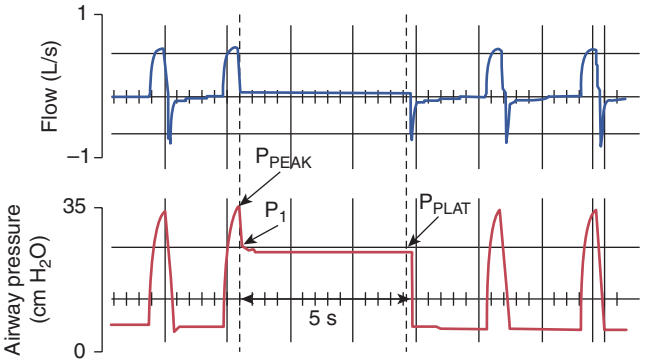

FIGURE 10-3 End-inspiratory occlusion during constant flow controlled ventilation. As soon as the airway is occluded, flow suddenly falls to zero and airway pressure drops from a peak (P_{PEAK}) to a lower value (P_1), and then slowly declines to an apparent plateau (P_{PLAT}).

EFFECTS OF POSITIVE END-EXPIRATORY PRESSURE IN ANESTHETIZED SUBJECTS

Anesthetized healthy subjects may have decreased aerated lung volume, consequent to the decline in FRC associated with the supine posture[93,127,128,261,262] and the potential for airway closure and atelectasis.[85,96,100,127,128,190] Both anesthesia and paralysis affect the mechanical characteristics of the respiratory system,[85,263,264] which can be also impaired by abdominal and thoracic surgical procedures.[125,128,265–267]

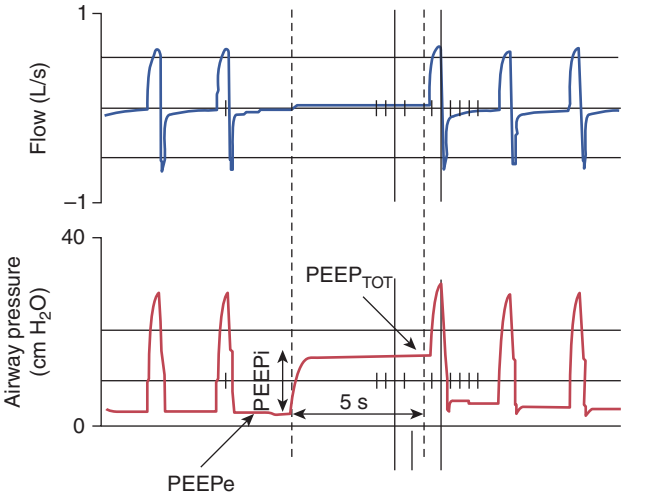

FIGURE 10-4 End-expiratory occlusion. Airway pressure rises following an end-expiratory occlusion and reaches a plateau, which corresponds to total PEEP ($PEEP_{TOT}$). Auto or intrinsic PEEP (PEEPi) is the difference between $PEEP_{TOT}$ and the externally applied preset PEEP (PEEPe). PEEPi measured by an end-expiratory occlusion is termed static.

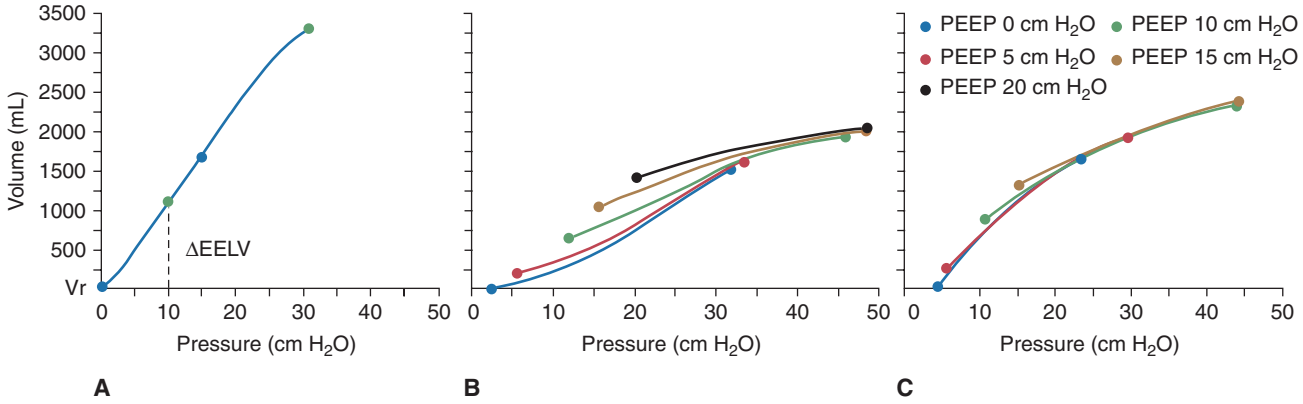

FIGURE 10-5 Pressure–volume (P-V) curves recorded from different PEEP levels in a healthy subject (**A**), a patient with ARDS (**B**), and a patient with an acute exacerbation of COPD (**C**). All curves are related to the relaxation volume of the respiratory system. For each curve, end-expiratory and end-inspiratory points are indicated by *circles*. In the healthy subject, PEEP 10 cm H_2O generates an increase in end-expiratory lung volume and a rightward shift of the P-V curve. The new curve is superimposed on the curve acquired without PEEP, indicating the absence of recruitment. In the patient with ARDS, increasing PEEP produces increases in end-expiratory lung volume and significant lung recruitment, as indicated by the upward shift of the P-V curves. In the patient with COPD, the application of PEEP results in end-expiratory lung volume increase with worsening of hyperinflation, as indicated by the superposition of P-V curves and the progressive decrease in the slope (compliance) of the curves. The reduction in aerated volume in ARDS produces a lower inflection point and flattening of the P-V curve at PEEP 0 cm H_2O. The presence of PEEPi during ventilation without PEEP in ARDS, and more so in COPD, induces a rightward shift of the initial P-V curve. In the healthy subject (*left panel*), the PEEP-induced increase in end-expiratory lung volume is indicated by the *dotted line*. *Vr*, Relaxation volume of the respiratory system.

It is thought that anesthesia primarily alters the elastic properties of the chest wall, causing a fall in FRC, whereas the changes in lung compliance may result from breathing at low lung volumes.[128,263,268,269] Application of PEEP in anesthetized and paralyzed subjects produces an increase in end-expiratory lung volume[125,128,270–272] and upward displacement of respiratory system, lung and chest wall pressure–volume relationships (Fig. 10-5A).[272–274] Several authors, however, report little or no increase in static respiratory compliance with PEEP.[272,275,276] In some studies, PEEP increased both chest wall and lung compliance.[272] In other studies, chest wall compliance increased and lung compliance decreased,[276] or no effect was observed.[275]

The effect of PEEP on the elastic properties of the respiratory system varies with the amount of applied PEEP[273] and preexisting derangement in respiratory mechanics. Compared with zero end-expiratory pressure (ZEEP), D'Angelo et al[273] found that PEEP of 9 cm H_2O increased both respiratory system and lung static compliance; the compliances, however, decreased when PEEP was raised above 20 cm H_2O, indicating lung overdistension. Dechman et al[277] also observed an increase in lung compliance at PEEP 10 cm H_2O in patients undergoing closed-chest surgery, but not in patients undergoing open-chest surgery, who exhibited a progressive decrease in dynamic lung compliance. The mechanical characteristics of the chest wall may influence the effect of PEEP in subjects with normal lungs during anesthesia.[263] In patients undergoing abdominal surgery, Pelosi et al[122] reported that 10 cm H_2O PEEP did not improve respiratory function in normal subjects, although it increased end-expiratory lung volume and lung and chest wall compliance in morbidly obese patients. Others reported similar improvements in end-expiratory lung volume and/or in respiratory system compliance both in obese patients[125,127,128] and in healthy subjects with impaired chest wall compliance caused by pneumoperitoneum during laparoscopic surgery.[125,267]

In general, PEEP decreases airway resistance.[122,267,272,273] The decrease in airway resistance is generally small and mainly related to increase in lung volume,[272] although other mechanisms, such as a PEEP-induced modification of basal vagal tone,[278] might also play a role.

EFFECT OF POSITIVE END-EXPIRATORY PRESSURE ON LUNG VOLUME IN ACUTE RESPIRATORY DISTRESS SYNDROME

Since the first description by Asbaugh et al,[1] ARDS has been recognized as a condition characterized by reduction in aerated lung and respiratory system mechanical derangements.[76,79,279,280] In ARDS, massive lung edema, atelectasis, and tissue consolidation cause a marked decrease in FRC.[76,79] This fall in normally ventilated lung volume is the main cause of the impaired respiratory mechanics.[165] Conversely, an increase in aerated lung volume is long recognized as the main cause of the benefit of PEEP on lung function.[42,76] The increase in lung volume may result from two different mechanisms: recruitment of terminal lung units not accessible to ventilation because of collapse or flooding, and distension or overdistension of already open lung units.

Several authors reported an increase in end-expiratory lung volume and FRC following the application of PEEP in patients with ARDS (see Fig. 10-5B).[14,18,36,42,76,199,214,281,282] In absence of PEEPi, the increase in lung volume above FRC at end-expiration, or change in end-expiratory lung volume

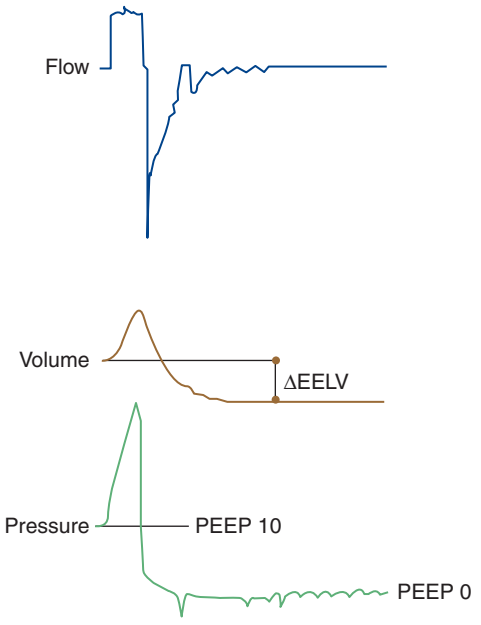

FIGURE 10-6 Measurement of PEEP-induced change in end-expiratory lung volume (ΔEELV). PEEP 10 cm H_2O is abruptly brought to zero. A prolonged expiration ensues, and relaxation volume is achieved. The difference between the volume exhaled during this expiration and the tidal volume delivered by the ventilator equals the increase in EELV induced by PEEP.

(ΔEELV), depends on the amount of applied PEEP and the compliance of the respiratory system. Different techniques can be used to measure FRC and EELV, such as helium dilution,[283–288] nitrogen[285,288–290] and sulphur hexafluoride[288,291–294] washout, positron emission tomography,[295] and CT scan.[36,78,199] These measurements are not routinely obtained in the clinical setting because of technical limitations and/or logistic complexities.

A surrogate approach has been used for assessing PEEP-induced ΔEELV; this involves measuring the volume exhaled between PEEP and elastic equilibrium volume of the respiratory system (Fig. 10-6).[25,197,200–204,266,296,297] While the ventilator is delivering V_T, the preset PEEP is rapidly brought to zero. During the following expiration, sufficient time (5 to 10 seconds) is provided to enable complete exhalation; thus the elastic equilibrium, relaxation volume, will be reached.[25,176,197,200,202] The difference between the volume exhaled during this prolonged expiration and the volume insufflated during the preceding inspiration represents the ΔEELV produced by $PEEP_{TOT}$. The excess volume caused by PEEPi should be separately assessed, and accounted for, to avoid overestimation of PEEP-induced ΔEELV. PEEP-induced variations in EELV can also be measured by inductive[208,296,298–301] or optoelectronic plethysmography.[19,302]

An increase in EELV may also occur when PEEP distends or overdistends already aerated lung regions (Fig. 10-7 and see Table 10-1). Hence, measurement of ΔEELV, without quantification of lung recruitment, may be misleading. *Lung recruitment* refers to re-aeration of collapsed or fluid-filled terminal airways and alveoli. These areas become accessible to ventilation (anatomic recruitment) and may participate in gas exchange if local perfusion is preserved (functional recruitment). Lung recruitment can be quantified by using pressure–volume curves, traced from different levels of PEEP, or by CT scan analysis (see Table 10-1). Other techniques have been proposed, but their application in clinical practice is at present very limited.[295,303–306]

Measurement of PEEP-induced lung recruitment using pressure–volume curve stems from the pioneering

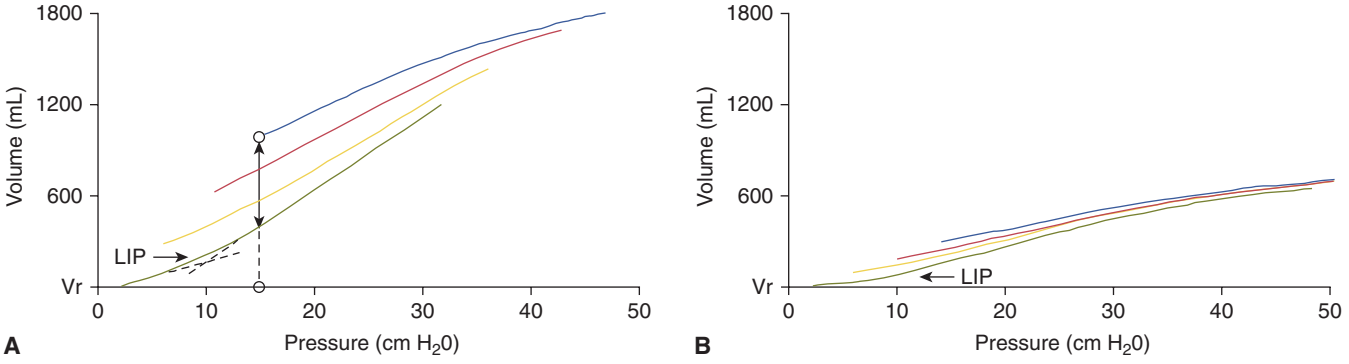

FIGURE 10-7 Pressure-volume (P-V) curves at different levels of PEEP (0, 5, 10, and 15 cm H_2O), related to relaxation volume (*Vr*) of the respiratory system, in two patients with ARDS. In the left panel (**A**), PEEP induces progressive upward shifts of P-V curves, indicating recruitment. At PEEP 15 cm H_2O, PEEP-induced increase in end-expiratory lung volume above Vr is indicated by the *dotted line* between the two *open circles*. Alveolar recruitment induced by PEEP 15 cm H_2O, compared to PEEP 0 cm H_2O, and measured at a pressure of 15 cm H_2O is shown by the *double-arrow solid line*. In the right panel (**B**), P-V curves are particularly flattened, suggesting a marked decrease in aerated lung volume. Increasing PEEP results in minimal recruitment: P-V curves are almost totally superimposed and progressively shifted to right. In both panels, all P-V curves tend to converge at high lung volumes, suggesting that total lung capacity is approached. PEEP-induced recruitment is greater when the slope of the linear segment above the lower inflection point (*LIP*)—that is, linear compliance—of curve recorded from 0 cm H_2O (the lowest curve) is high (A). When the curve at 0 cm H_2O has a very low linear compliance, PEEP-induced recruitment is trivial (B). PEEP-induced recruitment also proceeds far above LIP (up to pressures greater than 40 cm H_2O), suggesting that lung reopening is a pan-inspiratory phenomenon (A).

observations of Katz et al[14] on the time course of PEEP-mediated increase in lung volume. After applying PEEP, these authors observed that end-expiratory lung volume increased to approximately 66% of its total change within the first breath; it reached 90% in approximately five breaths, and was fully complete only after several minutes, suggesting time-dependence for lung recruitment.[14] For a given pressure, lung volume measured during ventilation with 13 cm H_2O PEEP was larger than the volume predicted for that pressure by the static compliance computed at 3 cm H_2O PEEP. This observation suggests that some lung units were not ventilated at the lower PEEP, but were recruited by the higher PEEP.[14] Quantification of lung recruitment induced by PEEP was not attempted until Ranieri et al[200–202] proposed a simple method using pressure–volume curve analysis. This approach consists of aligning on the same pressure–volume diagram curves obtained at ZEEP and varying PEEP levels. With this technique, which assumes that FRC (i.e., the relaxation volume at ZEEP) remains constant,[14,200,201] the ΔEELV induced by PEEP is added to the volume insufflated during the maneuver for recording pressure–volume curve at the corresponding PEEP level.[197,247,297] Lung recruitment is then computed as the difference in volume between pressure–volume curves obtained at different PEEP levels at a given value of elastic recoil pressure (generally 20 cm H_2O). Anatomic recruitment is reflected by an upward shift of the pressure–volume curve (see Fig. 10-7). If PEEP fails to recruit new regions, no volume gain at a given pressure will be observed; the resulting pressure–volume curve will be shifted rightward and superposed on the curve acquired at ZEEP.[197,201]

The CT scan is used to measure recruitment.[215,307,308] PEEP-induced lung recruitment is computed as the decrease in volume of nonaerated lung parenchyma[78,164,216,221,307] or, as recently proposed, the increase in volume of gas penetrating nonaerated and poorly aerated lung regions.[18,308–311] With this technique, however, recruitment is assessed by comparing scans taken at different pressures (ZEEP and PEEP), and not at the same pressure as is done with the pressure–volume curve technique. Consequently, no matter how it is computed, recruitment at a given PEEP will include also a certain volume of gas corresponding to lung units that inflate normally from end-expiration at ZEEP up to the pressure corresponding to that PEEP. This helps explain some of the differences in the amounts of recruitment with the CT and pressure–volume techniques.[312] Conversely, the CT scan offers a unique opportunity to estimate the amount of PEEP-induced hyperinflation (see Table 10-1),[18,36,78,199,225,311,313] computed as the increase in gas volume within normally aerated lung regions; hyperinflation, however, does not necessarily mean overstretching.[307]

Bedside lung ultrasound has been proposed as a mean to estimate PEEP-induced recruitment. In forty patients with ARDS, Bouhemad et al compared the pressure–volume curve method and lung ultrasound to assess recruitment with PEEP 15 cm H_2O.[303] Significant correlations were found between an ultrasound re-aeration score and recruitment measured by pressure–volume curve, and between ultrasound score and oxygenation. This new technique did not, however, allow assessment of lung hyperinflation. Further studies are needed to evaluate the usefulness of this technique.

In patients with ARDS, PEEP increases end-expiratory lung volume and produces varying recruitment (see Table 10-1).[18,25,76,78,169,197,199–204,208,216,221,225,275,282,296,311,313–317] Recent work[197] shows that PEEP achieves progressive recruitment, from 84 mL at PEEP 5 cm H_2O (range: 41 to 156 mL) to 304 mL at 15 cm H_2O (range: 114 to 545 mL). The large interindividual differences suggest that, in certain patients, PEEP increases lung volume without achieving significant recruitment, likely reflecting overdistension of previously aerated lung regions. Indeed, PEEP-induced overdistension has been shown in several studies.[200–202] [18,36,199,225,311] In most cases, recruitment and overdistension occur concomitantly, rather than sequentially, in different regions of the lung following PEEP application.[199,225,308,309,311,313] Vieira et al[36] found that applying PEEP 10 and 15 cm H_2O in patients with ARDS who did not have a clear LIP on the pressure–volume curve produced progressive recruitment of nonaerated lung areas and overdistension of aerated lung zones. The interplay between these two phenomena depends on several factors, such as lung and chest wall mechanics,[266,318] stage of disease,[319,320] lung morphology,[199,225,309] and amount of PEEP.[225]

Recent studies highlight the importance of assessing lung recruitability for an individually tailored optimization of PEEP. By using CT scan in sixty-eight patients with ARDS, Gattinoni et al. assessed the percentage of potentially recruitable lung, as defined by the proportion of lung tissue in which re-aeration was restored at airway pressure between 5 and 45 cm H_2O, and the effects of PEEP.[33] Lung recruitability was 13% ± 11% of the lung weight, varied widely across the studied population (from 0% to more than 50%), and was highly correlated with lung recruitment induced by an increase in PEEP from 5 to 15 cm H_2O. Patients with higher lung recruitability had more severe disease (lower oxygenation and respiratory system compliance) and a higher mortality rate.

Assessment of lung recruitability is important for setting PEEP: the use of high PEEP in patients with a low percentage of potentially recruitable lung provides little, if any, benefit and may actually be harmful if it produces overdistension.[321] Lung recruitability may influence the effects of PEEP on alveolar strain (the ratio between the amount of gas delivered during a tidal breath and the amount of aerated lung available for ventilation) and alveolar opening and closing.

Caironi et al reported that an increase in PEEP from 5 to 15 cm H_2O in patients with a lower percentage of potentially recruitable lung did not significantly affect the amount of opening and closing lung tissue, which was already negligible at lower PEEP.[27] Conversely, in

patients with a higher recruitability, opening and closing was dramatically reduced (approximately equal to 50%) by increase in PEEP. Interestingly, increases in PEEP led to an identical increase in alveolar strain in the two groups of patients. In patients with higher recruitability, the lung volume available for ventilation conceivably increases during inspiration as recruitment of nonaerated lung regions at end-expiration progressively occurs. These findings further suggest a relationship between the amount of intratidal lung recruitment and the effective end-inspiratory alveolar strain, such that the larger the amount of potentially recruitable lung, the lower the risk of PEEP-induced overdistension. In addition, opening and closing lung tissue turned out to be an independent risk factor for death (odds ratio 1.10 for each 10 g increase), while alveolar strain did not.[27] This suggests that in patients with higher lung recruitability, the beneficial impact of reducing intratidal opening and closing by increasing PEEP prevails over the effects of increasing alveolar strain. In this regard, lung imaging morphology (chest radiograph or CT scan) may help in assessing lung recruitability: patients with a lower percentage of potentially recruitable lung generally show a "lobar" pattern of lung consolidation, whereas patients with greater lung recruitability often present diffuse lung collapse.[27,199,225,321]

The integrated analysis of respiratory mechanics, lung volumes, and lung imaging enhances recognition of the effects of PEEP on recruitment and overdistension, and hence facilitates to set optimal PEEP at the bedside.

EFFECT OF POSITIVE END-EXPIRATORY PRESSURE ON RESPIRATORY MECHANICS IN ACUTE RESPIRATORY DISTRESS SYNDROME

Contrasted with normal subjects, the rate of change per unit of pressure is smaller, and linear compliance of the pressure–volume curve falls to very low values in patients with ARDS (because of the decrease in normally ventilated alveolar units); the whole curve is also flattened and shifted downward, and the inflection knees, normally seen at low (LIP) and high (UIP) lung volumes, may appear in the range of tidal ventilation[247] (see Figs. 10-5B and 10-7). The presence of LIP and UIP in the V_T range suggest considerable susceptibility of the ARDS lung to detrimental mechanical shear forces, generated by cyclic end-expiratory alveolar opening and collapse[78,165,322] and end-inspiratory overstretching.[201,323] These forces are considered the main mechanism of ventilator-induced lung injury.[324,325] Recent evidence suggests that airspace reopening can occur along the entire pressure–volume curve.[197,216,307,326–329] Moreover, the shape and characteristics of the pressure–volume curve can be greatly influenced by several factors including pathophysiologic mechanisms, stage of disease,[282,322] chest wall mechanics,[198,266] breathing pattern, and differences in measurement technique.[330]

As already mentioned, one typical feature of ARDS is the fall in respiratory system compliance (see Figs. 10-5B and 10-7), described both in experimental[331–334] and clinical settings.[42,76,176,322,335] Decreased compliance was initially attributed to increased lung stiffness.[280] Subsequent studies have demonstrated that the decreased compliance in ARDS has different pathophysiologic mechanisms.[333,334] In an animal model, Grossman et al[333] showed that the loss of aerated lung units, secondary to alveolar flooding, accounted for virtually all of the decreased static lung compliance. With CT scan analysis, Gattinoni et al[165] found that several parameters of the pressure–volume curve, including linear compliance, were correlated with the amount of aerated areas (mainly distributed in the nondependent, ventral lung regions) but not with nonaerated areas (preferentially distributed in the dependent, dorsal lung regions). Indeed, compliance was in the normal range when normalized to FRC (so-called specific compliance), suggesting that the aerated areas had normal intrinsic elasticity.[165] According to this concept, respiratory system compliance provides an indirect estimate of the amount of aerated lung (see Figs. 10-5B and 10-7).

Through recruitment, PEEP prevents the fall in static compliance,[5] and restores the normal pressure–volume pattern, by suppressing small airway closure and collapse of unstable lung units.[281,336–339] Data suggest that the effects of PEEP on recruitment and overdistension can be predicted by the shape of the pressure–volume curve at ZEEP.[197,200,201,225,326,328,340] Three distinct patterns of pressure–volume curve have been described in patients with ARDS.[200,201,225] A concave shape, with a clear LIP, indicates that compliance is progressively increasing above this point, suggesting ongoing recruitment during inflation (see Fig. 10-7).[200,201,340] A convex shape, showing an UIP, denotes progressive decrease in compliance, and likely overstretching (see Fig. 10-7).[200,201] A linear pressure–volume curve, with absent or very low LIP, may be observed in localized lung injury.[225]

Rouby et al[191,309,310] hypothesized that a linear pressure–volume curve results from two separate regional curves: a concave curve, related to normally aerated lung regions, and a convex curve, related to nonaerated areas. PEEP may have different effects on lung volumes and respiratory mechanics according to these patterns. When a concave shape is observed at ZEEP, PEEP results in lung recruitment, as documented by an upward shift of the pressure–volume curve and disappearance of LIP (see Fig. 10-7).[197,200,201,225] With a convex profile and low linear compliance at ZEEP, PEEP-induced recruitment is minimal or zero: the pressure–volume curve is superimposed on that obtained at ZEEP, with a further decrease in compliance (see Fig. 10-7).[197,200,201,225]

A linear compliance on the pressure–volume curve at ZEEP may be a useful indicator of lung recruitability (see Fig. 10-7). A tight correlation between linear compliance at ZEEP and amount of PEEP-induced recruitment has been suggested.[197] Because compliance, as assessed on the pressure–volume curve, is a function of normally aerated lung regions,[165] two different situations can be imagined: (a) the

lung is principally characterized by unstable lung regions, which are collapsed at the end expiration but progressively pop open during tidal inflation, and (b) the lung is predominantly consolidated, with no large areas expanding during inflation (compliance is very low). Application of PEEP results in significant recruitment in the former case; in the latter case, PEEP may overstretch already ventilated areas without producing significant recruitment.[200,201] Independently of its effect on recruitment and overdistension, PEEP constantly and significantly decreases the linear compliance of the pressure–volume curve.[25,197,201,326,328] This contrasts with the classical notion that compliance increases with recruitment and decreases with overdistension.[42] Lung units that pop open at a certain pressure have an infinitely high compliance and contribute to the higher compliance observed at ZEEP, as opposed to that observed when the lung is fully recruited at PEEP. A corollary is that UIP may indicate the end of tidal recruitment and/or the beginning of alveolar overdistension, although both mechanisms may coexist at high pressure (see Fig. 10-7).[25,326] Therefore, PEEP-related decrease in pressure–volume linear compliance may predominantly reflect recruitment below UIP; a decrease in compliance above this point may reflect overdistension.

LIP has long been considered the pressure at which collapsed lung units open during inflation, it is therefore considered the ideal pressure at which to set PEEP.[322] No relationship between LIP and either opening or closing alveolar pressures, however, was subsequently found,[197] indicating that LIP is not useful for optimizing PEEP setting. Other studies confirmed that recruitment and derecruitment are continuous processes unrelated to LIP (see Fig. 10-7).[25,204,215,216,326,328,329] Nevertheless, the presence of a clear LIP followed by a high inflation compliance on the pressure–volume curve recorded from ZEEP may predict the effect of PEEP on recruitment (see Fig. 10-7).[165,197,225,328] Vieira et al[225] showed that patients with a diffuse loss of aeration had a marked LIP at ZEEP, whereas LIP was absent or blunted in patients with a focal loss of aeration. High PEEP induced progressive recruitment without overdistension in the former group, whereas it caused a significant overdistension of normally aerated regions in the latter group.[225] Some think that LIP is caused by time-constant inequalities within the lung and/or reopening of compressed peripheral airway associated with expiratory flow limitation.[183,184,341,342] Accordingly, the disappearance of LIP following application of low or moderate PEEP might indicate that PEEP can prevent small airway closure and make the distribution of tidal ventilation more homogeneous.[184,342] This could also explain the difference between the reported values of LIP, 5 to 15 cm H_2O, and the substantially higher pressures required to reverse atelectasis.[216,245,343]

Some studies suggest that the point of maximum curvature of the deflation limb of the pressure–volume curve may be used to set PEEP so as to optimize lung recruitment, but the feasibility of this approach is limited.[215,344]

The mechanical properties of the chest wall may influence the effects of PEEP.[198,266,282] Mergoni et al[198] found that in some patients the LIP on the pressure–volume curve of the respiratory system at ZEEP reflected the chest wall, rather than the lung. Application of PEEP abolished LIP in all instances, but oxygenation significantly improved, suggesting recruitment, only in patients exhibiting a LIP on the lung pressure–volume curve.[198] Gattinoni et al[282] found that increasing levels of PEEP decreased respiratory and lung static compliance, without any recruitment, in patients with primary pulmonary ARDS; in patients with secondary extrapulmonary ARDS, PEEP induced significant recruitment and increased respiratory, lung, and chest wall compliance.[282] These findings have been confuted by other studies, even by the same group.[25,33,197,199,225,345]

The change in static compliance produced by PEEP has been proposed as a guide for optimizing PEEP[42] and as a prognostic factor for predicting mortality in patients with ARDS.[346] Because of nonlinearity of the pressure–volume relationship in ARDS, however, and the aforementioned complex effect of recruitment on the pressure–volume relationship,[326–328] static compliance (calculated as the pressure-to-volume differences between two points) may not describe adequately the changes in respiratory mechanics produced by PEEP.[247,297] Indeed, as previously shown[347] and recently outlined,[182,327,345] static compliance may vary for different V_Ts. A mathematical model suggests that the highest static compliance computed at a low V_T during a decremental, but not incremental, PEEP trial may help to identify the level of PEEP needed to prevent end-expiratory alveolar collapse.[327] These theoretical findings are supported by data in animals,[348,349] but have not been sufficiently tested in humans.

Some authors recommend the monitoring of dynamic compliance as a means of assessing the mechanical properties of the respiratory system under dynamic condition (ongoing ventilation) and to identify the level of PEEP that prevents alveolar derecruitment.[350,351] Data on this issue, however, are far from conclusive.

Several studies[179,182,185,314,352] reveal that PEEP increases additional resistance through increased viscoelastic dissipation[180] that is consequent to a PEEP-mediated increase in end-expiratory lung volume, as suggested by the correlation between changes in tissue resistance and end-expiratory lung volume.[352] Other studies,[275,353] although confirming the rise in tissue resistance, also report a decrease in airway resistance, especially at high PEEP. Normalizing resistances for lung volume (i.e., specific resistance) caused these changes to disappear.[275] Partitioning resistance into lung and chest wall components, Pelosi et al[275] found that the increase in total and tissue respiratory system resistance, consequent to PEEP, could be mainly ascribed to the lung rather than the chest wall. Gattinoni et al[282] found that total respiratory resistance increased with PEEP in pulmonary ARDS, mainly because of a marked increase in lung additional resistance.[282] In contrast, patients with extrapulmonary ARDS, characterized by higher chest wall tissue

resistance and lower lung tissue resistance than pulmonary ARDS, did not show any change in total respiratory resistance with PEEP.[282]

EFFECT OF POSITIVE END-EXPIRATORY PRESSURE ON RESPIRATORY MECHANICS IN CHRONIC OBSTRUCTIVE PULMONARY DISEASE

In COPD patients, lung and chest-wall static compliance are reported to be similar to those of normal subjects,[354] unless expiratory flow limitation and dynamic hyperinflation causes lung overdistension. Depending on the level of PEEP, static compliance may decrease (if overdistension occurs),[238,294,355,356] stay unchanged,[357] or even slightly increase (if recruitment of new lung units occurs)[252] (see Fig. 10-5C).

Total end-expiratory alveolar pressure ($PEEP_{TOT}$) may markedly exceed preset PEEP when PEEPi is present (see Fig. 10-4). Rossi et al[260] demonstrated that failure to take PEEPi into account caused static compliance to be underestimated by up to 48%. During volume-targeted controlled ventilation, an increase in inspiratory flow resulting in a prolonged expiratory time causes PEEPi to decrease. Thus, the value of static compliance calculated without correcting for PEEPi will falsely (and paradoxically) increase.[260,252] The presence of a LIP on the pressure–volume curve at ZEEP may be partly caused by PEEPi, at least in patients with expiratory flow limitation.[358]

Patients with COPD have a high resistance to air flow.[59,238,357,359,360] In patients with expiratory flow limitation, PEEP should have little influence on expiratory flow until PEEP exceeds PEEPi.[260] Other studies, however, suggest that PEEP 5 to 10 cm H_2O might partly decrease expiratory resistance, particularly at the end-expiration, and result in faster and more uniform lung emptying.[294,357,361,362]

EFFECTS OF POSITIVE END-EXPIRATORY PRESSURE ON DIAPHRAGMATIC ACTIVATION

Recent studies provide novel information about the effects produced by PEEP application on diaphragmatic electrical activity, assessed by transesophageal electromyography. Allo et al[363] induced ARDS in rabbits by intratracheal instillation of hydrochloric acid: eleven animals, five of which had been previously vagotomized, underwent a short-term protocol where PEEP and inspiratory assistance delivered by neurally adjusted ventilatory assist (NAVA) were varied over a few minutes. After hydrochloric acid instillation in the nonvagotomized rabbits, tonic (i.e., continuous throughout the respiratory cycle) diaphragmatic electrical activity increased without PEEP, while phasic (i.e., timed with inspiration) diaphragmatic electrical activity became smaller and irregular. A stepwise increase in PEEP progressively attenuated tonic diaphragmatic electrical activity and increased phasic diaphragmatic electrical activity; when PEEP was subsequently reduced, tonic and phasic diaphragmatic electrical activity returned back to the initial values. In the group of vagotomized rabbits, conversely, tonic diaphragmatic electrical activity did not rise after lung injury and was consequently unaffected by PEEP, while phasic diaphragmatic electrical activity and V_T were on average much higher than in the nonvagotomized animals. These data may suggest that tonic diaphragmatic electrical activity could result from vagally mediated reflexes acting to conserve end-expiratory lung volume and PEEP might decrease tonic diaphragmatic electrical activity by recruiting lung volume.

Using the same animal model, Beck et al[364] applied the same level of inspiratory assistance by NAVA through an endotracheal tube in the presence of PEEP (8.5 ± 3.3 cm H_2O) and in the absence of PEEP. An instantaneous increase in tonic diaphragmatic electrical activity was observed upon PEEP removal. Following extubation and initiation of NAVA without PEEP via a mask, however, tonic diaphragmatic electrical activity returned to the previous values. The authors considered the increase in tonic diaphragmatic electrical activity during invasive ventilation without PEEP as a mechanism through which the diaphragm assumes the role of conserving end-expiratory lung volume, replacing the activity of the glottal muscles that is lost when the endotracheal tube is in place.

In twenty adult patients with ARF of varied etiology undergoing NAVA, Passath et al[365] evaluated the effects of different levels of PEEP. A stepwise reduction of PEEP from 20 to 1 cm H_2O increased inspiratory diaphragmatic electrical activity by 34%, while V_T and breathing rate did not significantly change. The ratio of V_T to diaphragmatic electrical activity, an approximation of neuroventilatory efficiency, showed broad individual variability at different PEEP levels and may help in identifying the level of PEEP at which tidal breathing occurs at minimal diaphragmatic electrical activity cost.

Effect of Positive End-Expiratory Pressure on Ventilator-Induced Lung Injury

VENTILATOR-INDUCED LUNG INJURY

Recent decades have brought the recognition that mechanical ventilation per se, in ARDS, may damage the lung and/or aggravate preexisting lung injury.[325] This so-called ventilator-induced lung injury (VILI)[325,366,367] is now widely recognized and supported by a large number of animal experimental studies[220,368] and recent data in patients.[6,369,370] Attempts to prevent VILI have modified the ventilator approach to patients with ARDS.[324] Two main mechanisms for VILI are: (a) alveolar[220,368] and bronchial overdistension[371,372] occurring at high volume and transpulmonary pressure, and (b) repeated alveolar and small airways collapse and reopening at low end-expiratory volume.[217,371,373] The common pathway for these two mechanisms is mechanical stress on the terminal units (including

bronchiolar and alveolar walls).[374–376] Other factors, including elevated FI_{O_2}, high blood flow, high inspiratory flow, and intensity of local inflammation, may play a role in aggravating or inducing lung injury.

EFFECT OF POSITIVE END-EXPIRATORY PRESSURE ON VENTILATOR-INDUCED LUNG INJURY

PEEP may have opposing consequences, depending on its effects on the two aforementioned mechanisms of VILI (alveolar overdistension and cyclic alveolar collapse and reopening) (Fig. 10-8).[225,313] In one study, PEEP (13 cm H_2O) caused recruitment of nonaerated regions, and induced overdistension of already aerated lung areas in three patients.[36]

Since the 1970s, high ventilator pressures have been known to rupture alveoli and cause air leaks.[377] By increasing airway pressure, PEEP may promote alveolar overstretching,[39,201,202,225,311] ultrastructural damage,[372] worsening of pulmonary edema,[157] and triggering of local and systemic inflammation.[378] Some early studies suggest that end-inspiratory lung volume, rather than high intrathoracic pressure, may be the major determinant of ventilator-induced lung edema ("volutrauma"), at least in normal lungs.[220,379,380] PEEP, however, may also protect against edema accumulation during ventilation at high end-inspiratory pressure and

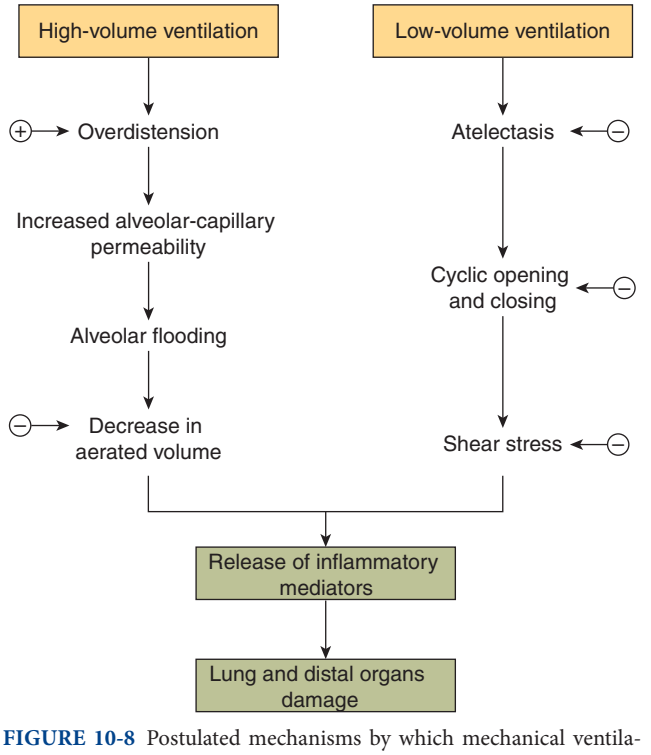

FIGURE 10-8 Postulated mechanisms by which mechanical ventilation may lead to ventilator-associated lung injury and organ injury. Beneficial (*minus sign*) and detrimental (*plus sign*) effects of PEEP on these mechanisms are shown.

end-inspiratory lung volume,[217–220,381] although alteration in microvascular permeability may not be prevented.[219,220] Several factors may explain these apparent contradictions: (a) differences in experimental setup (isolated lung vs. intact animals), (b) levels of PEEP and inspiratory airway pressure, and (c) driving pressure (difference between end-inspiratory and end-expiratory alveolar pressures, which, for a given pulmonary elastance, depends on V_T size).[325] In isolated lung with constant perfusion, PEEP augments edema formation probably because of increased filtration across extraalveolar vessels associated with lung overdistension.[382,383] Conversely, in intact animals, PEEP does not affect edema formation, probably because of balancing between the PEEP-induced increase in end-inspiratory lung volume (which increases fluid filtration), and concomitant reduction in cardiac output and blood pressure (which reduce filtration pressure).[384–386]

The role of PEEP-induced changes in hemodynamics on edema accumulation has been suggested by several authors.[219,387] In an animal model, Dreyfuss and Saumon[219] showed that lung edema was reduced during ventilation with PEEP 10 cm H_2O, as opposed to ZEEP, despite identical end-inspiratory pressures. When the drop in arterial pressure produced by PEEP was corrected by dopamine infusion, pulmonary edema increased in direct proportion to systemic blood pressure. The increase in permeability edema was, however, less than that observed during ventilation at ZEEP, suggesting that hemodynamic modification is not the only factor explaining the effect of PEEP on edema formation.[219,388] Indeed, reduction in driving pressure while keeping end-inspiratory lung volume and pressure constant (as obtained by increasing PEEP while reducing V_T) may reduce edema and the severity of cellular damage; these findings suggest that a decrease in tissue stress may explain this protective effect of PEEP.[217–220,389] The greater amount of alveoli available to clear edema, consequent to PEEP-induced alveolar recruitment, might also contribute.[388]

PEEP may also exert beneficial effects in localized lung injury. De Prost et al assessed the dispersion of localized alveolar flooding and alveolar protein permeability in rats undergoing local instillation of albumin solution followed by different ventilator strategies with varying levels of V_T and PEEP.[390] High V_T ventilation caused alveolar liquid dispersion, which PEEP had prevented; this occurred even when V_T was kept constant, thus producing higher end-inspiratory pressures that did not exceed the safe limit of 30 cm H_2O. PEEP also reduced the increase in alveolar protein permeability caused by high V_T. In an animal model of unilateral lung injury, Schreiber et al reported that stepwise increases in PEEP, from zero up to a relatively moderate level of 13 cm H_2O, reduced the inflammatory response in the injured lung, did not result in detrimental effects on inflammation in the healthy lung, and preserved oxygenation.[391]

PEEP-associated preservation of surfactant may further explain the benefit of PEEP on high-volume mediated

VILI.[217] Thus, severity of overinflation is one major determinant of VILI.[321,378,392] When ventilator-induced lung edema is produced by high V_T, the combination of PEEP and V_T reduction decreases the severity of injury at the same end-inspiratory pressure. When PEEP, however, is not accompanied by V_T reduction, excessive inspiratory pressures and additional overstretching occur, further increasing the rate of edema formation and tissue injury[219] and triggering systemic inflammation.[378]

In a mechanically heterogeneous lung, noninflating collapsed tissue is surrounded by open airspaces. Mead et al[374] suggested that recruitment of nonaerated lung units induces a local stress to alveoli and bronchioles, which is substantially higher than the average transpulmonary or transbronchial pressure, respectively, because of alveolar and small airways interdependence.[371,375] If this process recurs cyclically, high shear forces may damage the alveolar and airway epithelium, overstretch fragile microvessels, deplete surfactant, and initiate or worsen inflammation. By recruiting nonaerated portions, and stabilizing airways and lung units prone to repetitive opening and collapse, PEEP plays a key role in protecting the lung from the mechanical shear stress and tissue injury produced by ventilation at low end-expiratory lung volume ("atelectrauma").[373,374,393–398]

A large body of animal data supports the protective effect of PEEP on low-volume mediated VILI.[217,218,338,373,389,393,395,398–402] By minimizing shear stress associated with cyclic opening and collapse, PEEP may attenuate inequalities in the regional distribution of tidal ventilation, thus avoiding or limiting overdistension in the less-injured lung zones.[374,375] By increasing end-expiratory lung volume, PEEP can also prevent surfactant loss and preserve surfactant function.[400,403–406] By minimizing mechanical stress, PEEP may also ease the intensity of ventilator-induced lung inflammation[393,396,407] and remodeling,[397] and reduce the decompartmentalization of a number of inflammatory mediators[408] and bacteria from the lung into the circulation ("biotrauma").[409–411] These aforementioned mechanisms may play a role in initiating or propagating the systemic inflammatory response, which contributes to the multiple organ failure often observed in the terminal stage of ARDS.[412–414] The local and systemic beneficial effects of PEEP are, however, dependent on the level of applied PEEP. Several authors, in fact, have suggested that higher-than-optimal levels of PEEP, defined as the PEEP required for maximum oxygenation and/or minimum elastance, may worsen lung mechanics, increase the amount of atelectasis and the lung-tissue expression of type III procollagen messenger RNA (an early marker of lung parenchyma remodeling), and also promote bacterial translocation.[415,416]

Recent clinical trials show that protective ventilator strategies, reduced V_T (to limit the end-inspiratory stretch),[6,369,370] and high PEEP (to avoid cyclic opening and closing)[6,369] are associated with decreased pulmonary and systemic cytokine response,[369,370] less organ dysfunction,[417] and reduced mortality in patients with ARDS,[6,370] compared to conventional, injurious mechanical ventilation. Although the mechanisms whereby VILI causes organ dysfunction are not completely understood, a recent study suggests that cell apoptosis may be involved.[414] Rabbits ventilated with a low V_T and high PEEP showed less epithelial apoptosis in the kidney and small intestine than did rabbits ventilated with a high V_T and low PEEP.[414] The former rabbits had more apoptotic cells in the lung, whereas the latter rabbits had less lung apoptosis and necrosis of alveolar epithelial type III cells.[414] Analysis of plasma samples from a previous clinical trial[369] revealed higher levels of soluble Fas ligand (a proapoptotic factor) in patients who received conventional ventilation than in patients who received protective ventilation; changes in soluble Fas ligand were correlated with changes in plasma creatinine.[417]

Effects of Positive End-Expiratory Pressure on the Cardiovascular System

The lungs and heart are subject to variations in intrathoracic pressure. How alterations in intrathoracic pressure affect the heart and intrathoracic vessels varies substantially and depends on several factors, such as mechanical properties of the lung and chest wall, type of ventilation (spontaneous vs. mechanical), blood volume, and left-ventricular function. The complex interplay of these factors and the effects of PEEP on heart–lung interactions have been extensively reviewed.[418–426]

EFFECT ON VENOUS RETURN

Positive airway pressure causes a drop in cardiac output secondary to a decrease in cardiac filling (preload); this was initially attributed to a reduction in the pressure gradient for venous return, determined by the rise in right-atrial pressure consequent to increased intrathoracic pressure.[50,66,427–430] The PEEP-mediated decrease in the gradient for venous return, however, is less than expected because PEEP produces a concomitant rise in mean systemic pressure[431] (the circulatory filling pressure representing the upstream pressure for venous return). In patients without lung disease undergoing implantation of defibrillator devices under general anesthesia, Jellinek et al[432] measured right-atrial pressure and mean systemic pressure at airway pressure zero and 15 cm H_2O during 15-second periods of apnea when ventricular fibrillation was induced to test the defibrillator. Rising airway pressure produced a drop in left-ventricular stroke volume.[432] Right-atrial and mean systemic pressure, however, increased equally, showing that the reduction in venous return was not determined by a decrease in pressure gradient.[432] The rise in mean systemic pressure may result from a reduction in vascular capacitance determined by neurovascular reflexes,[433] displacement of blood from the pulmonary to the systemic circulation,[434] and descent of the diaphragm, which increases the upstream pressure for venous return by augmenting intraabdominal pressure.[435] These homeostatic

adaptations, however, may be counteracted by a concomitant increase in venous resistance,[431,436] suggesting that PEEP may alter venous return by affecting the peripheral venous circulation.

The effects of PEEP on hemodynamics strongly depend on intravascular volume. Cardiac output can be restored by increasing the ventricular filling through volume infusion.[47,437–440] PEEP discontinuation produces a rise in cardiac filling, proportional to the pressure withdrawn and the circulating blood volume.[47,441] In hypervolemic and hemodynamically stable patients who underwent cardiac surgery, van der Berg et al found that maintaining airway pressure up to 20 cm H_2O for 25 seconds produced minimal variations in right ventricular output despite a concomitant rise in right atrial pressure.[435]

In summary, PEEP reduces cardiac output through a decrease in venous return that is not a primary consequence of a decrease in its pressure gradient. Regardless of the cause, the drop in cardiac output can be counteracted by blood volume expansion.

EFFECT ON RIGHT-VENTRICULAR AFTERLOAD AND VENTRICULAR INTERDEPENDENCE

PEEP alters both left- and right-ventricular configurations and reduces left-ventricular diastolic compliance by augmenting right-ventricular afterload.[49,442–444] An increase in lung volume causes a rise in pulmonary vascular resistance by directly compressing the alveolar vessels.[445] The interconnections between lung volume and pulmonary blood flow are not straightforward, because blood expelled from the alveolar vessels can be retained in the extraalveolar vessels.[446,447] When airway pressure is augmented, right-ventricular outflow impedance (i.e., afterload) is also increased.[426,448] In patients with ARDS, high levels of PEEP can cause or worsen tricuspid regurgitation.[449]

The fall in cardiac output with PEEP has been also attributed to the stress exerted by the right ventricle on the interventricular septum,[443] which is displaced leftward and restricts left-ventricular filling.[49] Culver et al[450] altered right-ventricular afterload, through a partial occlusion of the main pulmonary arteries, and found that this did not produce the same hemodynamic changes induced by increases in lung volume; these findings suggest that ventricular interdependence (caused by an increased right-ventricular afterload) was unlikely to be the main mechanism for PEEP-mediated fall in cardiac output. Wise et al[69] evaluated the impact of PEEP 15 cm H_2O on left-ventricular compliance in a study where they bypassed the right heart to exclude the effects of interventricular interdependence; they concluded that the elevation in left-ventricular filling pressure was mainly consequent to pericardial compression. In patients with ARDS, Dhainaut et al[440] did not find any changes in ventricular diastolic compliance and ejection fraction when PEEP was increased up to 20 cm H_2O during controlled ventilation; they attributed the reduction in cardiac output mainly to the preload effect.

More recently, Gernoth et al reported that an open-lung strategy with high PEEP (20 cm H_2O), which improved oxygenation without significantly affecting Pa_{CO_2}, caused no major hemodynamic alteration, while right- and left-ventricular function, respectively, were improved and unchanged.[451] An impairment in right-ventricular function and hemodynamics, however, has been reported when PEEP is increased at constant plateau pressure, with significant worsening of respiratory acidosis despite improvement in oxygenation.[452]

In summary, PEEP increases pulmonary vascular resistance and right-ventricular afterload and may therefore increase the stress exerted by the right ventricle, which has to maintain an adequate output to guarantee left-ventricular filling. Right-ventricular systolic overload may result in leftward displacement of the interventricular septum; the effect on left-ventricular function seems to be adjunctive, rather than a major determinant of the PEEP-mediated reduction in cardiac output.

IMPACT OF RESPIRATORY MECHANICS ON THE HEMODYNAMIC EFFECT OF POSITIVE END-EXPIRATORY PRESSURE

A reduction in lung compliance reduces the transmission of airway pressure to the pericardial space,[453,454] and to the pleural space. The transmission of PEEP to the pleural space increases when chest wall compliance is reduced[455] and decreases when chest wall compliance is increased.[454] Venus et al[456] found that the fraction of PEEP transmitted to the pleura was reduced from 62% to 34% and to the pericardium from 54% to 36%, in intact and acutely injured lungs, respectively. V_T was kept constant throughout the study and the reduction in cardiac output produced by PEEP did not differ before and after inducing lung injury, because absolute pericardial pressure at end-expiration did not differ.[456]

EFFECT ON AFTERLOAD

Left-ventricular afterload is the force opposing contraction. It corresponds to the tension developed by the contracting cardiac muscle. It is determined by both the systemic arterial resistance and the transmural pressure exerted on the left-ventricular wall; that is, the difference between the systolic pressure and the pressure surrounding the heart (i.e., intrathoracic pressure). A reduction in left-ventricular afterload is achieved either by decreasing systemic arterial resistance (through vasodilator administration) [457]or increasing intrathoracic pressure.[69–71] In healthy subjects with normal cardiac function the dominant action of increase in intrathoracic pressure is reduction in venous return; the consequences of the lowered transmural pressure are rather small (see Fig. 10-2A). In patients with poor left-ventricular function and congestive heart failure, cardiac output is relatively insensitive to reduction in venous return because left-ventricular filling pressure and diastolic volume are elevated.[67] Thus, the net effect of a rise in intrathoracic pressure is a reduction in

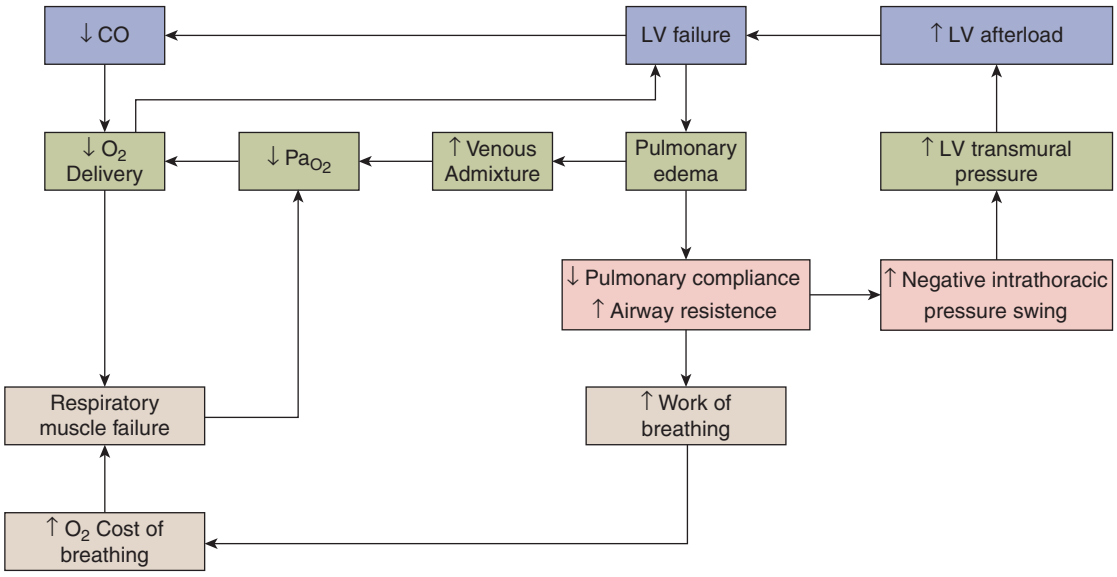

FIGURE 10-9 Pathophysiologic mechanisms and pathways of cardiogenic pulmonary edema. Worsening in pulmonary mechanics increases negative swings in intrathoracic pressure and left-ventricular afterload. Worsening in gas exchange decreases oxygen delivery to the heart and the respiratory muscle. See text for further explanation. *CO*, Cardiac output; *LV*, left ventricle; O_2, oxygen; Pa_{O_2}, partial pressure of arterial oxygen.

left-ventricular transmural pressure (see Fig. 10-2B).[68,458,459] Conversely, a decrease in intrathoracic pressure raises afterload by augmenting left-ventricular transmural pressure (see Fig. 10-2B).[332,460]

When afterload exceeds the capacity of the left ventricle, pulmonary edema ensues, establishing a vicious circle (Fig. 10-9). Because of worsening pulmonary compliance[332,460,461] and resistance,[460,462–464] the inspiratory muscles must exert a stronger effort to achieve adequate alveolar ventilation. Thus, inspiratory intrathoracic pressure becomes more negative, and afterload increases. The combination of reduced O_2 delivery[465] and increased metabolic cost of breathing[464–466] may precipitate respiratory muscle failure,[466] which further worsens gas exchange.

The impact on left-ventricular transmural pressure of the increase in intrathoracic pressure produced by CPAP 10 cm H_2O during expiration is rather small (see Fig. 10-2C). Conversely, the improvement in pulmonary mechanics[466] generated by the same CPAP may minimize the swings in intrathoracic pressure[466,467] and hence decrease afterload,[467,468] thereby improving left-ventricular function (see Figs. 10-2C and 10-10).[72,468] CPAP may simultaneously improve gas exchange[72,73,146] by reducing venous admixture[10,146] and avert failure of the respiratory muscles by improving their O_2 balance[10] (Fig. 10-10).

EFFECT ON OXYGEN DELIVERY

The effect of PEEP on O_2 delivery depends on its relative effects on cardiac output and arterial oxygen content: in other words, on the balance between the pulmonary and hemodynamic consequences of PEEP. PEEP-induced increase in Pa_{O_2} and arterial oxygen content may be accompanied by a decrease in O_2 delivery, because of concomitant decrease in cardiac output.[46] The impact of PEEP on O_2 delivery depends primarily on its hemodynamic effect. By decreasing cardiac output and consequently O_2 delivery, PEEP may worsen O_2 balance and promote pathologic supply-dependency of O_2 delivery.[430,469–472]

The effect of protective ventilation on O_2 delivery was evaluated in patients with ARDS.[473–475] In forty-eight patients with severe ARDS, Carvalho et al[474] found that PEEP up to 24 cm H_2O (average: 16 cm H_2O) produced an increase in cardiac output, heart rate, and O_2 delivery, and decreased systemic vascular resistance and plasma lactate. The authors speculated that the good tolerance of high PEEP may have been a consequence of the acute hemodynamic effects of hypercapnia and the observed very low lung compliance.[474] No correlation was found between changes in PEEP and cardiac output. A strong inverse correlation existed between changes in plateau pressure and cardiac output. These findings suggest, in line with other reports,[202,318] that the negative hemodynamic effect classically attributed to PEEP may depend more on the associated high inspiratory pressure (if V_T is not concomitantly reduced).[474]

Noncardiorespiratory Effects of Positive End-Expiratory Pressure

RENAL AND HORMONAL EFFECTS

PEEP decreases urinary output,[47,54,55,476–500] sodium excretion,[55,476–478,480–482,484–490,493,500] and creatinine clearance.[476,480,481,484,490] Although there is general consensus about these effects of PEEP, studies investigating the mechanisms

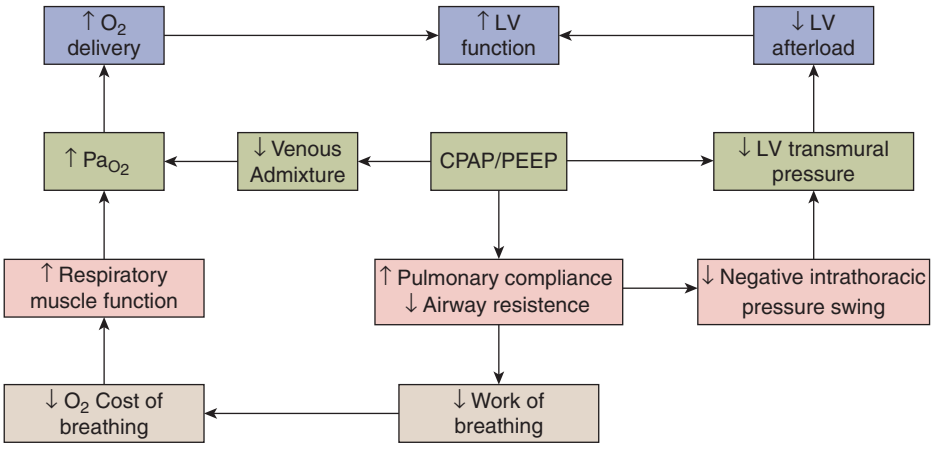

FIGURE 10-10 Cardiopulmonary effects of CPAP in cardiogenic pulmonary edema. By improving pulmonary mechanics, CPAP reduces negative swings in intrathoracic pressure and left-ventricular afterload. By improving gas exchange CPAP increases oxygen delivery to the heart and the respiratory muscle. See text for further explanation. *LV*, left ventricle; O_2, oxygen; Pa_{O_2}, partial pressure of arterial oxygen.

are conflicting. Discrepancies are related to differences in experimental design, such as diverse subjects, trial duration, type and severity of underlying disorder, volemic state, use of drugs and anesthetics (which commonly cause sympathetic depression), and level of PEEP. The decrease in urinary output caused by PEEP has been attributed to multiple factors, such as fall in cardiac output[54,477,491] and renal blood flow,[477,479,487,491,495] reduced intravascular volume,[54] reflex sympathetic nerve activation,[497] and altered release of hormones including catecholamines,[476] renin–angiotensin–aldosterone system,[476,488,498–500] antidiuretic hormone,[476,488] and atrial natriuretic factor.[485,486,488–490,493]

In dogs receiving a constant fluid infusion, Berry et al[55] observed that the time needed for urinary output to approximate the rate of fluid infusion was 20, 27, and 46 hours during spontaneous breathing, positive-pressure ventilation and positive-pressure ventilation plus PEEP 10 cm H_2O, respectively. Priebe et al[54] found that renal impairment caused by PEEP 10 cm H_2O in anesthetized dogs primarily resulted from a reduction in intravascular volume. In swine, Venus et al[476] found that the addition of PEEP to positive-pressure ventilation caused a fall in cardiac and urinary output, associated with increase in plasma antidiuretic hormone, renin, epinephrine, and norepinephrine in normovolemic animals, but not in animals that received volume expansion through crystalloids. In six neurologic patients with intact cardiopulmonary and renal function who were receiving positive-pressure ventilation plus PEEP 15 cm H_2O, an increase in lower body pressure via military antishock trousers improved systemic and renal hemodynamics and decreased plasma norepinephrine, with no change in total blood volume.[499] Urinary output and sodium excretion did not improve. The authors concluded that increased plasma renin and sympathetic activation were the main determinants of renal impairment with PEEP.[499]

Annat et al[477] evaluated the short-term effects of PEEP 10 cm H_2O in normovolemic patients without cardiac and renal abnormalities and little or no respiratory failure who were receiving positive-pressure ventilation. PEEP decreased urinary output by 34%, renal blood flow by 32%, and sodium excretion by 33%; the associated drop in cardiac output was 15%.[477] PEEP also increased urinary antidiuretic hormone and plasma renin and aldosterone.[477] In a similar setting, Payen et al[491] found that PEEP 15 cm H_2O reduced urinary output (55%) and fractional sodium excretion (39%); cardiac index fell by 21%. Plasma antidiuretic hormone did not vary, and norepinephrine increased.[491]

PEEP increases sympathetic activity.[501] Nevertheless, the observation by Fewell et al[494] that the effects of PEEP on renal function are mediated by sympathetic activity has not been confirmed.[481,492] PEEP decreases plasma atrial natriuretic factor.[478,485,486,488,493] This may contribute to the reduction in urinary output and sodium excretion, probably as a result of the reduced atrial transmural pressure consequent to the raised intrathoracic pressure.[485]

In summary, PEEP may alter renal function by reducing cardiac output and renal blood flow to an extent that depends on the volemic state and on the amount of applied pressure, although other mechanisms, including several hormones, may play a role.

EFFECTS ON SPLANCHNIC CIRCULATION AND OXYGENATION

PEEP decreases splanchnic blood flow[43,57,58,502–504] and causes hepatic congestion.[503] The reduction in splanchnic blood flow is consequent to a fall in cardiac output secondary to impaired central hemodynamic[43,57,58,502–504]; it is less pronounced when cardiac output is maintained either by expanding blood volume[57,58] or inotropic drugs.[504] In hemodynamically stable patients with ARDS, Kiefer et al[505] found that PEEP 13 cm H_2O (5 cm H_2O increment above the preset values), did not decrease cardiac index

or splanchnic blood flow and metabolism, suggesting that PEEP does not affect splanchnic blood flow. Other factors, however, such as hepatic outflow resistance, may play a role.[58,506] In swine, Brienza et al[506] found that PEEP 15 cm H_2O reduced portal vein flow through an increase in liver venous resistance; the authors postulated a direct compressive effect caused by diaphragmatic descent on the liver.

Sha et al[502] applied increasing PEEP (up to 20 cm H_2O) and found proportional decreases in hepatic blood flow. Because the rate of decrease in hepatic O_2 delivery exceeded that of cardiac output and hepatic blood flow, the authors concluded that hepatic O_2 delivery was reduced primarily because of the drop in portal venous O_2 content.[502] Aneman et al[507] evaluated the impact of PEEP 10 cm H_2O on mesenteric and hepatic blood flow in patients under general anesthesia (during elective surgery for gastric or pancreatic neoplasm). Neither arterial pressure nor arterial, portal, and hepatic venous norepinephrine were significantly affected by PEEP.[507] A decrease in portal blood flow was associated with a rise in mesenteric vascular resistance; conversely, an increase in hepatic arterial flow was associated with a drop in hepatic arterial resistance.[507] Mesenteric O_2 delivery was reduced and hepatic O_2 delivery remained unchanged.[507] Mesenteric and hepatic $\dot{V}O_2$ did not significantly vary with PEEP.[507] In similar patients, Berendes et al[43] found that hepatic venous lactate did not change with PEEP up to 15 cm H_2O, and concluded that a critical reduction in splanchnic oxygenation did not occur.

In spontaneously breathing normal subjects, Fournell et al[508] reported that CPAP levels up to 10 cm H_2O progressively altered gastric mucosal microvascular O_2 saturation, as assessed by reflectance spectrophotometry. Lehtipalo et al[44] found that PEEP 10 cm H_2O had little effect on intestinal perfusion pressure; mesenteric blood flow and oxygenation were maintained until the intestinal perfusion pressure exceeded 33 mm Hg. In patients with septic shock, Träger et al[509] increased PEEP up to 15 cm H_2O. PEEP decreased cardiac index and hepatic venous O_2 saturation.[509] Hepatic metabolic performance, assessed by glucose production, fell at each PEEP level in patients who did not survive, whereas it decreased only at the highest PEEP among survivors.[509] In 141 unselected critically ill patients, PEEP greater than 5 cm H_2O during mechanical ventilation was found to be a risk factor for liver dysfunction, as defined by serum bilirubin equal to or greater than 2 mg/dL for at least 48 hours.[510]

In sixty-five patients who underwent liver transplantation, Saner et al found in the immediate postoperative period that application of PEEP up to 10 cm H_2O did not affect venous liver outflow, portal vein and hepatic artery flow, and systemic hemodynamics.[511] In a retrospective observation study, Kocabayoglu et al reviewed the records of 50 patients who underwent mechanical ventilation for more than 7 days because of pulmonary complications following liver transplantation and found that PEEP equal to or greater than 10 cm H_2O did not harm liver-graft function.[512]

In summary, PEEP reduces hepatic and splanchnic blood flow when determining a drop in cardiac output, although other factors, such as regional outflow resistance or derangements in microcirculation consequent to sepsis, are likely to play a role.

EFFECTS ON INTRACRANIAL PRESSURE AND CEREBRAL PERFUSION

High intracranial pressure (ICP) and reduced cerebral perfusion pressure (the difference between mean arterial pressure and ICP) are common in several acute neurologic and neurosurgical intensive care unit patients, particularly those who have focal or generalized cerebral edema. Hypoxemic respiratory failure secondary to ARDS is a fearful complication in these patients leading to use of PEEP.[513]

ICP may be altered by PEEP through a rise in right-atrial pressure, which increases superior vena cava pressure and hence reduces cerebral venous return.[53,514,515] The effects of PEEP on ICP depend on the amount of intracranial compression, and are of little importance when cerebral compliance is not altered.[52] In a study evaluating twenty-five head-injured patients, Apuzzo et al[52] found that PEEP caused an increase in ICP in only twelve patients who had low cerebral compliance, and reduced cerebral perfusion pressure below 60 mm Hg in only six of the twelve patients.[52] In normal healthy volunteers, Hormann et al[516] found that alterations in ICP and cerebral perfusion pressure produced by CPAP 12 cm H_2O were slight and not of clinical relevance. Body position also affects the impact of PEEP on ICP. PEEP raises ICP through an increase in the downstream venous pressure; thus, elevating the head above the chest should lessen the transmission of intrathoracic pressure to the venous sinuses and mitigate the effects of PEEP on ICP. In supine anesthetized patients undergoing posterior fossa surgery, Lodrini et al[517] found that PEEP up to15 cm H_2O caused proportional increases in central venous pressure and ICP; in the sitting position, PEEP also increased central venous pressure, but ICP changed little in most of the patients.

Muench et al found that increases in PEEP up to 25 cm H_2O in healthy pigs did not produce any adverse effect on ICP, cerebral blood flow, or tissue oxygenation. On the contrary, in patients with subarachnoid hemorrhage, reduction in mean arterial pressure consequent to application of PEEP up to 20 cm H_2O caused a significant decrease in cerebral blood flow attributable to the altered cerebrovascular autoregulation.[518] Caricato et al studied the effects of increasing PEEP up to 12 cm H_2O in twenty-one patients with severe head injury or subarachnoid hemorrhage and who were receiving mechanical ventilation; static compliance of the respiratory system was normal in thirteen patients and reduced in the other eight.[519] The authors found that PEEP caused a decrease in mean arterial pressure and cerebral perfusion pressure in the first subgroup of thirteen patients, whereas it did not produce any significant change in the eight patients

with reduced respiratory compliance.[519] In twelve severely brain-injured patients with ARDS and high ICP, Mascia et al randomly applied 5 and 10 cm H_2O of PEEP; recruited volume and elastance were used to classify patients as recruiters ($n = 6$) and nonrecruiters ($n = 6$).[520] Pa_{CO_2}, ICP, Doppler flow velocity, and jugular saturation increased significantly with higher PEEP in the nonrecruiters, but did not change in the recruiters.[520]

Several studies in neurologic, neurosurgical, or brain-injured patients found that judicious use of PEEP was not detrimental.[521–526] As PEEP may affect cerebral circulation, adequate monitoring of cerebral and respiratory function should be used to titrate its application.[527]

EFFECTS ON BRONCHIAL CIRCULATION AND THORACIC LYMPH DRAINAGE

By increasing intrathoracic pressure, PEEP alters bronchial blood flow[528–530] and thoracic lymph drainage, which could affect the process of lung repair and edema removal.[531] Blood from the bronchial vessels is drained to the right side of the heart via the azygos and bronchial veins and to the left atrium through anastomoses between systemic and pulmonary circulation. In ventilated open chest dogs, Baile et al[528] investigated the effect of increasing PEEP on systemic to pulmonary (anastomotic) flow (Qbra) and on bronchial blood flow (Qbr), which was further partitioned into tracheal, bronchial, and parenchymal fractions. Bronchial and parenchymal, but not tracheal, fractions of Qbr decreased with PEEP.[528] Qbr and Qbra did not differ at PEEP 3 and 10 cm H_2O.[528] At PEEP 15 cm H_2O, Qbr exceeded Qbra, indicating a decrease in the anastomotic drainage.[528] In patients undergoing cardiopulmonary bypass, Agostoni et al[530] observed that an increase in alveolar pressure of approximately 10 cm H_2O decreased Qbra by 40%.

Local release of mediators, rise in pulmonary vascular resistance, and reflex bronchial vasoconstriction may explain Qbra reduction.[529] To assess the influence of vagal reflexes on PEEP-mediated reduction in Qbra, Lakshminarayan et al[532] isolated and perfused the left lower lobe in open chest dogs, and found that increasing PEEP from 5 to 15 cm H_2O halved Qbra. At PEEP 5 cm H_2O, bilateral cervical vagal cooling decreased Qbra.[532] An increase of PEEP to 15 cm H_2O did not further diminish it, suggesting that the effect of PEEP on Qbra might be partly vagally mediated.[532]

PEEP may obstruct lymph drainage from the thoracic duct into the jugular vein.[531,533] By altering thoracic lymph return, PEEP might affect edema removal from the lungs.[531]

INTRINSIC POSITIVE END-EXPIRATORY PRESSURE

During passive exhalation, airflow is driven by the difference between alveolar and airway opening pressures and opposed by expiratory resistance. In absence of expiratory muscle activity and externally applied PEEP, alveolar pressure corresponds to the elastic recoil of the respiratory system for a given V_T: alveolar pressure is thus equal to respiratory system elastance/V_T or V_T/respiratory system compliance. The product of respiratory system compliance and airway expiratory resistance is the expiratory time constant (τ). During expiration, $V = V_T\, e^{-(t/\tau)}$ where V is the amount of V_T not yet exhaled (i.e., above FRC), t is the time elapsed from the onset of expiration, and e is the base of natural logarithms (2.7189). When $t = \tau$, V is roughly 37% (1/2.7189) of V_T. It takes five τ to almost entirely (99%) exhale V_T.

In healthy adult subjects, τ is approximately 0.3 second. Therefore, the time required to exhale V_T is approximately 1.5 seconds. Assuming a respiratory rate of 12 breaths/min and an inspiratory duty cycle (T_I/T_{TOT}) of 40%, expiratory time (T_E) is 3 seconds, which considerably exceeds the time necessary for the lungs to deflate to FRC. If either breathing frequency or T_I/T_{TOT} increase, T_E diminishes. Any condition causing an increase in expiratory resistance, including an artificial airway,[534] or a loss in elastic recoil prolongs τ and thus the time required for complete V_T exhalation. When shortened T_E and/or prolonged τ impede a complete exhalation to FRC, dynamic hyperinflation occurs. End-expiratory relaxation volume will exceed FRC to an extent that is proportional to τ and V_T and inversely related to T_E (Fig. 10-11).

Expiratory flow may also be limited in the course of V_T exhalation because the airways collapse at a choke point where intrathoracic pressure equals intrabronchial pressure (so-called equal pressure point). The airways located downstream of the equal pressure point are then compressed because intrathoracic pressure exceeds the

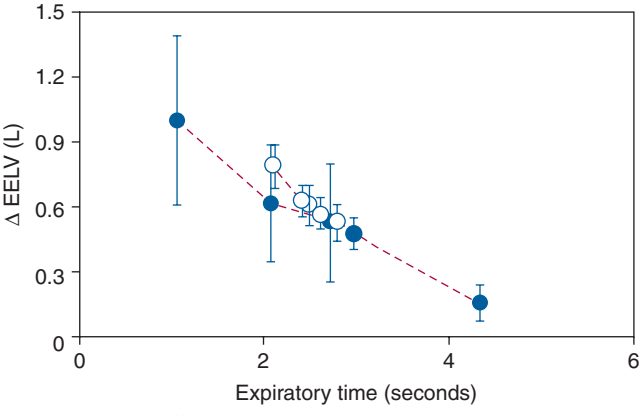

FIGURE 10-11 Effects of varying expiratory time on end-expiratory trapped volume in patient with airway obstruction. ΔEELV indicates end-expiratory lung volume above functional residual capacity. The shorter the expiratory time, the greater the amount of end-expiratory trapped volume. Data are expressed as mean ± standard deviation (*closed circles*) and mean ± standard error (*open circles*), and taken from references 237 and 359, respectively. Tidal volume was always 1 L in reference 237, and averaged 0.576 L (± 0.026) in reference 359. In reference 359, changes in expiratory time were obtained by manipulating the ventilator preset inspiratory time, while leaving respiratory rate (and hence minute ventilation) unmodified. In reference 237, inspiratory duty cycle remained unchanged and expiratory time was changed by modifying respiratory rate; accordingly minute ventilation also varied.

intrabronchial pressure. Thus, alveolar pressure–airway opening pressure no longer represents the pressure driving expiratory flow. Expiratory flow limitation is very common in patients with an acute exacerbation of COPD.[238,535–538] It has also been reported in patients with asthma,[539,540] obesity,[271,541] and ARDS.[183,184,535,542]

Regardless the underlying mechanism, after a few breaths a steady state is achieved that depends on the variations in the different components of respiratory mechanics. For a certain trapped volume, the amount of PEEPi is determined by the corresponding respiratory system compliance.

Measurement of Intrinsic Positive End-Expiratory Pressure

PEEPi can be detected qualitatively by observing the flow-time curve, available on most ventilators. In absence of PEEPi, expiratory flow is zero before the onset of the subsequent inspiration (Fig. 10-12A). The persistence of expiratory flow at end-expiration indicates the presence of PEEPi, during either mechanical ventilation (Fig. 10-12 B) or spontaneous breathing (Fig. 10-12C).

Because the ventilator built-in pressure gauge is open to atmosphere, PEEPi cannot be detected by simply inspecting airway pressure. During controlled ventilation, PEEPi can be measured by occluding the airway opening at end-expiration for a few seconds[59,543] (see Fig. 10-4), the end-expiratory occlusion maneuver. This value is static PEEPi (PEEPi,stat). Unless some alveolar units are not at all communicating with the central airways (because the corresponding peripheral airways are completely occluded),[544] PEEPi,stat represents the average pressure in the different lung regions.[9,238,545–547] A second approach is to measure the difference between preset PEEP and airway pressure at the onset of inspiratory flow[260,546,547]; this value is dynamic PEEPi (PEEPi,dyn). PEEPi,dyn can be considered as the lowest regional end-expiratory alveolar pressure that has to be overcome to begin inspiratory flow.[9,238,545–547] PEEPi,dyn and PEEPi,stat approximate each other, in animals[546] and in human subjects[547] in the absence of severe airway disorders, when PEEPi is consequent to T_E shortening and/or increasing minute ventilation (V_E). In animals receiving high doses of aerosolized methacoline[546] and patients affected by severe airway obstruction,[547] PEEPi,dyn is considerably lower than PEEPi,stat. A low ratio of PEEPi,dyn to PEEPi,stat suggests time constant inequalities within the lung and high lung tissue viscoelastic pressure losses.[183,546–549]

When the inspiratory muscles are contracting, assessing PEEPi is more complex. When inspiration is active and expiration relaxed, PEEPi,dyn can be measured with a balloon-tipped esophageal catheter.[2,545,550,551] PEEPi,dyn equals the difference in esophageal (pleural) pressure between the onset of negative deflection (indicating the start of the inspiratory effort), and the pressure at the transition between expiratory and inspiratory flow

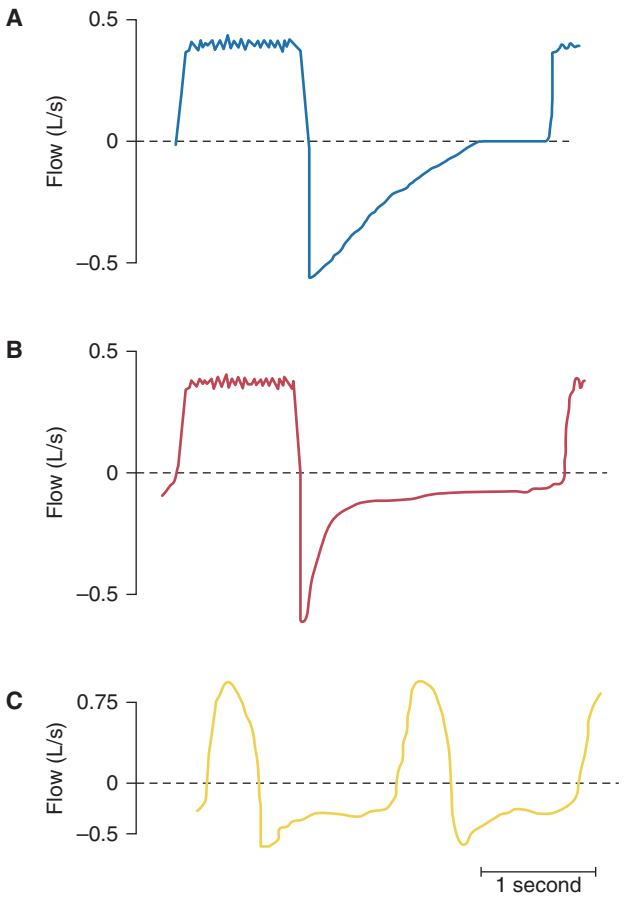

FIGURE 10-12 Flow-time tracings during controlled ventilation in a normal anesthetized subject (**A**), in a patient with severe COPD during controlled ventilation (**B**) and during spontaneous breathing (**C**). In the normal subject (A), expiratory flow reaches zero before expiration ends. In the patient with COPD, expiratory flow remains below zero value before the subsequent inspiration, denoting dynamic hyperinflation, during both controlled ventilation and spontaneous breathing.

(Fig. 10-13).[2,545,551] When the expiratory muscles are contracting, which is common in flow-limited patients,[552–555] especially during partial ventilator support,[2,554,556,557] the pressure developed in the abdomen is transmitted through the relaxed diaphragm and raises intrathoracic pressure. Consequently, assessing PEEPi via esophageal pressure will overestimate the true end-expiratory elastic recoil pressure.[2,552–558] With a second balloon-tipped catheter in the stomach, it is possible to measure, and correct for, the amount of intrathoracic pressure rise caused by expiratory muscles contraction[2,554,556]; briefly, the expiratory rise in gastric pressure is subtracted from the esophageal pressure at the onset of the subsequent inspiration (Fig. 10-14).[554,556] Another method is to subtract the rise in gastric pressure, during an end-expiratory occlusion, from airway pressure.[559] Partitioning the rise in intrathoracic pressure from recording of airway, esophageal and gastric pressures is complex, and infrequently performed in the clinical setting.

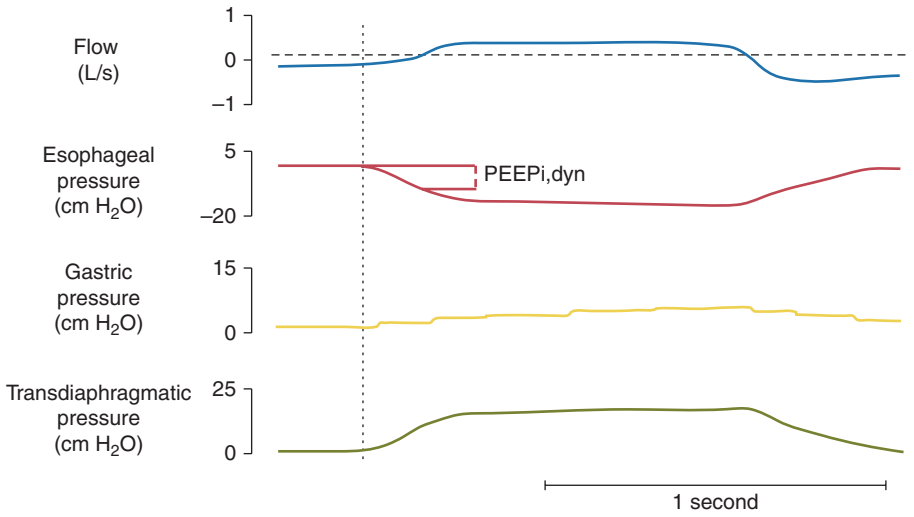

FIGURE 10-13 Measurement of dynamic intrinsic PEEP (PEEPi,dyn) in a spontaneously breathing patient without expiratory muscle activity. The *dashed horizontal line* indicates zero flow. The *dotted vertical line* indicates the onset of the inspiratory effort. The *solid vertical line* indicates the start of inspiratory flow. Gastric pressure rises during inspiration and descends during expiration, indicating that expiratory muscles were not active. PEEPi,dyn is the difference in esophageal pressure between onset of inspiratory effort and start of inspiratory flow.

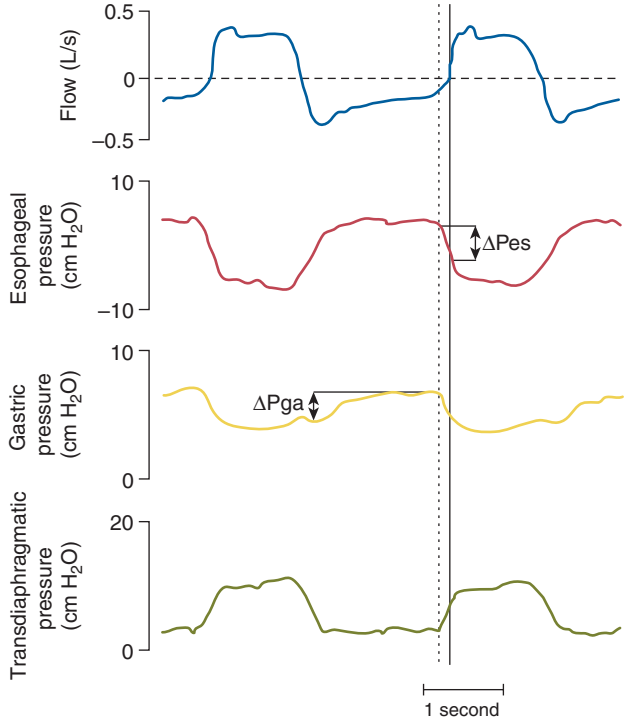

FIGURE 10-14 Measurement of dynamic intrinsic PEEP (PEEPi,dyn) in a spontaneously breathing patient with expiratory muscle activity. The *dashed horizontal line* indicates zero flow. The *dotted vertical line* indicates onset of inspiratory effort. The *solid vertical line* indicates the start of inspiratory flow. Unlike in Figure 10-13, gastric pressure rises during expiration (ΔPga) and descends at the following inspiration, indicating expiratory muscle recruitment. ΔPga must be subtracted from the difference in esophageal pressure between onset of inspiratory effort and start of inspiratory flow (ΔPes) to determine PEEPi,dyn.

Physiologic Effects of Intrinsic Positive End-Expiratory Pressure

During volume-targeted controlled ventilation PEEPi does not affect V_T, whereas it elevates peak airway pressure, which is a dependent variable (i.e., it varies depending on the impedance of the respiratory system) (Fig. 10-15A). Conversely, during pressure-targeted controlled ventilation, the independent variable is the preset positive pressure applied to the airway during inspiration, the presence of PEEPi decreases the actual lung distending pressure and therefore V_T (Fig. 10-15B).

PEEPi resembles in several respects external PEEP. In patients with hypoxemic ARF consequent to ARDS or cardiogenic pulmonary edema, an increase in end-expiratory lung volume, produced by T_E shortening, secondary to tachypnea or inverse-ratio ventilation, can decrease intrapulmonary shunt as much as can external PEEP.[560] In patients without COPD, Brandolese et al[192] found that external PEEP produced more consistent increases in Pa_{O_2} than did an equivalent level of PEEPi. The authors attributed the less-favorable impact of PEEPi on Pa_{O_2} to less-homogeneous gas distribution between different lung units.[192] PEEPi decreases cardiac output[59,192,238,560] and blood pressure[59,238] to an extent similar to that produced by external PEEP for the same increase in lung volume.[560] Connery et al[561] reported fatal cardiac arrest and life-threatening hypotension during manual ventilation with large V_T and high respiratory frequencies in two patients with severe COPD. By increasing alveolar pressure, PEEPi may also cause barotrauma.[562]

In spontaneously breathing patients, PEEPi poses a threshold load that has to be overcome before inspiratory flow can be initiated;[9,545,550,563] this load is perceived as inspiratory difficulty.[564] With any mode of partial ventilator

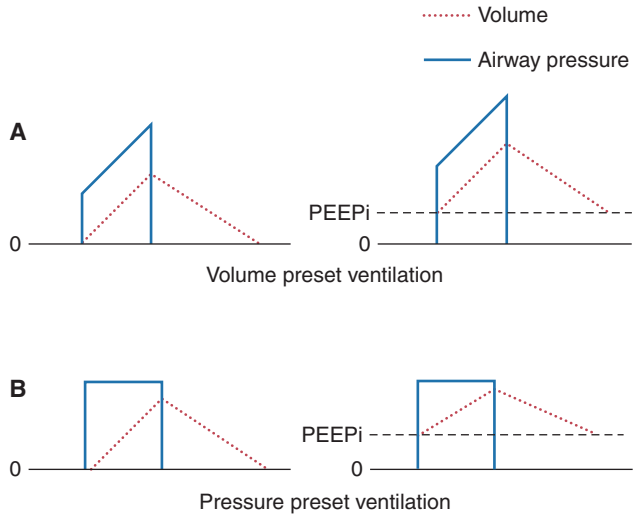

FIGURE 10-15 Simulation of the effects of PEEPi on volume-targeted (**A**) and pressure-targeted (**B**) controlled ventilation. Volume and airway pressure are indicated by *dotted* and *solid lines*, respectively. In the *left panels*, when PEEPi is absent, tidal volume is the same for both modes. In the *upper* (A) *right panel*, during volume-targeted ventilation, PEEPi cause a rise in airway pressure, while preset tidal volume is unchanged. During pressure-targeted ventilation, *lower* (B) *right panel*, preset pressure does not vary, and, consequently, tidal volume falls.

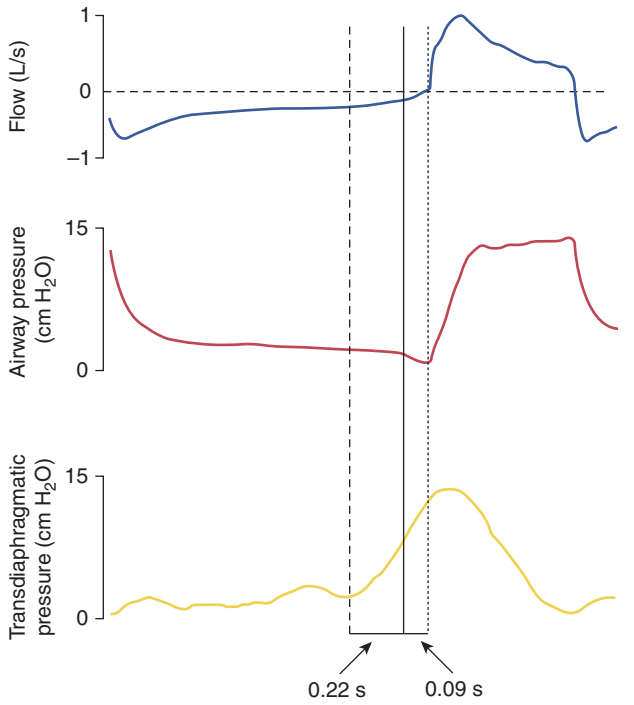

FIGURE 10-16 Effect of intrinsic PEEP (PEEPi) on ventilator triggering. The *dashed horizontal line* indicates zero flow. The *dashed vertical line* on the left indicates the onset of the inspiratory effort. The *dotted vertical line* on the right corresponds to the start of inspiratory flow. The *solid vertical line* indicates the point at which the ventilator is triggered and the mechanical assistance initiated. The amount of effort spent in overcoming PEEPi corresponds to the difference in transdiaphragmatic pressure between the points crossed by the *dashed* and *solid lines*. PEEPi increases the magnitude of the inspiratory effort and remarkably lengthens the effort-to-assist delay.

support, this threshold must be overcome before the ventilator can be triggered (Fig. 10-16).[2,61,63,551,565–568] Inspiratory efforts that are not intense enough to overcome PEEPi fail to trigger the ventilator,[63,64,569–571] a phenomenon referred to as *wasted* or *ineffective inspiratory efforts* (Fig. 10-17). Wasted efforts occur with all triggered modes,[570] and are more frequent at higher ventilator assistance[63,64,570] because of higher PEEPi, consequent to increased lung volume,[63,64,570] and diminished respiratory drive.[570]

Acute hyperinflation impairs the force-generating capacity of the diaphragm by moving the diaphragm to an inefficient part of its force-length relationship[572–574] and increasing the O_2 cost of breathing.[575] In healthy volunteers, Beck at al[576] showed that greater diaphragmatic activation to generate a certain amount of pressure increased with increasing lung volume, and pressure generated by maximal diaphragmatic activation decreased with increasing lung volume. In spontaneously breathing dogs, Kawagoe et al[577] found that a threshold load associated with PEEPi produced pulmonary artery hypertension and decreases in cardiac output and blood flow to the liver, pancreas, sternomastoid and parasternal muscles, while little change in blood flow to the diaphragm.[577] An equivalent resistive load increased diaphragmatic blood flow, without changes in cardiac output or regional blood flow.[577] Both loads produced noncompensated respiratory acidosis, but the severity was greater for the threshold load.[577] An acute inspiratory threshold load causes a greater diaphragmatic sarcomere disruption in patients with COPD than in patients without lung disease[578]; hyperinflation explains approximately 40% of the injury.[578]

The complex interactions of dynamic hyperinflation and PEEPi on preload were reviewed by Ranieri et al.[579] During spontaneous breathing or triggered ventilation, venous return is decreased by the higher end-expiratory lung volume and intrathoracic pressure or increased by the larger negative inspiratory swings in intrathoracic pressure, with latter dominating.[579]

Clinical Consequences of Intrinsic Positive End-Expiratory Pressure

The extra load imposed on the respiratory muscles by PEEPi may be large (Fig. 10-18) and have relevant clinical consequences. In patients with COPD in ARF, Coussa et al[580] found that work of breathing was increased because of increased resistance and PEEPi. PEEPi accounted for more than 30% of the overall workload (Fig. 10-18A). In a ventilator-dependent patients with COPD, Appendini et al[64] found that the effort to overcome PEEPi accounted for more than 40% of overall inspiratory effort[64] (Fig. 10-18B).

Jubran and Tobin[581] studied thirty-one patients with COPD undergoing a T-tube trial, seventeen of whom

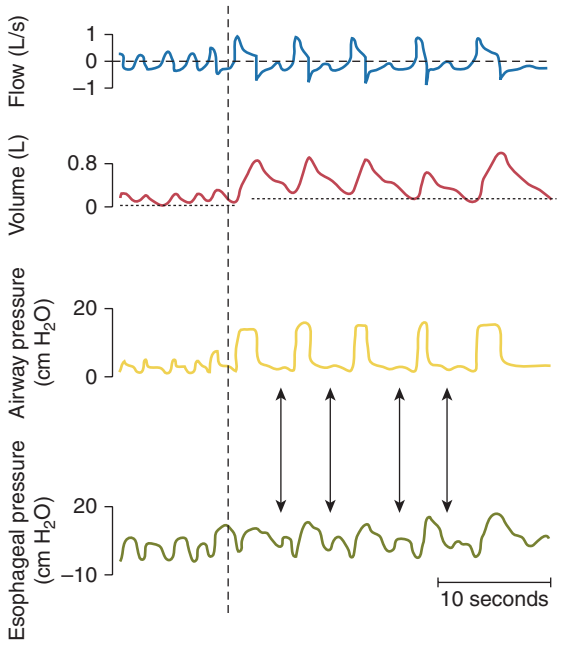

FIGURE 10-17 Ineffective or wasted inspiratory efforts. The *dashed horizontal line* on the flow tracing indicates zero. The *dashed vertical line* indicates the onset of the ventilator assistance. To the left of the dashed line, the patient is spontaneously breathing with the ventilator set in CPAP mode. The breathing pattern is rapid and shallow. Initiation of pressure support increases tidal volume and decreases respiratory rate, as assessed on the flow and airway pressure tracings. The respiratory rate, assessed by swings in esophageal pressure is higher. The *arrows* show that half the inspiratory efforts fails to trigger the ventilator. The *dotted horizontal lines* on the volume tracing indicate that end-expiratory lung volume increased after institution of pressure support (dynamic hyperinflation).

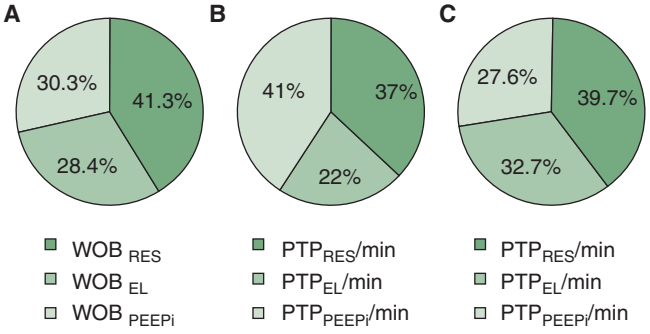

FIGURE 10-18 Fractions of the respiratory load in ventilator-dependent patients with COPD. **A.** Elastic (*EL*), resistive (*RES*), and *PEEPi* fractions of work of breathing (*WOB*) in sedated and paralyzed patients with COPD in acute respiratory failure while receiving controlled ventilation. **B.** Elastic (*EL*), resistive (*RES*), and *PEEPi* components of inspiratory effort, assessed as esophageal pressure-time product (*PTP*), during a brief period of spontaneous breathing in patients with COPD who could not be weaned. **C.** Same measurement as in *B* in patients with COPD who failed a T-tube trial. Despite the different settings, PEEPi accounted for a considerable fraction of inspiratory load.

failed and fourteen were successfully extubated. At the onset of the trial, PEEPi was higher in the failure group than in the success group.[581] Between the start and end of the trial, the fraction of inspiratory effort caused by PEEPi more than doubled in the failure group, while it did not change in the success group.[581]

In thirty patients who failed an initial weaning trial but who later succeeded, Vassilakopoulos et al[582] found that dynamic hyperinflation and PEEPi were higher at the time of weaning failure.

Impact of External Positive End-Expiratory Pressure on Dynamic Hyperinflation and Intrinsic Positive End-Expiratory Pressure

Depending on the mechanisms of dynamic hyperinflation and PEEPi, external PEEP can have different effects, as elegantly pointed out by Marini (Fig. 10-19).[583] When PEEPi is not caused by flow limitation, external PEEP is entirely transmitted to the distal airway, producing a concomitant rise in alveolar pressure (Fig. 10-19B). In six patients with acute asthma or a COPD exacerbation, Tuxen et al[237] increased dynamic hyperinflation and PEEPi by increasing

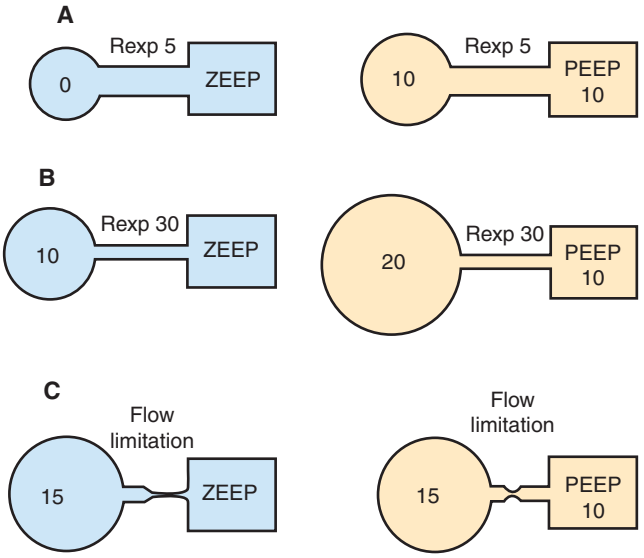

FIGURE 10-19 Schematic of the effects of PEEP on alveolar pressure in normal conditions (A), high airway resistance but no expiratory flow limitation (B), and expiratory flow limitation and dynamic airway compression (C). The *circles* represent the alveoli, the *rectangles* represent the ventilator, and the *tubes* represent the bronchi. *PEEP*, Positive end-expiratory pressure expressed in cm H_2O; *Rexp*, expiratory resistance expressed in cm H_2O/L/s; *ZEEP*, zero positive end-expiratory pressure. **A.** At ZEEP (*left panel*), the alveolar pressure falls to zero. Applied PEEP (*right panel*) is entirely transmitted to the alveoli. **B.** At ZEEP (*left panel*), the high expiratory resistance causes alveolar pressure to remain positive at end-expiration. Applied PEEP (*right panel*) is entirely transmitted to the alveoli. **C.** At ZEEP (*left panel*), the alveolar pressure is positive. Applied PEEP does not exceed the critical pressure at the choke point and does not affect alveolar pressure.

V_E from 10 L/min to 16 L/min and 22 L/min. Increasing levels of PEEP up to 15 cm H_2O produced increases in end-expiratory lung volume and intrathoracic pressure, accompanied by a parallel hemodynamic deterioration.[237] At the lowest V_E, trapped volume was small, suggesting little if any flow limitation.[237]

When flow limitation and dynamic airway compression are present, PEEP is not transmitted to the distal airway and does not increase alveolar pressure as long as it does not exceed the critical pressure corresponding to the choke point (see Fig. 10-19C).[583] The waterfall analogy helps in understanding this concept. The equal-pressure point is viewed as the crest of a waterfall, and the airway segment between the choke point and the airway opening as the downstream water.[584,585] Increasing the level of downstream water (external PEEP) does not alter upstream water flow (air flow), as long as it does not exceed the crest (critical pressure at the choke point).[585] In flow-limited patients with COPD who had PEEPi 10 cm H_2O and trapped volume of 1 L, Ranieri et al[238] applied PEEP 5, 10, and 15 cm H_2O. Up to PEEP 10 cm H_2O, changes in peak and plateau airway pressure, end-expiratory lung volume, and total PEEP (i.e., PEEPi + external PEEP) were minimal; hemodynamic impairment was absent. PEEP 15 cm H_2O increased peak and plateau airway pressure, trapped volume and total PEEP, with worsening of hemodynamics.[238] Changes in end-expiratory lung volume and cardiac index started to occur when external PEEP matched approximately 85% of PEEPi,stat.[238] In eight patients with severe airway obstruction undergoing controlled mechanical ventilation, Caramez et al evaluated the application of a PEEP level that exceeded by 50% the PEEPi value; in five patients, such PEEP levels produced a reduction in airway plateau pressure and total PEEP.[586] In flow-limited patients with COPD receiving a triggered ventilation, Appendini et al found that PEEP slightly lower than PEEPi,dyn did not cause further hyperinflation.[2]

Flow limitation associated with small airway closure and PEEPi may be present in ventilated patients with ARDS.[183] In patients with ARDS who have flow limitation and PEEPi, Koutsoukou et al[184] found that PEEP 10 cm H_2O, produced a small increase in total PEEP and alveolar recruitment, but a significant increase in Pa_{O_2}; the latter was attributed to improved regional PEEPi in homogeneity. In another group of patients who did not exhibit flow limitation and had little PEEPi, PEEP 10 cm H_2O increased total PEEP and produced greater alveolar recruitment, which was the chief reason for an increase in Pa_{O_2}.[184] Analogous results were reported by Vieillard-Baron et al,[342] who found flow limitation and PEEPi in 73% of patients with ARDS receiving volume-controlled ventilation.

An increase in respiratory rate is commonly used during lung-protective ventilation in patients with ARDS to limit the hypercapnia consequent to V_T reduction. de Durante et al reported the occurrence PEEPi when patients with ARDS were ventilated with the low-V_T protocol of the ARDS Network (6 mL/kg) as opposed to a traditional V_T (12 mL/kg); respiratory rate was adjusted to achieve a V_E that maintained arterial pH between 7.30 and 7.45 (rate: 34 ± 1 breaths/min) during the low-V_T protocol, and rate was decreased to maintain the same V_E (rate: 14 ± 1 breaths/min) during the traditional-V_T protocol.[587] PEEPi averaged 5.8 cm H_2O with low V_T and 1.4 cm H_2O with a traditional V_T.[587] Analogous results were obtained by Richard et al[588] and, though to a lesser extent, by Hough et al.[589] Preliminary data indicate that PEEPi is reduced when higher PEEP levels are applied, confirming that flow limitation occurs also in ARDS patients.[590]

In actively breathing patients, the threshold load imposed by PEEPi may be offset by applying CPAP[9,60,591,592] or external PEEP.[2,61,63,566] If excessive or improperly applied,[583] external PEEP can worsen hyperinflation[238,593,594] placing the diaphragm at an additional disadvantage[573,574,576] and causing further hemodynamic impairment.[238,593]

USE OF POSITIVE END-EXPIRATORY PRESSURE IN THE CLINICAL SETTING

Acute Respiratory Distress Syndrome

The rationale for PEEP in patients with ARDS is to increase the amount of aerated lung volume,[197,200,221] improve respiratory mechanics,[197,200,338] reduce intrapulmonary shunt[140,595] and ameliorate gas exchange,[1,18,76,197,200] stabilize unsteady lung units,[596] and reduce the risk of VILI.[338,393] From its introduction almost fifty years ago,[1] PEEP remains a cornerstone in management of patients with ARDS.[597] It is easy to see no randomized trial evaluated ventilator strategies without PEEP in patients with ARDS, except in the very early phase.[151,598] A few studies have assessed the effect of PEEP on clinical outcome of patients with ARDS (Table 10-2).[6,599–604] One early study reported that high PEEP levels did not improve survival and caused more adverse events, when compared to patients treated with low PEEP.[599]

In the last decade, research has focused on ventilator strategies that protect the lung from VILI. These investigations have shown that ventilator settings may per se affect outcome.[605]

Three randomized, controlled trials suggest that high levels of PEEP (15 to 20 cm H_2O), used in the context of a lung-protective strategy, may improve both the physiologic[369] and clinical[6,604] outcome in patients with ARDS. Amato et al[6] found that low V_T combined with PEEP set 2 cm H_2O above the LIP (average: 16 cm H_2O) reduced mortality compared to a conventional approach where PEEP was titrated to optimize oxygenation (see Table 10-2). Ranieri et al[369] compared a strategy of high PEEP and low V_T, respectively based on LIP and UIP, against a conventional approach, where lower PEEP and higher V_T were targeted to normalize gas exchange (see Table 10-2). The control group exhibited more inflammatory mediators than the lung-protective group.[369] The control group also had a higher rate of organ failure and mortality and fewer ventilator-free days.[369,417] The occurrence

TABLE 10-2: RANDOMIZED CONTROLLED TRIALS EVALUATING THE EFFECT OF POSITIVE END-EXPIRATORY PRESSUREON CLINICAL AND PHYSIOLOGIC OUTCOMES

Reference	Population	Arm	No. of patients	Associated settings	PEEP setting	Mean PEEP (cm H_2O)	Outcomes
Carroll 1988 (599)	Surgical	Intervention	22	VT = 12 mL/kg PIP unlimited	Titrated to reduce shunt or to reach an oxygenation target	15	ICU mortality: 27%
		Control	28	VT = 12 mL/kg PIP unlimited	Minimal PEEP to reach an oxygenation target	4	ICU mortality: 4%
Amato 1998 (6)	Medical	Intervention	29	VT <6 mL/kg PIP <40 cm H_2O CPAP recruiting	2 cm H_2O > LIP (minimum 5 cm H_2O)	16	Mortality: 45% Barotrauma: 7%
		Control	24	VT = 12 mL/kg PIP unlimited	Titrated to P/F ratio (minimum 5 cm H_2O)	7	Mortality: 71% Barotrauma: 42%
Ranieri 1999 (369)	Medical-surgical	Intervention	18	VT for Pplat < UIP (or VT = 5 to 8 mL/kg)	2-3 cm H_2O > LIP (minimum 15 cm H_2O)	15	BAL/systemic levels of inflammatory mediators: ↓ Ventilator-free days: 12* Mortality: 38%* Organ failure score: unchanged
		Control	19	VT for Pa_{CO_2} 35 to 40 mm Hg Pplat < 35 cm H_2O	Titrated to SaO_2 (minimum 5 cm H_2O)	7	BAL/systemic levels of inflammatory mediators: ↑ Ventilator-free days: 4* Mortality: 58%* Organ failure score: increased (mainly renal)
Brower (ARDS Network) 2004 (601)	Medical-surgical	Intervention	276	VT = 6 mL/kg Pplat < 30 cm H_2O	Titrated to oxygenation (minimum 12 cm H_2O)	13†	Mortality: 25%‡ Unassisted breathing: 72% Barotrauma: 11% Days without organ failure: 16
		Control	273	VT = 6 mL/kg Pplat < 30 cm H2O	Titrated to oxygenation (minimum 5 cm H_2O)	8	Mortality: 28%‡ Unassisted breathing: 73% Barotrauma: 10% Days without organ failure: 16

Villar 2006 (604)	Medical-surgical	Intervention	50	VT = 5 to 8 mL/kg FI_{O_2} according to oxygenation	2 cm H_2O > LIP	14	ICU mortality: 32% Ventilator-free days: 11 Barotrauma: 2% New organ failures: 0.3
		Control	45	VT = 9 to 11mL/kg FI_{O_2} according to oxygenation	Titrated to oxygenation (minimum 5 cm H_2O)	9	ICU mortality: 53% Ventilator-free days: 6 Barotrauma: 4% New organ failures: 1.2
Meade (LOVS) 2008 (602)	Medical-surgical	Intervention	475	VT = 6 mL/kg Pplat <30 cm H_2O	Titrated to oxygenation (minimum 5 to 10 cm H_2O)	14†	Mortality: 36% Days of mechanical ventilation: 10 Barotrauma: 11% Refractory hypoxemia: 5%
		Control	508	VT = 6 mL/kg Pplat <30 cm H2O	Titrated to oxygenation (minimum 5 cm H_2O)	9	Mortality: 40% Days of mechanical ventilation: 10 Barotrauma: 9% Refractory hypoxemia: 10%
Mercat (ExPress) 2008 (603)	Medical-surgical	Intervention (increased recruitment)	385	VT = 6 mL/kg Pplat = 28 to 30 cm H_2O	Titrated to reach the plateau pressure target	14	Mortality: 35% Ventilator-free days: 7 Pneumothorax: 7% Organ failure-free days: 6 Rescue therapies: 19%
		Control (minimal distension)	382	VT = 6 mL/kg Pplat <30 cm H_2O	Titrated to oxygenation (5 to 9 cm H_2O)	7	Mortality: 39% Ventilator-free days: 3 Pneumothorax: 6% Organ failure-free days: 2 Rescue therapies: 35%

of PEEPi, consequent to high respiratory rate in the low V_T group, may have contributed[587,588] to the positive results in the ARDS Network trial that compared low and high V_T in patients with ARDS.[370] Villar et al compared a protective strategy, with PEEP set 2 cm H_2O above LIP (average: 14 cm H_2O) and low V_T (average: 7 mL/kg) to a conventional approach with PEEP set according to oxygenation (average: 9 cm H_2O) and higher V_T (average: 10 mL/kg).[604] Intensive care unit mortality, hospital mortality, and number of organ failures after randomization were lower, while the number of ventilator-free days at day 28 was greater in the protective-strategy group than in the conventional-strategy group. Of note, patients included in this study had more severe disease ($Pa_{O_2}/FI_{O_2} \leq 200$ with PEEP ≥5 cm H_2O) and persistent ARDS (criteria lasting 24 hours with standardized settings), than in previous studies (see Table 10-2).

Three randomized trials have compared the impact of different PEEP levels on clinical end points (see Table 10-2).[601–603] These trials randomized patients with ARDS to high or low PEEP levels to determine whether high PEEP, by enhancing lung recruitment, reduces VILI and improves outcome (see Table 10-2).[601–603] In the two arms of each trial, V_T was 6 mL/kg of predicted body weight and plateau pressure was less than 30 cm H_2O. In two studies, PEEP was titrated according to predefined combinations of PEEP and FI_{O_2}, to achieve an identical oxygenation goal (Pa_{O_2} 55 to 88 mm Hg or arterial oxyhemoglobin saturation [SpO_2] 88% to 95% and Pa_{O_2} 55 to 80 mm Hg or SpO_2 88% to 93%).[601,602] In the third trial, PEEP (and, consequently, plateau pressure) was set as low as possible (total PEEP between 5 and 9 cm H_2O), without falling below oxygenation targets (Pa_{O_2} 55 to 80 mm Hg or SpO_2 88% to 95%), in the low-PEEP group (minimal distension strategy); in the high-PEEP group (increased recruitment strategy), PEEP was kept as high as possible without increasing plateau pressure above 28 to 30 cm H_2O, regardless of its effect on oxygenation. The ARDS Network study Assessment of Low Tidal Volume and Elevated End-Expiratory Volume to Obviate Lung Injury (ALVEOLI) was interrupted after enrolment of 549 patients because no difference was detected in any predefined clinical outcome variable between the two groups (see Table 10-2).[601] Several methodological biases cast doubt on the conclusions.[606,607]

In the Lung Open Ventilation to Decrease Mortality in the Acute Respiratory Distress Syndrome (LOVS) trial, hospital mortality was not different between groups (36% and 40%, in the experimental and control groups, respectively). The higher PEEP group had better secondary end points related to hypoxemia, such as lower rates of refractory hypoxemia (5% vs. 10%), death with refractory hypoxemia (4% vs. 9%), and use of rescue therapies (5% vs. 9%).[602] The Comparison of Two Strategies for Setting Positive End-Expiratory Pressure in Acute Respiratory Distress Syndrome (ExPress Study) trial reported similar 28-day and hospital mortality in the two PEEP groups; ventilator-free days and organ failure-free days were higher, while the use of rescue therapy for severe hypoxemia was lower in the high-PEEP group as opposed to the low-PEEP group.[603] Interestingly, improvments in these secondary end points were more pronounced in the sicker ARDS patients than in the milder ones. Patients with more severe ARDS also showed a trend toward a reduced mortality ($p = 0.08$) in the high-PEEP group. Several meta-analyses have been subsequently performed to assess the effect on clinical outcomes of low versus high PEEP,[608–611] and these suggest that higher PEEP may improve survival, particularly in patients with more severe ARDS.

In summary, current evidence support the use of high PEEP, especially in the sickest patients with ARDS; in fact, high PEEP is safe, decreases the number of patients with severe hypoxemia and at high risk of death, and is associated with greater numbers of ventilator-free days and organ failure-free days. Nevertheless, it is uncertain how best to select the right patients and the optimal level of PEEP. The first issue is directly related to the current definitions of ARDS.[612] Villar et al report that severity of lung injury and outcomes vary widely in patients meeting the current definition of ARDS, and proposed the adoption of standardized ventilator settings so as to identify patients with similar severity of lung injury and mortality.[613] Several approaches have been proposed to optimize PEEP in ARDS, but none has proven effective in improving clinical outcome (Table 10-3).[6,22,42,164,171,201,215,303,309,322,327,344,351,599,601,614–623]

Optimal PEEP in ARDS should recruit as much nonaerated lung as possible, while avoiding lung overdistension, hemodynamic impairment, and global and regional disturbances of O_2 balance (Fig. 10-20). In the ALVEOLI and LOVS studies, PEEP was set according to preset PEEP/FI_{O_2} tables and PEEP-induced recruitment was estimated by improvement in oxygenation.[601,602] It is well known that changes in oxygenation depend not only on recruitment, but also on cardiac output.[48,138,140,191] Thus, oxygenation may have improved without any lung recruitment. Grasso et al[318,321] analyzed the physiologic effects of the ALVEOLI protocol. They demonstrated that the protocol has unpredictable effects on lung recruitment. Indeed, the protocol may increase the risk of overdistension when high PEEP is applied in patients with a low potential for recruitment, such as those with a focal distribution of lung atelectasis.[27,225,321] As recently suggested,[27,33,624] assessment of lung recruitability can be important when attempting to optimize PEEP on an individual basis. Results from the ExPress study support this reasoning and suggest that setting PEEP at the highest level compatible with a plateau pressure of 28 to 30 cm H_2O and a VT of approximately 6 mL/kg of predicted body weight is an acceptable approach (Fig. 10-20).

In ARDS, lung units are unstable and have a strong tendency to collapse. Thus, any ventilator circuit disconnection or leakage, leading to a complete or partial drop in pressure, can cause harmful falls in lung volume and oxygenation.[296]

Another approach to setting PEEP based on real-time, continuous analysis of the dynamic airway pressure-time profile ("stress index") has been proposed for optimizing ventilator settings in ARDS.[201,340,625] In animal studies and in a single study in patients, this approach was able to predict a ventilator strategy that minimizes VILI.[321,340,625] The

TABLE 10-3: METHODS FOR SELECTING OPTIMAL POSITIVE END-EXPIRATORY PRESSURE

Reference	Year	PEEP target	Proposed method
Suter (42)	1975	Maximal oxygen delivery	Maximal static compliance during stepwise incremental PEEP
Kirby (22)	1975	Intrapulmonary shunt < 15%	Stepwise incremental PEEP to reach the target, while supporting cardiac output with fluids and vasopressors
Hurewitz (617)	1981	Drop of mixed venous oxygen tension	Stepwise incremental PEEP to reach the target
Weisman (618)	1982	Adequate Pa_{O_2} with minimal FI_{O_2}	Stepwise incremental PEEP to reach the target
Murray (619)	1984	Minimal arterial end-tidal CO_2 gradient	Stepwise incremental PEEP to reach the target
Matamis (322)	1984	Best improvement in gas exchange, intrapulmonary shunt, and respiratory mechanics	PEEP set at the lower inflection point on inspiratory P-V curve
Albert (620)	1985	Adequate Pa_{O_2} with $FI_{O_2} < 0.6$	Lowest PEEP to reach the target
Hartman (616)	1992	Maximal peripheral tissue perfusion	Maximal subcutaneous oxygen tension during stepwise incremental PEEP
Gattinoni (164)	1993	Prevention of compression atelectasis	Maximal PEEP (equal to superimposed hydrostatic pressure) corresponds to 70% of the dorsal-ventral height of thorax (in cm)
Ranieri (201)	1994	Linear airway pressure-time profile	PEEP variations to reach the target
Amato (6)	1998	Maximal recruitment	PEEP set 2 cm H_2O above the lower inflection point on the inspiratory P-V curve
Hickling (327)	2001	Maximal static compliance	Stepwise decremental PEEP trial
Rouby (309)	2002	Best oxygenation with the lowest FI_{O_2} (>0.6)	Lung morphology, slope and inflection points of the P-V curve, PEEP trial
Brower (601)	2004	Oxygenation (Pa_{O_2} 55 to 80 mm Hg, SpO_2 88% to 95%)	PEEP-FI_{O_2} combination table
Albaiceta (215)	2005	Expiratory point of maximum curvature	Deflation limb of the P-V curve
Suarez-Sipmann (351)	2007	Maximum dynamic compliance	Stepwise decremental PEEP trial
Talmor (626)	2008	Transpulmonary pressure between 0 and 10 cm H_2O	Esophageal pressure measurement

Abbreviations: CO_2, carbon dioxide; FIo_2, fractional inspired oxygen; Pa_{O_2}, arterial oxygen tension; *P-V*, pressure-volume; SpO_2, percutaneous oxygen saturation.

implementation of automatic tools that facilitate standardized assessment and continuous monitoring of respiratory mechanics might allow this approach to be incorporated into clinical practice. Another approach for choosing PEEP is based on the estimation of trans-pulmonary pressure with the placement of an esophageal-balloon catheter. Talmor et al compared a level of PEEP, where transpulmonary pressure at end-expiration was maintained between 0 and 10 cm H_2O, against standard strategy, where PEEP was set according to PEEP/FI_{O_2} tables.[626] Compared to the standard approach, the transpulmonary pressure-guided strategy resulted in a higher level of PEEP (17 vs. 10 cm H_2O), and better oxygenation and respiratory system compliance. This interesting approach may prove useful in the future.

Postoperative State

Postoperative hypoxemia is mainly caused by atelectasis.[85,96,627] After various surgical procedures, atelectasis develops in 30% to 50% of cases,[628] and leads to ARF requiring intubation and mechanical ventilation in 8% to 10% of patients.[628–631] The application of CPAP (5 to 10 cm H_2O) via a face mask, alone or combined with pressure support, reduces atelectasis and improves oxygenation after both cardiac[134,632] and noncardiac surgery,[633–637] without increasing surgical complications, such as anastomotic leaks.[638] By reducing atelectasis, CPAP may decrease bacterial growth in the lung, mitigating bacterial translocation into the bloodstream, and normalizing alveolocapillary permeability.[411,639]

Onset and duration of CPAP seem to be critical for avoiding or reversing atelectasis. Studies that failed to demonstrate benefit used CPAP several hours after surgery[640] or for a relatively short time.[641–643] Despite well-recognized physiologic benefits, only recently have randomized trials assessed the effects of CPAP on outcome variables.[644,645] In seventy patients, Fagevik Olsen et al[644] reported that, compared to breathing exercises, use of CPAP after thoracoabdominal resection of esophageal cancer resulted in a lower intubation rate. Squadrone et al[645] randomized patients who developed hypoxemia following major abdominal surgery to either O_2 alone (FI_{O_2} 50%) or O_2 plus CPAP 7.5 cm H_2O. The study was interrupted after 209 patients were enrolled, because the intubation rate was lower in the CPAP group than in the O_2 group (1% vs. 10%).[645] The patients who received CPAP at the end of treatment had higher oxygenation and lower rates of pneumonia, infection, and sepsis than the O_2 group.[645] Although limited to selected patients undergoing elective abdominal surgery, these data show that improvement in physiologic parameters achieved with

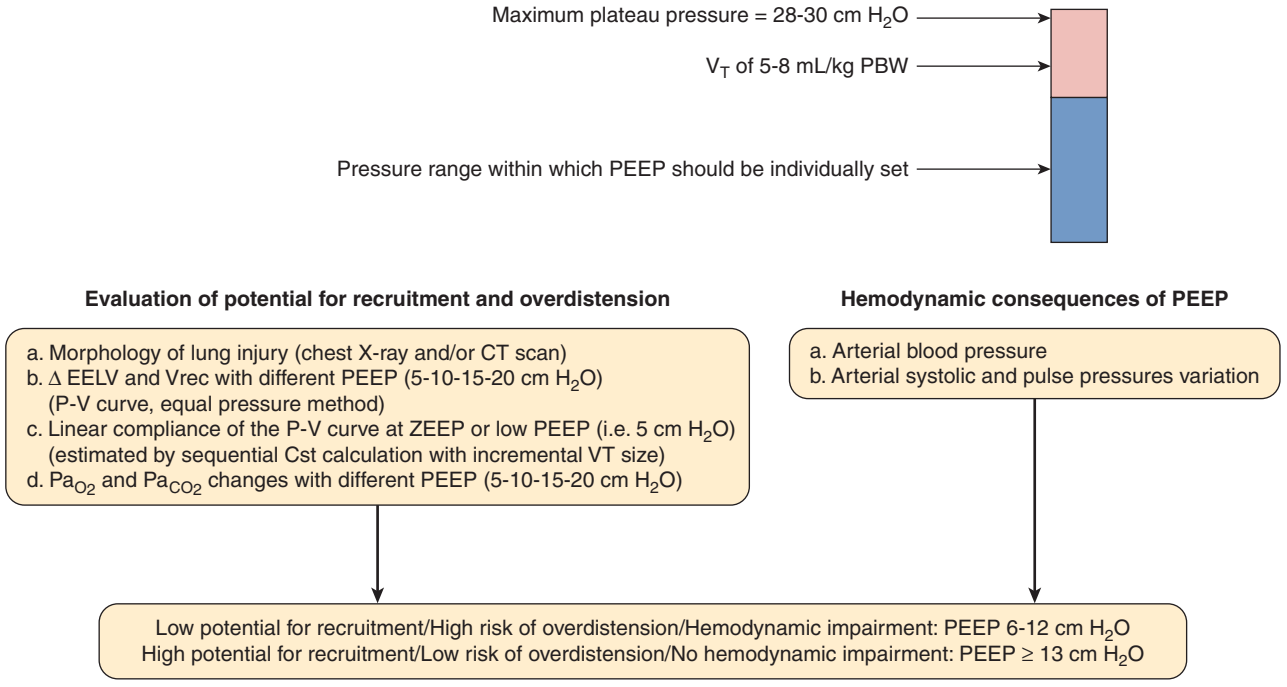

FIGURE 10-20 Proposed algorithm for setting PEEP in ARDS. First, a safe plateau pressure limit of 28 to 30 cm H_2O is recommended; it should not be exceeded except when chest wall compliance is very low (30 to 35 cm H_2O). Second, V_T is preset, which corresponds to a certain pressure oscillation. Third, PEEP should not exceed the pressure difference between plateau pressure and the tidal pressure oscillation. After hemodynamic stabilization, the potential for recruitment, the risk of overdistension, and the hemodynamic consequences are individually assessed for different levels of PEEP. Potential for recruitment is greater when: (a) lung injury is diffuse; (b) alveolar recruitment is large (i.e., >100 mL); (c) the ratio between alveolar recruitment and change in end-expiratory lung volume is high (greater than 15% to 20%); (d) linear compliance of the pressure-volume curve at 0 cm H_2O is high (>40 mL/cm H_2O); (e) static compliance measured at low or no PEEP progressively increases with increasing V_T; and (f) Pa_{O2} increases and Pa_{CO2} concomitantly decreases. By contrast, the risk for overdistension is greater when changes in the above parameters go in the opposite direction. PEEP-induced hemodynamic impairment may be considered clinically relevant when arterial systolic pressure falls more than 20 mm Hg and/or variations in both arterial systolic pressure or pulse pressure appear or increase. The use of standardized ventilator settings (particularly PEEP) to assess oxygenation and severity of lung injury may be useful for identifying the more severe patients who are likely to have a better response to PEEP. *Cst*, static compliance; *CT*, computed tomography; *ΔEELV*, change in end-expiratory lung volume; *P-V*, pressure-volume; *PBW*, predicted body weight; *PEEP*, positive end-expiratory pressure; *Vrec*, recruited volume; V_T, tidal volume; *ZEEP*, zero end-expiratory pressure.

CPAP can translate into a better clinical outcome. Of note, CPAP was applied almost continuously for a prolonged time (19 ± 22 hours).[645] One recent meta-analysis, based on more than nine randomized controlled trials that included a total of 654 patients undergoing abdominal surgery, suggested that CPAP decreases the risk of postoperative pulmonary complications, including atelectasis, pneumonia, and endotracheal intubation.[646]

In summary, CPAP is a simple, practical and safe technique for managing postoperative hypoxemia. It may improve outcome in selected patients, provided it is applied for a sufficient time.

Chronic Obstructive Pulmonary Disease

ARF in patients with COPD is characterized by high airway resistance and PEEPi,[176,545,550,580,647] which increase respiratory muscle load.[2,61,64,550,569] Hyperinflation simultaneously reduces the force-generating capacity of the diaphragm.[574,576] When the force-load balance is altered to a level that severe respiratory acidosis ensues, mechanical ventilation becomes necessary. The ventilator acts as an accessory pump that helps reversing the unfavorable force-load balance. By reducing O_2 cost of breathing and correcting arterial blood gases, mechanical ventilation can improve respiratory muscle function (force). Inspiratory assistance by the ventilator, however, does not reduce the inspiratory resistive load consequent to airway resistance or the threshold load consequent to PEEPi.

Pharmacotherapy can have favorable effects on both load reduction and force restoration.[648] Agents act on bronchial smooth muscle (β_2-agonists, anticholinergic)[649–652] or inflammatory process (glucocorticoids and antibiotics).[649,650,652,653] These agents decrease airway resistance, dynamic hyperinflation and PEEPi in ventilated patients.[654–659] Glucocorticoids and antibiotics are commonly administered parenterally. In ventilated patients, bronchodilators are more effectively and safely given via a small volume nebulizer or a metered-dose inhaler connected to an appropriate spacer.[660]

External PEEP reduces the threshold load imposed on the inspiratory muscles. PEEP, however, does not reduce

hyperinflation and its effects on diaphragmatic force-generating capacity. Application of PEEP in patients with COPD may cause a decrease in expiratory resistance and promote a faster and more uniform lung emptying,[357] although the clinical relevance of these findings remains to be determined. CPAP is effective in reducing dyspnea,[9,60,592] decreasing work of breathing,[9,60,591,592] and improving cardiac function.[579] During triggered ventilation, PEEP reduces inspiratory effort[2,61,63,566] and ventilatory drive,[566] and facilitates triggering of the ventilator[2,61,63,566] by reducing both inspiratory effort and the delay between onset of inspiratory effort and initiation of assistance, improving patient–ventilator interaction, and reducing ineffective inspiratory efforts.[63,64]

Despite a large body of physiologic data, no randomized trial has evaluated the effectiveness of PEEP with CPAP in improving outcome in ventilated patients with COPD. Most trials that evaluated the effectiveness of noninvasive ventilation in patients with acute hypercapnia secondary to COPD exacerbation used PEEP 4 to 5 cm H_2O in addition to pressure support.[661–663]

NAVA is a novel mode of ventilation that utilizes diaphragmatic electrical activity, measured with an electrode array in the lower esophagus, to trigger and drive the ventilator.[664] The ventilator is triggered, irrespective of PEEPi, as soon as the diaphragm contracts.[664] By reducing the delay between onset of inspiratory effort and initiation of machine support,[665] NAVA markedly enhances patient–ventilator coordination without the need for external PEEP, thereby eliminating the difficulties in selecting the appropriate PEEP level and avoiding the risk of further hyperinflation.[664]

Acute Severe Asthma

Patients with acute severe asthma have high airway resistance, dynamic hyperinflation, and PEEPi, which increase respiratory muscles load and decrease force-generation capacity.[666] These patients are generally less responsive to external PEEP.[237] Although some flow limitation may be present,[539] the main cause of dynamic hyperinflation and PEEPi is the prolonged time constant, secondary to the high expiratory resistance. In the absence of flow limitation, PEEP increases hyperinflation and alveolar pressure.[583,667] Some alveolar units may be entirely occluded by mucus plugs and thus completely disconnected from the central airway.[544]

Low levels of CPAP may decrease breathlessness.[668–670] Lin et al[671] reported that CPAP reduced the bronchial reactivity. In patients with asthma exposed to aerosolized histamine, Martin et al[672] found that CPAP 12 cm H_2O decreased both esophageal and transdiaphragmatic pressure swings. V_E increased and thus inspiratory work did not fall.[672] Meduri et al,[673] in a series that included seventeen patients with acute asthma, reported CPAP 3 to 5 cm H_2O combined with pressure support via a face mask improved gas exchange. Only two patients failed and required endotracheal intubation.[673] In a randomized trial of thirty patients treated in an emergency department for acute asthma, Sorosky et al[674] found that noninvasive ventilation with low CPAP produced greater and faster improvements in lung function and lower rate of hospitalization than did standard therapy.[674]

In summary, use of PEEP in patients receiving mechanical ventilation for acute severe asthma is often detrimental and is thus not advisable. Very few data suggest that low levels of noninvasive CPAP combined with pressure support in less severe and selected patients might be beneficial, although further evaluation is required.

Cardiogenic Pulmonary Edema

The benefit of CPAP on the failing left ventricle has already been discussed (see Fig. 10-10). Although most patients will positively respond to standard medical treatment, some do not and require endotracheal intubation and ventilator assistance.

Over the last three decades there has been growing interest in the delivery of CPAP via a noninvasive interface, as a means of avoiding endotracheal intubation and invasive mechanical ventilation. In patients with cardiogenic pulmonary edema, several randomized controlled trials have compared CPAP versus standard medical therapy,[10,73,146,153,675] bilevel positive airway pressure (BiPAP) (i.e., PEEP plus inspiratory pressure support),[154,676–681] or both.[679,682,683] That is eight trials have compared CPAP versus standard treatment[10,73,146,153,675,679,682,683] and nine trials have compared CPAP versus BiPAP.[154,676–683] Nine studies[153,154,676–681,683] had been powered a priori, according to their primary end points; three were prematurely interrupted after interim analysis.

The eight studies comparing CPAP versus standard treatment[10,73,146,153,675,679,682,683] included a total of 537 patients receiving CPAP and 564 control patients; of note, one single study included 346 and 367 patients in the CPAP and standard treatment groups, respectively.[679] CPAP was 10 cm H_2O in four studies,[10,73,675,682,683] 7.5 cm H_2O in one study,[153] varied between 2.5 and 12.5 cm H_2O in one study,[146] and between 5 and 15 cm H_2O in another one.[679] CPAP produced a greater and more rapid physiologic improvement in all studies but one.[682] Five studies[10,73,146,153,675] reported a prompter and greater improvement in oxygenation with CPAP, although in only three studies[10,153,675] was Pa_{O_2}/FI_{O_2} assessed. Bersten et al[10] and Gray et al[679] observed improvement in pH and Pa_{CO_2} with CPAP. Dyspnea was reduced by CPAP in three studies,[153,679,683] but not in a fourth study.[682] CPAP produced a lower rate of therapeutic failure and intubation in four studies[10,146,153,683] and decreased hospital mortality in only one study.[682] None of the eight studies revealed differences in the length of hospital stay.

The nine studies comparing CPAP with BiPAP[154,676–683] included a total of 652 CPAP and 657 BiPAP patients. Six studies used CPAP 10 cm H_2O. The setting of BiPAP varied. Park et al[683] added a small level of inspiratory positive airway pressure to expiratory positive airway pressure 10 cm H_2O. Mehta et al[154] and Crane et al[682] decreased expiratory positive

airway pressure from 10 to 5 cm H_2O and raised inspiratory positive airway pressure to 15 cm H_2O, in order to achieve a mean pressure of 10 cm H_2O throughout the entire breath in both groups. Bellone et al[676] also used PEEP 5 cm H_2O and an initial pressure support of 15 cm H_2O (i.e., inspiratory positive airway pressure 20 cm H_2O). In the remaining studies PEEP varied from 5 to 10 cm H_2O, while the inspiratory assistance was regulated to achieve a given V_T.[677–681]

Mehta et al[154] found a more rapid improvement in Pa_{CO_2} and other physiologic variables with BiPAP than with CPAP. The other studies[676–683] did not find differences in early physiologic variables. Eight studies[154,676–681,683] did not reveal differences in any clinical outcome variable. Crane et al[682] found hospital survival higher in the CPAP than BiPAP group. Metha et al[154] interrupted their study because myocardial infarction was increased in their BiPAP group; eight following randomized trials, however, did not confirm this finding.[676–683]

Three meta-analyses, not including the most recent studies,[677–681] conclude that CPAP and BiPAP are equally effective in decreasing rate of intubation and mortality as compared to the sole standard medical treatment.[684–686]

In summary, CPAP improves and expedites physiologic improvement, whereas the effects on rate of endotracheal intubation and mortality remain controversial. Several factors such as equipment, timing of intervention, underlying disease and comorbidities may explain the differences in outcome among studies. Early use of CPAP (10 cm H_2O) in addition to the medical therapy is advisable in patients with ARF secondary to cardiogenic pulmonary edema.

Prehospital Setting

Very recently, some investigators proposed early out-of-hospital application of noninvasive CPAP for treatment of hypoxemic ARF, predominantly, although not exclusively, secondary to cardiogenic pulmonary edema.

Hubble et al first reported, in a nonrandomized control trial, on the application of CPAP 10 cm H_2O via face mask in addition to standard treatment in 120 patients with presumed cardiogenic pulmonary edema presenting to an emergency service. This group of patients was compared with a group of ninety-five patients with equivalent characteristics transported by a second emergency medical service who received standard treatment only. The diagnosis was confirmed in ninety and sixty-five patients in the treatment and control groups, respectively. When considering patients with confirmed diagnosis, the treatment group had a lower rate of endotracheal intubation and mortality compared to the controls; in addition, they showed a better improvement in respiratory rate, dyspnea, and pulse heart rate.[687] Subsequently, the same research group undertook a theoretical analysis in which they modeled the cost-effectiveness of prehospital CPAP.[688]

In an observational study, Foti et al applied prehospital noninvasive CPAP via helmet to 121 patients with suspected cardiogenic pulmonary edema; sixty-two patients were treated by physicians with CPAP (approximately equal to 10 cm H_2O) in addition to medical treatment, while the remaining fifty-nine patients were treated by nurses with CPAP (approximately equal to 7.5 cm H_2O) only. The diagnosis was confirmed in fifty-four and fifty patients in the former and latter group, respectively. In both groups, oxygen saturation, breathing frequency, and hemodynamics equally improved; rate of intubation and mortality were not different between the groups.[689] These positive results were drawn into question by Frontin et al who carried out a randomized controlled trial where 124 out-of-hospital patients with presumed cardiogenic pulmonary edema received either standard treatment plus CPAP or standard treatment only. Success of treatment, as defined by a respiratory rate less than 25 breaths/min and oxygen saturation greater than 90%, was no different between the groups; rate of intubation and mortality at 5 and 30 days were also unaffected by CPAP. CPAP 10 cm H_2O was applied through a face mask fitted with a valve and controlled with a portable-flow generator. The amount of generated flow, however, was not defined; failure to control for this variable opens the possibility of overestimating the positive pressure actually applied.[690]

Thompson et al[691] performed a randomized controlled trial on patients with ARF of varied etiologies where seventy-one patients received either medical therapy plus CPAP 10 cm H_2O (intervention group) or medical therapy plus oxygen or bag-valve-mask ventilation or intubation, according to local usual care (control group). The incidence of tracheal intubation was lower in the intervention group, a result that could be strongly biased by the fact that intubation was allowed as initial treatment in the control group. Mortality was reduced in the intervention group, as opposed to controls. As in the previous study, CPAP was applied through a face mask fitted with a valve and controlled with a portable flow generator, but the generated flow was maybe not controlled.

In summary, despite a strong rationale,[692] the available data do not permit one to make definite recommendations about the appropriateness of using noninvasive CPAP in the prehospital setting.

Prophylactic Positive End-Expiratory Pressure

The term *prophylactic PEEP* was used in early studies of using PEEP in high-risk patients with the aim of reducing the incidence of ARDS.[598,693–698] Both experimental[386,404,699–701] and clinical studies[693–695,702] suggest that PEEP might favorably influence the course of lung injury in patients at risk for ARDS. The hypothesis, however, was refuted by Pepe et al[598] who randomized ninety-two ventilated patients at risk for ARDS to receive no PEEP or PEEP 8 cm H_2O. Early use of PEEP improved oxygenation, but it did not avert the development of ARDS[598] (Table 10-4). Of note, the V_T in the study of Pepe et al was high (12 mL/kg).[598] Such a high V_T might have recruited[202,204]

TABLE 10-4: RANDOMIZED CONTROLLED TRIALS EVALUATING THE EFFICACY OF PROPHYLACTIC POSITIVE END-EXPIRATORY PRESSURE

Reference	Population	Arm	No. of patients	Associated settings	PEEP setting	Mean PEEP (cm H_2O)	Outcomes
Pepe 1984 (598)	Medical-Surgical At risk for ARDS	Intervention	44	V_T = 12 mL/kg	Predetermined	8	Incidence of ARDS: 25% Mortality: 30% Barotrauma: 43%
		Control	48	V_T = 12 mL/kg	-	0	Incidence of ARDS: 27% Mortality: 38% Barotrauma: 50%
Delclaux 2000 (151)	Medical ARDS	Intervention	40*	O_2 with CPAP for SaO_2 >90%	Clinical response Tolerance	5-10	Endotracheal intubation: 38% ICU length of stay (days): 9 ICU mortality: 23% Hospital mortality: 30%
		Control	41*	O_2 alone for SaO_2 > 90%	–	0	Endotracheal intubation: 44% ICU length of stay (days): 9 ICU mortality: 22% Hospital mortality: 27%
Maitre 2000 (708)	Medical ARDS Undergoing FOB	Intervention	15	O_2 with CPAP for SaO_2 > 90%	Predetermined	7.5	Oxygenation: unchanged Ventilatory assistance after FOB: 0%
		Control	15	O_2 alone for SaO_2 > 90%	–	0	Oxygenation: ↓ Ventilatory assistance after FOB: 33%
Manzano 2008 (703)	Patients without ARDS	Intervention	64	V_T = 8 to 9 mL/kg	Predetermined According to the degree of abdominal distension	5-8	Hospital mortality: 30% Ventilator-associated pneumonia: 9% Incidence of ARDS: 5% Barotrauma: 2%
		Control	63	V_T = 8 to 9 mL/kg	–	0	Hospital mortality: 25% Ventilator-associated pneumonia: 25% Incidence of ARDS: 14% Barotrauma: 8%

*subgroup of patients with early ARDS.

and overdistended the lung, masking any benefit of prophylactic PEEP. This concern is supported by barotrauma rate of around 50% in that study.[598]

A more recent randomized controlled trial compared PEEP (8 cm H_2O) with no PEEP in 131 nonhypoxemic patients who had received mechanical ventilation for less than 24 hours.[703] In this study, interrupted because of low patient recruitment, PEEP did not affect hospital mortality (30% vs. 25%), but decreased the rate of ventilator-associated pneumonia (9% vs. 25%) and the number of patients who developed hypoxemia (19% vs. 54%). There was a nonsignificant trend toward a reduction in the rate of ARDS (5% vs. 14%) (see Table 10-4). Three studies clarified the mechanisms through which PEEP may protect against ventilator-associated pneumonia, suggesting that fluid leakage across the cuff of the endotracheal tube is affected by PEEP.[704–706] Two in vitro studies showed that fluid leakage, constantly present when PEEP was not applied, progressively decreased with increasing PEEP and was abolished at 15 cm H_2O.[705,706] In intensive care unit patients, Lucangelo et al found that the minimum PEEP able to avoid fluid leakage around the cuff was 5 cm H_2O.[704]

PEEP equal to or less than 5 cm H_2O is sometimes used in intubated patients to counteract the fall in lung volume secondary to intubation, supine positioning, and/or muscle paralysis. A retrospective analysis of a large multinational cohort study conducted in 13,322 patients to evaluate current practice and outcomes of mechanical ventilation in the intensive care unit found that patients invasively ventilated without PEEP had significantly higher hospital mortality than those ventilated with PEEP.[707]

Intraoperative PEEP may have beneficial effects on the occurrence of pulmonary complications after surgery. A recent meta-analysis, including eight randomized controlled trials for a total of 330 patients, assessed the effects of intraoperative application of PEEP to mechanical ventilation on postoperative mortality and pulmonary outcomes.[118] Mechanical ventilation with PEEP had no significant effect on mortality, compared to mechanical ventilation without PEEP, although PEEP was associated with improved oxygenation and decreased rate of postoperative atelectasis.

Use of CPAP in the very early stage of ARDS was evaluated in spontaneously breathing patients and during fiberoptic bronchoscopy. The investigators tested whether CPAP prevents the severe hypoxemia and respiratory failure requiring intubation.[151,708] CPAP by face mask improved oxygenation, but did not improve the need for endotracheal intubation, length of hospital stay, or mortality (see Table 10-4).[151] Early use of noninvasive CPAP, with or without pressure support, may benefit specific high-risk patients, such as immunocompromised patients.[211,709–711] In obese patients undergoing gastroplasty, Joris et al[712] found that prophylactic nasal CPAP, with pressure support, immediately after surgery reduced pulmonary dysfunction and accelerated recovery, compared with O_2 alone. CPAP is also useful during fiberoptic bronchoscopy,[708] a procedure that can worsen oxygenation and respiratory mechanics.[713–715] In a double-blind trial, Maitre et al[708] compared mask CPAP to O_2 therapy alone during bronchoscopy in severe hypoxemic spontaneously breathing patients (see Table 10-4). During and immediately after the procedure oxygenation was well preserved in the CPAP group, whereas it fell in the O_2 group. CPAP prevented subsequent respiratory failure necessitating ventilator support.[708]

It has been suggested that PEEP may prevent VILI.[716] Despite robust physiologic rationale, no clinical evidence shows that PEEP protects against VILI. In a retrospective cohort study, Gajic et al[717] reported that approximately 25% of patients ventilated for more than 48 hours developed ARDS. V_T size was the only ventilator setting that independently identified risk for ARDS.[717] No relationship was found between PEEP and the risk of ARDS, possibly because the scatter in the data was insufficient to detect such an effect.[717]

In anesthetized patients with healthy lung, Wolthius et al compared the effects on pulmonary and plasma inflammatory mediators of two ventilatory strategies, high V_T (12 mL/kg) without PEEP and low V_T (6 mL/kg) with PEEP (10 cm H_2O).[718] The latter strategy resulted in lower interleukin-8, myeloperoxidase, and elastase in the lung, as compared to the former approach, suggesting that ventilation with PEEP and low VT may limit VILI even in patients without preexisting lung injury. Another study, performed in animals with healthy lungs, however, showed contrasting results.[719]

COMPLICATIONS AND CONTRAINDICATIONS

Table 10-5 summarizes the complications and side effects of PEEP. Complications are directly related to level of PEEP. Table 10-6 lists contraindications to the use of PEEP. In our opinion, there are only two absolute contraindications: life-threatening hypovolemic shock and undrained high-pressure pneumothorax. For all other conditions, there is little risk in using a low level of PEEP (up to 5 cm

TABLE 10-5: COMPLICATIONS OF POSITIVE END-EXPIRATORY PRESSURE

Pulmonary overdistension
Barotrauma
VILI
Increased dead space
Impaired CO_2 elimination
Reduced diaphragm force-generation capacity
Reduced cardiac output and oxygen delivery
Impaired renal function
Reduced splanchnic blood flow
Hepatic congestion
Decreased lymph drainage

TABLE 10-6: CONTRAINDICATIONS TO POSITIVE END-EXPIRATORY PRESSURE

Absolute contraindications
Life-threatening hypovolemic shock
Undrained high-pressure pneumothorax
Relative contraindications
Unresolved bronchopleural fistula
Intracranial hypertension and low cerebral compliance
Chronic chest wall restrictive disorders
Dynamic hyperinflation without expiratory flow limitation

H_2O), but benefits and drawbacks of higher levels of PEEP need to be carefully weighed in each patient.

CONCLUSIONS

PEEP is widely used in the clinical setting.[13] It is an essential component of ventilatory management of patients with both hypoxemic ARF, resulting from lung edema caused by increased microvascular permeability or hydrostatic pressure, and hypercapnic ARF, secondary to respiratory muscle failure.

Seventy-five years after the pioneering work of Poulton and Oxon[11] and Barach et al,[12] a large body of data has produced a general consensus on the usefulness of PEEP in the treatment of patients with acute respiratory failure. Although a few recent trials have assessed the effect of varied levels of PEEP on clinical outcomes, such as survival, complications, length of stay, and intensive care unit costs, doubts continue as to the optimal level of PEEP in the different clinical situations and on the best manner to determine it. Knowledge of pathophysiologic mechanisms and physiologic consequences of PEEP remains indispensable prerequisites for any decisions made at the bedside and must be the foundation for designing meaningful randomized, controlled trials.

AIRWAY PRESSURE RELEASE VENTILATION

Christian Putensen

Controlled mechanical ventilation (CMV) is traditionally provided via an artificial airway to completely unload a patient's work of breathing and assure adequate gas exchange during the acute phase of respiratory insufficiency, until the underlying respiratory function has resolved.[1] The criteria used to determine when to terminate mechanical ventilation are essentially based on the clinical, and often, subjective assessment of the intensive care physician or on standardized weaning methods.[2,3] The actual process of weaning the patient from CMV is carried out by allowing spontaneous breathing attempts with a T piece or continuous positive airway pressure (CPAP) or by gradually reducing mechanical assistance.[4,5] Not surprisingly, gradual reduction of partial ventilator support benefits only patients who have difficulty in sustaining unassisted breathing.[4] Although introduced as weaning techniques, partial support modes have become standard methods of providing primary mechanical ventilatory support in critically ill patients.

BASIC PRINCIPLES OF AIRWAY PRESSURE RELEASE VENTILATION

Airway pressure release ventilation (APRV)[6] ventilates by time-cycled switching between two pressure levels in a high-flow (or demand-valve) CPAP circuit, permitting unrestricted spontaneous breathing in any phase of the mechanical ventilator cycle (Fig. 11-1). The degree of ventilator support with APRV is determined by the duration of the two CPAP levels and the mechanically delivered tidal volume (V_T).[6,7] V_T depends mainly on respiratory compliance and the difference between the CPAP levels. By design, changes in ventilatory demand do not alter the level of mechanical support during APRV. When spontaneous breathing is absent, APRV is not different from conventional pressure-controlled, time-cycled mechanical ventilation.[6,7]

Synonyms used for APRV are biphasic positive airway pressure[7] (BIPAP) and bilevel airway pressure (Bilevel). Biphasic positive airway pressure is identical to APRV

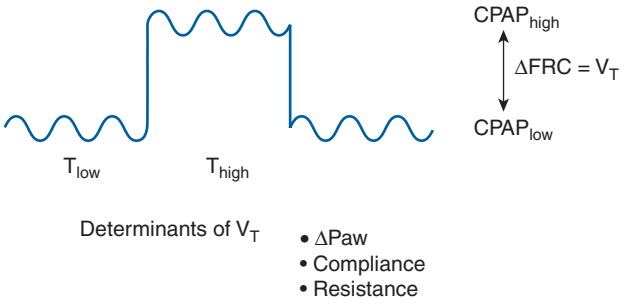

FIGURE 11-1 Airway pressure release ventilation ventilates by time-cycled switching between a high and low continuous positive airway pressure (CPAP) level in the circuit. Consequently, unrestricted spontaneous breathing is permitted in any phase of the mechanical ventilator cycle. Change between the two CPAP levels results in a change in functional residual capacity (ΔFRC), which equals the mechanical delivered tidal volume (V_T). V_T depends mainly on respiratory compliance and resistance and the airway pressure difference (ΔPaw) between the CPAP levels. Setting the time for the low (T_{low}) and the high (T_{high}) CPAP enables the adjustment of ventilator rate.

except that no restriction is imposed on the duration of the low-CPAP level (release pressure).[6,7] Based on the initial description, APRV keeps the duration of the low-CPAP level (release time) at 1.5 seconds or less.

PHYSIOLOGIC EFFECTS

Ventilation Distributions

Radiologic studies demonstrate that ventilation is distributed differently during pure spontaneous breathing and CMV.[8] During spontaneous breathing, the posterior muscular sections of the diaphragm move more than the anterior tendon plate.[8] Consequently, when patients are supine, the dependent lung regions tend to be better ventilated during spontaneous breathing (Fig. 11-2). If the diaphragm is relaxed, it will be moved by the weight of the abdominal cavity and intraabdominal pressure towards the cranium; mechanical V_T will be distributed more to the anterior, nondependent, and less perfused lung regions.[9] When compared with spontaneous breathing, the latter leads, both in patients with healthy lungs and patients with diseased lungs, to lung areas in the dorsal lung regions close to the diaphragm, being less ventilated (or atelectatic). Recent results demonstrate that the posterior muscular sections of the diaphragm move more than the anterior tendon plate when large breaths or sighs are present during spontaneous breathing.[10]

Computed tomography (CT) of patients with acute respiratory distress syndrome (ARDS) reveals radiographic densities corresponding to alveolar collapse localized primarily in the dependent lung regions, which correlates with intrapulmonary shunting and accounts entirely for the observed arterial hypoxemia.[11] Formation of radiographic densities is attributed to alveolar collapse caused by superimposed pressure on the lung and a cephalad shift of the diaphragm, most evident in dependent lung areas during CMV.[12] Persisting spontaneous breathing is considered to improve the distribution of ventilation to dependent lung areas and thereby improve ventilation–perfusion ($\dot{V}_A/\dot{Q}$) matching, presumably by diaphragmatic contraction that opposes alveolar compression.[13] This concept is supported by CT observations in anesthetized patients demonstrating that contractions of the diaphragm induced by phrenic nerve stimulation favor distribution of ventilation to dependent, well-perfused lung areas, decreasing atelectasis formation.[14]

Spontaneous breathing with APRV in experimentally induced lung injury is associated with less atelectasis formation on end-expiratory spiral CT of the whole lungs and on CT scans above the diaphragm (Fig. 11-3).[15–17] Although other inspiratory muscles may contribute to improvement in aeration during spontaneous breathing, the craniocaudal gradient in aeration, aeration differences, and the marked

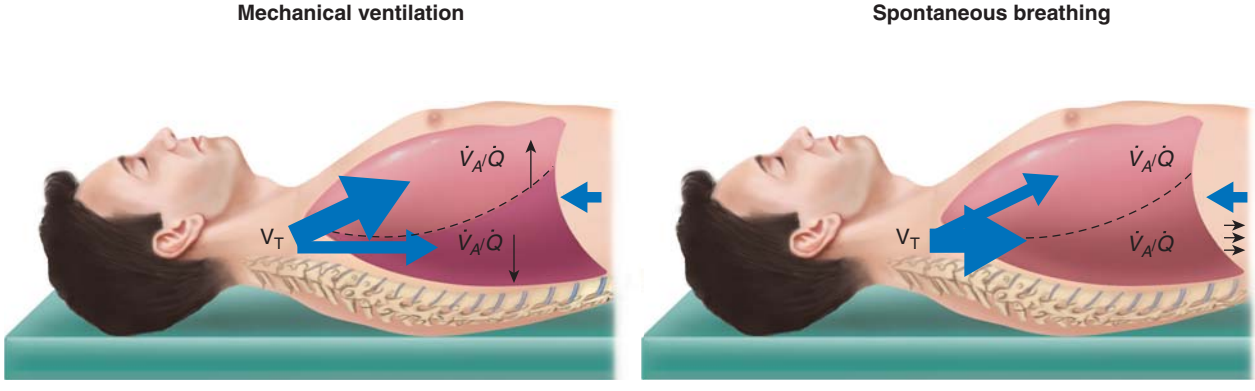

FIGURE 11-2 During spontaneous breathing, the posterior muscular sections of the diaphragm move more than the anterior tendon plate. Consequently, in the supine position, spontaneous ventilation is preferably directed to well-perfused, dependent lung regions. Conversely, a mechanically delivered tidal volume is directed primarily to nondependent lung areas, away from regions with maximal blood flow. Thus, spontaneous breathing contributes to better ventilation–perfusion ($\dot{V}_A/\dot{Q}$) matching.

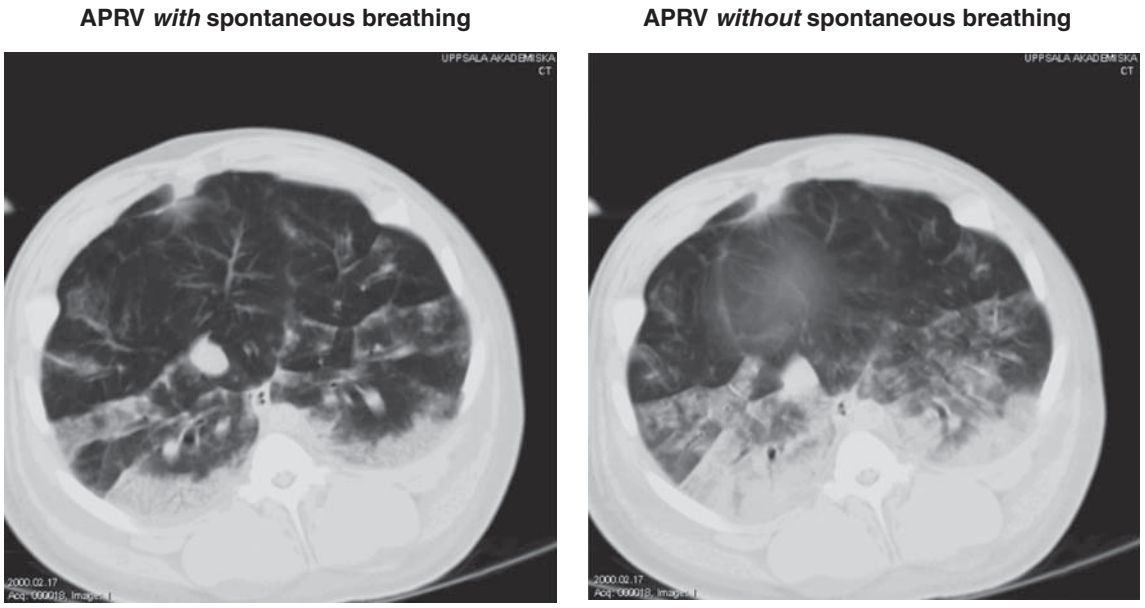

FIGURE 11-3 Computed tomography of a lung region above the diaphragm at end-expiration in oleic acid-induced lung injury with and without spontaneous breathing during APRV. Atelectasis formation is reduced with spontaneous breathing.

differences in aeration in regions close to the diaphragm between APRV with and without spontaneous breathing suggest that diaphragmatic contractions play a dominant role on the observed aeration differences and improvement of end-expiratory lung volume.[15–17] Experimental data suggest that recruitment of dependent lung areas may be caused essentially by an increase in transpulmonary pressure (Ptp) secondary to the decrease of pleural pressure (Ppl) with spontaneous breathing during APRV.[18]

Because the posterior muscular sections of the diaphragm contract more than the anterior tendon plate, a decrease in Ppl and the concomitant localized increase in Ptp should explain entirely the successful recruitment of atelectatic areas in the dependent lung regions adjacent to the diaphragm.[8,10,14–17] In the apical lung regions, differences in tidal volume distribution between the dependent and nondependent lung is not significantly different with spontaneous breathing.[15,16] Inhomogeneous distribution of tidal ventilation during CMV in patients with acute lung injury (ALI)[19,20] may be explained by regional differences in Ptp. A cephalocaudal decrease in Ptp may be partially explained by the transmission of abdominal pressure to the thoracic cavity,[12] decreasing from base to apex. In addition, compression of lung tissue by the weight of the lungs and the heart may differ regionally.[12,19,20] Although increase in Ptp caused by spontaneous breathing is maximal in the dependent lung areas adjacent to the diaphragm,[8,10,14–17] it is unlikely that the resulting absolute Ptp in the dependent lung regions is higher than in cephalad lungs areas in the absence of spontaneous breathing. This concept is supported by experimental findings that gas volume and aeration are not higher in dependent lung regions with spontaneous breathing than in cephalad lung regions in the absence of spontaneous breathing.[17] Furthermore, CT observations in experimentally induced lung injury demonstrate that, during spontaneous breathing with APRV a large portion of the V_T is distributed to the initially collapsed dependent lung regions, resulting in less cyclical alveolar collapse.[16]

Pulmonary Gas Exchange

In patients with ARDS, APRV with spontaneous breathing of 10% to 30% of the total minute ventilation (V_E) accounts for an improvement in $\dot{V}_A/\dot{Q}$ matching, intrapulmonary shunting, and arterial oxygenation.[13] These results confirm earlier investigations in animals with induced lung injury,[21–23] which demonstrated improvement in intrapulmonary shunt and arterial oxygenation during spontaneous breathing with APRV. An increase in arterial oxygenation in conjunction with greater pulmonary compliance indicates recruitment of previously nonventilated lung areas. Clinical studies in patients with ARDS show that spontaneous breathing during APRV does not necessarily lead to instant improvement in gas exchange. Instead, improvement in oxygenation continues over the 24 hours after the start of spontaneous breathing.[24]

In patients at risk of developing ARDS, maintaining spontaneous breathing with APRV resulted in lower venous admixture and better arterial oxygenation over a period of more than 10 days as compared to CMV with subsequent weaning.[25] These findings are supported by randomized controlled trials and case-matched analysis.[26–28]

Cardiovascular Effects

Application of a ventilator breath generates an increase in airway pressure and, therefore, in intrathoracic pressure, which, in turn, reduces venous return to the heart. In normovolemic and hypovolemic patients, this action produces a reduction in right-ventricular and left-ventricular filling and results in decreased stroke volume, cardiac output, and oxygen delivery.[29] To normalize systemic blood flow during mechanical ventilation, intravascular volume often needs to be increased and/or the cardiovascular system needs pharmacologic support. Reducing mechanical ventilation to a level that provides adequate support for existing spontaneous breathing should help reduce the cardiovascular side effects of ventilator support.[30]

Periodic reduction of intrathoracic pressure, achieved by maintaining spontaneous breathing during ventilator support, promotes venous return to the heart and right-ventricular and left-ventricular filling, thereby increasing cardiac output and oxygen delivery.[31] Experimental[21–23] and clinical[13,25] studies show that when spontaneous breathing during APRV achieves 10% to 40% of total V_E, with no change in V_E or airway pressure limits, the cardiac index increases. A simultaneous rise in right-ventricular end-diastolic volume during spontaneous breathing with APRV indicates improved venous return to the heart.[13] In addition, outflow from the right ventricle, which depends mainly on lung volume (the major determinant of pulmonary vascular resistance), may benefit from decrease in intrathoracic pressure during APRV.[13]

Patients with left-ventricular dysfunction may not benefit from either the augmentation of venous return to the heart or the increase in left-ventricular afterload that occurs with the lowering of intrathoracic pressure. Thus, switching abruptly from CMV to pressure-support ventilation (PSV) with a simultaneous reduction in airway pressure can cause further decompensation in patients with existing cardiac insufficiency.[32] Räsänen et al[33] showed a need for adequate ventilatory support and CPAP levels in patients with respiratory and cardiogenic failure. Provided that spontaneous breathing receives adequate support and that satisfactory CPAP levels are applied, maintaining spontaneous breathing during APRV should not be a disadvantage and is not per se contraindicated in patients with ventricular dysfunction.[33]

Oxygen Supply and Demand

An increase in cardiac index and arterial oxygenation (Pa_{O_2}) during APRV improves the relationship between tissue oxygen supply and demand because oxygen consumption remains unchanged despite the work of spontaneous breathing. In accordance with previous experimental[21,22] and clinical findings,[13] total oxygen consumption is not measurably altered by adequately supported spontaneous breathing in patients with low lung compliance. An increase in oxygen delivery with unchanged oxygen consumption indicates an improved tissue oxygen supply and demand balance, as reflected by a decrease in oxygen extraction ratio and higher mixed venous partial pressure of oxygen.

Organ Perfusion

By reducing cardiac index and venous return to the heart, CMV can have a negative effect on the perfusion and functioning of extrathoracic organ systems. An increase in venous return and cardiac index, secondary to the periodic fall in intrathoracic pressure during spontaneous inspiration, should significantly improve organ perfusion and function during partial ventilator support. In patients with ARDS during spontaneous breathing with APRV, renal perfusion and glomerular filtration rate improve.[34] Using the colored microsphere technique, Hering et al[35,36] observed (in an experimental model) that spontaneous breathing during APRV improves systemic and mucosal-submucosal blood flow in the gastrointestinal tract as compared to CMV (with and without permissive hypercapnia); hepatic arterial blood flow remained essentially unchanged. In the absence of an increased intracranial pressure, regional cerebral and spinal cord blood flows were higher with spontaneous breathing.[37]

RATIONALE, ADVANTAGES, AND LIMITATIONS

Based on physiologic observations, APRV is advantageous for recruiting atelectasis adjacent to the diaphragm, thereby improving pulmonary gas exchange in patients with ALI, ARDS, and atelectasis after major surgery. Because increase in Ptp is localized to the areas near the diaphragm and is caused by a decrease in pleural pressure, the concomitant decrease in intrathoracic pressure contributes to improved cardiovascular function. Areas of atelectasis not adjacent to the diaphragm may not be successfully recruited by spontaneous breathing during APRV.

To enable spontaneous breathing, lower levels of sedation (Ramsay Score of 2 to 3) are required. Less sedation helps to reduce the dosages of vasopressor and inotropic agents, while maintaining cardiovascular function stability. In addition, less sedation reduces the duration of ventilator support.[25] The use of APRV, however, has to be limited to patients who do not require deep sedation for management of their underlying disease (e.g., cerebral edema with increased intracranial pressure).

Two periods during the APRV cycle are particularly vulnerable to patient–ventilator asynchrony. When airway pressure release occurs during spontaneous inspiration and when restoration of CPAP occurs during spontaneous expiration, ventilation may be impaired because spontaneous and ventilator efforts oppose each other. Rarely, a

reduction in ventilatory efficiency, indicated by a decrease in alveolar ventilation and an increase in work of breathing, may result from temporary asynchrony. Synchronized APRV and optimizing ventilator settings and sedation may be required in this rare event.[38]

As a concept, APRV does not provide breath-to-breath assistance to spontaneous inspiration. Previous investigations demonstrated that separation from mechanical ventilation in difficult-to-wean patients may be prolonged with use of intermittent mandatory ventilation (IMV) and may be expedited with breath-to-breath assistance to inspiratory efforts during PSV.[4] Thus, APRV is not expected to be an advantage in difficult-to-wean patients.

INDICATIONS AND CONTRAINDICATIONS

Indications

Based on clinical[13,25,26–28,39] and experimental[15–17,21,22] data, APRV is indicated in patients with ALI, ARDS, and atelectasis after major surgery. APRV recruits atelectasis adjacent to the diaphragm, thereby restoring pulmonary gas exchange, and improves cardiovascular and extrathoracic organ function in patients with ALI or ARDS, and atelectasis after major surgery.

Contraindications

Because lower levels of sedation (Ramsay Score of 2 to 3) are used to enable spontaneous breathing, APRV should not be used in patients who require deep sedation for management of their underlying disease (e.g., cerebral edema with increased intracranial pressure).

To date, no data are available on use of APRV in patients with obstructive lung disease. Theoretically, use of a short release time should not be beneficial in patients with obstructive lung disease who have prolonged expiratory time constants. Currently, use of APRV is not supported in these patients by clinical research.

Likewise, use of APRV has not been investigated in patients with neuromuscular disease, and is not supported by any evidence.

COMPARISON WITH OTHER MODES

Airway Pressure Release Ventilation versus Pressure-Support Ventilation

APRV and PSV were compared in twenty-four patients with ALI and/or ARDS using equal V_E or airway pressure limits. Because insufflation during PSV is flow-cycled, alveolar end-inspiratory pressure may not reach the preset level. Thus, in patients with reduced lung compliance, equal airway pressure limits achieve a lower V_T during PSV as compared with APRV. Consequently, a compensatory increase in respiratory rate is required during PSV to maintain alveolar ventilation. To deliver APRV and PSV with comparable V_T at an acceptable respiratory rate, the pressure level has to be increased during PSV.[13]

In contrast to spontaneous breathing with APRV, assisted inspiration with PSV did not produce significant improvement in intrapulmonary shunt, gas exchange or cardiac output when compared with CMV.[13] Apparently, the spontaneous contribution to a mechanically assisted breath was not sufficient to counteract the $\dot{V}_A/\dot{Q}$ maldistribution and cardiovascular depression caused by positive-pressure ventilation. A possible explanation might be that inspiration is terminated by the decrease in inspiratory gas flow during PSV, which may reduce ventilation in areas of the lung that have a slow time constant.

Airway Pressure Release Ventilation versus Intermittent Mandatory Ventilation

In a randomized multicenter trial in fifty-two patients with ALI, APRV with lower peak airway pressures resulted in a better alveolar ventilation and equal arterial oxygenation as compared with IMV.[26] A similar trial in fifty-eight patients with ALI supports these findings, but did not show a difference in mortality.[40] In eight patients recovering from open-heart surgery, APRV provided adequate ventilation with lower airway pressures and less dead-space ventilation than did IMV or PSV.[41] Arterial oxygenation was not different between the modalities.

Airway Pressure Release Ventilation versus Assist-Control Ventilation

A comparison of 234 patients ventilated with APRV with 234 patients ventilated with assist-control ventilation in a case-matched analysis revealed no differences in days of mechanical ventilation or weaning, rate of reintubation, length of stay in the intensive care unit or the hospital, and mortality in the intensive care unit or the hospital.[28] In this study, APRV was used in almost all disease states that lead to acute respiratory failure. The doses and duration of sedatives and analgesics were not different between the groups and the amount of spontaneous ventilation during APRV was not reported. Likewise, a randomized controlled trial involving sixty-two trauma patients showed no differences between APRV and assist-control ventilation for ventilator days, length of stay in the intensive care unit, pneumothorax, ventilator-associated pneumonia, or mortality.[27]

VARIATION IN DELIVERY AMONG VENTILATOR BRANDS

Synchronized Airway Pressure Release Ventilation

Asynchronous interferences between spontaneous and mechanical ventilation may increase the work of breathing and reduce the effective support during APRV.[38] Synchronization of the switching between the two CPAP levels to spontaneous inspiration or expiration has been incorporated in all commercially available demand-valve APRV circuits to avoid asynchronous interferences between spontaneous and mechanical breaths. A trigger window of 0.25 seconds is usually used to enable synchronization of the switching between the two CPAP levels and spontaneous breathing efforts. Bench-model data indicate that the synchronization of spontaneous inspiration with the switch to the high CPAP level, but not the synchronization of spontaneous expiration synchronized with pressure release, may be beneficial. Patient data on the advantage of synchronized APRV are lacking currently. Because patient-triggered mechanical cycles during IMV are not advantageous for patients, there is no reason why this should be different for APRV. Synchronization during APRV may produce inconstant times for the high and low CPAP. Synchronization of APRV is switched off in the APRV mode of Dräger Evita IV, XL, and V500 ventilators. In the Servo I, the Bennett 840, Hamilton G5, and the Viasys Vela and Avea ventilators, APRV is synchronized with spontaneous ventilation.

Modifications of Airway Pressure Release Ventilation

Most commercially available ventilators offer hybrid modes of ventilation such as APRV + PSV and APRV + automatic tube compensation (Table 11-1). Very few of these combinations have been shown to benefit patients.[42] It is doubtful that simply combining different modalities will achieve an addition of their positive effects.[43,44] Indeed, it is possible that proven physiologic benefit of one modality might be minimized or even neutralized when it is by combined with another mode.

TABLE 11-1: MODIFICATIONS OF AIRWAY PRESSURE RELEASE VENTILATION

- Synchronized APRV
  - Change between CPAP levels is synchronized with spontaneous breathing
  - Advantage of synchronization is not proven
- Intermittent mandatory pressure release ventilation
  - Spontaneous breathing on the high CPAP level is assisted with PSV
  - Advantage is not supported by data
- APRV + PSV
  - Spontaneous breathing on the low CPAP level is assisted with PSV
  - Advantage is not supported by data
- APRV + ATC
  - Spontaneous breathing on both CPAP levels is assisted with ATC
  - May reduce work of breathing in selected patients without deteriorating gas exchange

Abbreviations: *APRV*, Airway pressure release ventilation; *ATC*, automatic tube compensation; *CPAP*, continuous positive airway pressure; *PSV*, pressure-support ventilation.

ADJUSTMENTS AT THE BEDSIDE

Setting Ventilation Pressures and Tidal Volumes during Airway Pressure Release Ventilation

Mechanical ventilation with positive end-expiratory pressure (PEEP) titrated above the lower inflection pressure of a static pressure–volume curve and a low V_T is thought to prevent tidal alveolar collapse at end-expiration and overdistension of lung units at end-inspiration in patients with ARDS.[45] This lung-protective strategy causes improvement in lung compliance, venous admixture, and Pa_{O_2} without causing cardiovascular impairment in ARDS.[45] Mechanical ventilation using V_T of not more than 6 mL/kg (ideal body weight) has been shown to result in a better outcome when compared with a V_T of 12 mL/kg (ideal body weight) in patients with ARDS.[45,46] Based on these results, CPAP levels during APRV should be titrated to prevent end-expiratory alveolar collapse and tidal alveolar overdistension.[45,46] When CPAP levels during APRV were adjusted in patients with ARDS according to a lung-protective strategy, occurrence of spontaneous breathing led to improved cardiorespiratory function without affecting total oxygen consumption secondary to the work of breathing.[13] Moreover, pulmonary compliance should be greatest in this range of airway pressures and, thus, a small change in transpulmonary pressure achieves normal tidal breathing with minimal elastic work of breathing (Fig. 11-4).[47] Because APRV does not provide assistance on every inspiratory effort, the CPAP levels need to be carefully adjusted to achieve efficient spontaneous ventilation with minimal work of breathing.

Setting Times during Airway Pressure Release Ventilation

The duration of the high-CPAP level needs to allow at least complete inflation of the lungs, as indicated by an end-inspiratory phase of no flow when spontaneous breathing is absent. Spontaneous breathing occurs normally on the

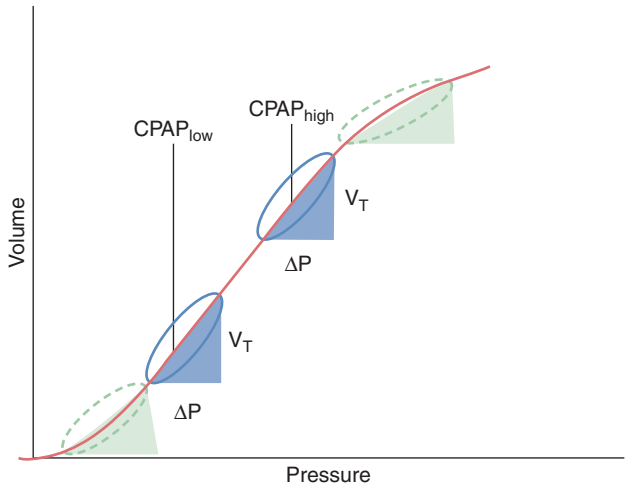

FIGURE 11-4 During airway pressure-release ventilation, both CPAP levels should be titrated to achieve the greatest compliance. Thus, a small change in transpulmonary pressure (*ΔP*) achieves normal tidal breathing (V_T), while elastic work of breathing (*shaded area*) is minimal. If the CPAP levels are too high or too low (*dashed lines*), elastic work of breathing will be increased unnecessarily (*shaded areas*).

high-CPAP level. Thus, duration of the high-CPAP level should be adjusted so that it is long enough to allow spontaneous breathing. If the release time is shorter than four times the time constant of the lungs (τ = compliance × resistance), alveolar pressure will not equilibrate at the low-CPAP level, and intrinsic PEEP (PEEPi) will result.[48,49] Incomplete expiration and the likelihood of PEEPi is indicated by gas flow at end-expiration (Fig. 11-5). In the presence of PEEPi, alveolar pressure amplitude will be reduced; consequently, alveolar ventilation decreases and partial pressure of carbon dioxide increases. To date, data do not indicate that PEEPi is superior to external PEEP in preventing derecruitment of the lungs. Thus, duration of the low CPAP level should be adjusted to allow complete expiration to resting lung volume.

Other Concepts of Setting Airway Pressure Release Ventilation

Other approaches use high-CPAP levels, which are briefly released to near-ambient pressure during APRV. Depending on the time constant of the lungs, brief release times may cause PEEPi. Clinical studies, however, demonstrate that external PEEP is superior to PEEPi in restoring gas exchange in patients with ALI. Not surprisingly,

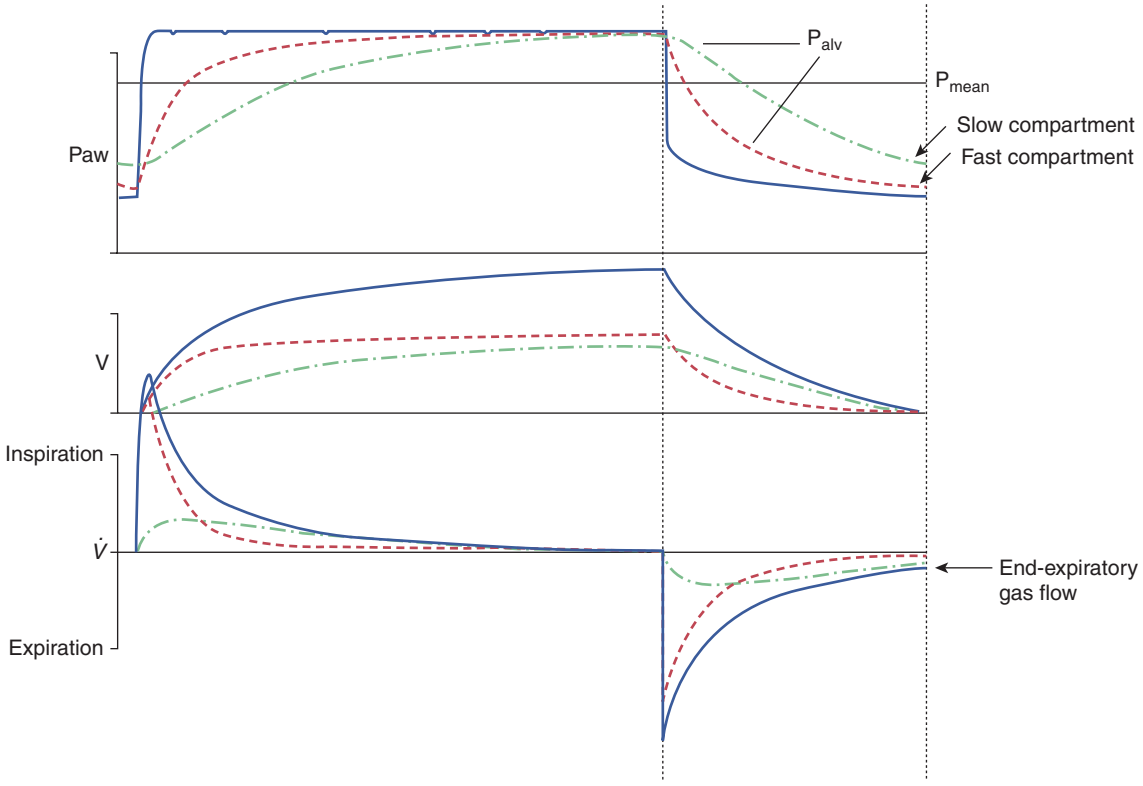

FIGURE 11-5 Computer simulation of airway pressure (*Paw*), volume (*V*), and gas flow ($\dot{V}$) for the respiratory system, and both a fast and slow lung compartment with a short release time. Expiration in the slow compartment is not completed at end-expiration; consequently, gas flow is still present at end-expiration and associated with intrinsic PEEP.

in patients with ARDS, Cane et al[26] observed an increase in atelectasis upon briefly releasing high-CPAP levels to near-ambient pressure during APRV. Recent trials and case series based on this method of adjusting APRV reported better oxygenation when APRV was used as a rescue strategy in severely hypoxemic patients with ARDS.[27,50,51]

TROUBLESHOOTING

Analgesia and Sedation during Airway Pressure Release Ventilation

Analgesia and sedation are used not only to ensure satisfactory pain relief and anxiolysis, but also to help the patient adapt to mechanical ventilation.[52] The additional use of neuromuscular paralysis is controversial.[53] The level of analgesia and sedation required during CMV is equivalent to a Ramsay score higher than 5; that is, a deeply sedated patient unable to respond when spoken to and who has no sensation of pain. During APRV, a Ramsay score of 2 to 3 can be targeted; that is, an awake, responsive, and cooperative patient. In nearly 600 postcardiac surgery patients,[39] and in patients with multiple injuries,[25] maintaining spontaneous breathing during APRV led to less consumption of analgesics and sedatives as compared with initial use of CMV followed by weaning with partial ventilator support. Higher doses of analgesics and sedatives used in patients managed with CMV are associated with the use of higher doses of vasopressors and inotropic agents to maintain stable cardiovascular function,[25] and have been suggested to produce a higher incidence of delirium, longer duration of mechanical ventilation and stay in the intensive care unit, and mortality.[54]

IMPORTANT UNKNOWNS

Although prospective randomized trials have found improved cardiopulmonary function in the absence of an increased mortality or longer duration of mechanical ventilation with the use of APRV, concerns have been raised as to whether an increased transpulmonary pressure consequent to spontaneous breathing efforts can contribute to ventilator-induced lung injury. In addition, the effect of lower levels of sedation during APRV on the incidence of delirium and mortality has yet to be investigated.

THE FUTURE

Randomized controlled studies and case-matched analysis have demonstrated that early spontaneous breathing with APRV in patients with ALI/ARDS and in patients with pulmonary dysfunction after trauma and major surgery leads to improved arterial oxygenation and cardiovascular function. Larger randomized multicenter trials are needed to test the validity of these results in critically ill patients.

SUMMARY AND CONCLUSION

Based on available data, it is suggested that spontaneous breathing during ventilator support does not need to be suppressed, even in patients with severe pulmonary dysfunction, if there is no contraindications (e.g., increased intracranial pressure). Improvement in pulmonary gas exchange, systemic blood flow, and oxygen supply to the tissue with less consumption of analgesics and sedatives has been observed even in severe ARDS. Maintaining spontaneous breathing with APRV has not yet been shown to significantly change outcome. CMV followed by weaning with partial ventilator support is the standard in ventilation therapy, but the place of spontaneous breathing with APRV should be reconsidered in view of available data. Today's standard practice should be to maintain spontaneous breathing as early as possible during ventilator support and to continuously adapt the level of support according to the individual needs of the patient.

PROPORTIONAL-ASSIST VENTILATION

Magdy Younes

Proportional-assist ventilation (PAV) is a form of synchronized ventilator support in which the ventilator generates pressure in proportion to *instantaneous* patient effort (Fig. 12-1).[1] The ventilator simply amplifies inspiratory efforts. Unlike other modes of partial support, there is no target flow, tidal volume, or ventilation or airway pressure. Rather, PAV's objective is to allow the patient to comfortably attain whatever ventilation and breathing pattern his or her control system desires.[1] The main operational advantages of PAV are automatic synchrony with inspiratory efforts and adaptability of the assist to changes in ventilatory demand (Fig. 12-1).

BASIC PRINCIPLES AND ALGORITHMS: HOW CAN A VENTILATOR DELIVER PRESSURE IN PROPORTION TO PATIENT EFFORT WITHOUT DIRECTLY MEASURING EFFORT?

A simple PAV delivery system illustrates how this happens (Fig. 12-2).[2] Alveoli and chest wall are represented as an elastic compartment that opposes expansion. Elastic recoil pressure (Pel; hatched arrow in Fig. 12-2) is a function of how much lung volume deviates from passive functional residual capacity (FRC) and the stiffness of the system: Pel = V × E, where V is volume above FRC and E is respiratory system elastance. In a passive system, Pel increases alveolar pressure as the lung is artificially inflated. During assisted ventilation, inspiratory muscles are active. These muscles decrease alveolar pressure by an amount corresponding to their pressure output (Pmus) (Fig. 12-2). At any instant, alveolar pressure (Palv) is the difference between Pel (V × E), which tends to increase it, and Pmus, which tends to decrease it:

$$Palv = (V \times E) - Pmus \quad (1)$$

The elastic compartment is connected to the external tubing via airways and the endotracheal tube. The ventilator controls pressure at the external airway (Paw). Air flows into the lungs when Paw exceeds Palv. Flow is a function of the difference between Paw and Palv (resistive pressure) and the resistance of the intervening tubing (R). Thus

$$Flow = (Paw - Palv)/R \quad (2)$$

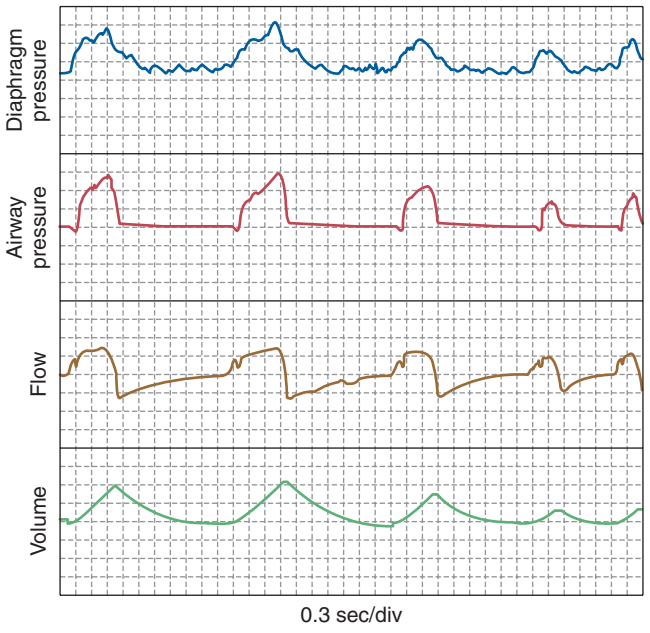

FIGURE 12-1 Relationship between assist provided (airway pressure) and independently measured diaphragmatic pressure in proportional-assist ventilation. Note that amplitude and duration of assist correspond to amplitude and duration of inspiratory efforts.

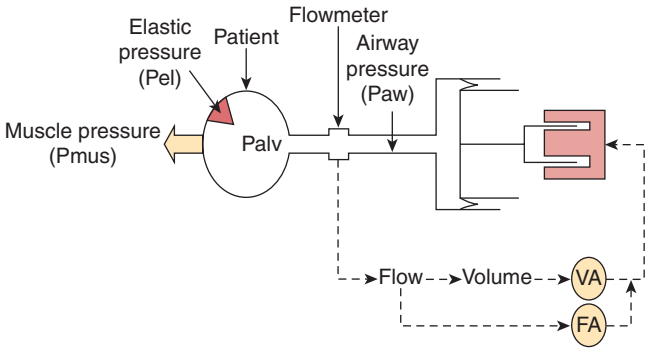

FIGURE 12-2 Diagram illustrating how a PAV delivery system generates pressure in proportion to effort. The gas-delivery system consists of a freely moving piston pressurized by a fast-acting motor. Force exerted by motor is a function of flow and volume leaving the ventilator. A stronger effort results in greater reduction in alveolar pressure (*Palv*), drawing more gas from the piston and resulting in more assist. If the volume-assist (*VA*) and flow-assist (*FA*) components are set to the same fraction of elastance and resistance, respectively, the pressure generated becomes proportional to effort (*Pmus*). See text.

Substituting equation (Eq.) 1 for Palv in Eq. 2 and rearranging, we get

$$\text{Flow} \times R = \text{Paw} - (V \times E) + \text{Pmus}$$

or

$$\text{Pmus} + \text{Paw} = \text{flow} \times R + V \times E \qquad (3)$$

This equation simply states that the distending force is the sum of patient-generated (Pmus) and ventilator-generated (Paw) pressures and that this distending force is opposed by the sum of resistive pressure drop (resistive pressure, or flow × R) and elastic recoil pressure (Pel, or V × E).

The gas-delivery system in Figure 12-2 is a freely moving piston pressurized by a fast-responding linear motor. This arrangement emphasizes that PAV gas-delivery systems must allow rapid and free flow of gas in response to changes in alveolar pressure. Flow and volume leaving the ventilator are measured. The gains of the flow and volume signals are adjustable by separate amplifiers: flow assist (FA) and volume assist (VA). The summed output of the two amplifiers is the input to the motor. Thus, the ventilator's pressure output is a function of instantaneous flow and volume that left the ventilator since triggering.

With this arrangement (see Fig. 12-2), a greater effort (more reduction in alveolar pressure) will draw more gas from the ventilator. This, in turn, results in more assist. This provides a positive relation between effort and assist but does not per se cause the assist to be proportional to instantaneous effort. Proportionality is achieved through customized adjustment of the FA and VA gains. The basis for these adjustments is as follows:

FA is the assist pressure per unit flow (in cm H_2O/L/s). These are resistance (R) units. If FA is 50% of R, the ventilator provides 50% of the resistive pressure (i.e., 50% of flow × R, Eq. 3). At 80% R, the ventilator assumes 80% of resistive work, and so on. Likewise, setting VA gain to 50% of E causes the ventilator to assume 50% of elastic pressure (i.e., 50% of V × E, Eq. 3), and so on. The total assist (Paw) is the sum of the flow and volume assists:

$$\text{Paw} = \%\text{flow} \times R + \%V \times E \qquad (4)$$

During the inspiratory phase, volume rises progressively, peaking at end inspiration. By contrast, flow peaks in early to middle inspiration and falls later. Thus, the relative contributions of resistive and elastic pressures vary considerably during the inspiratory phase. If the same percent is used for both components, total assist (Paw) represents the same percent of total pressure regardless of the relative contribution of each. Percent assist then is constant throughout. If different percent values are used for FA and VA, however, total assist (Paw) will represent a different percent of total applied pressure at different times. When percent assist (ventilator's contribution) is constant throughout inspiration, patient's percent contribution (i.e., 100 – percent assist) is also constant throughout and the relationship between Paw and Pmus (i.e., proportionality becomes constant) as given by

$$\text{Proportionality} = \text{percent assist}/(100 - \text{percent assist})$$

Thus, at 50% assist, proportionality is 1.0; Paw equals Pmus throughout. At 80% assist, proportionality is 4, and so on. Under these conditions, the shapes of the Pmus and Paw waveforms are identical, and the decline in Pmus at end inspiration is associated with a decline in Paw, ensuring synchrony (Fig. 12-3A). By contrast, if percent assist varies through inspiration (such as by using different percent

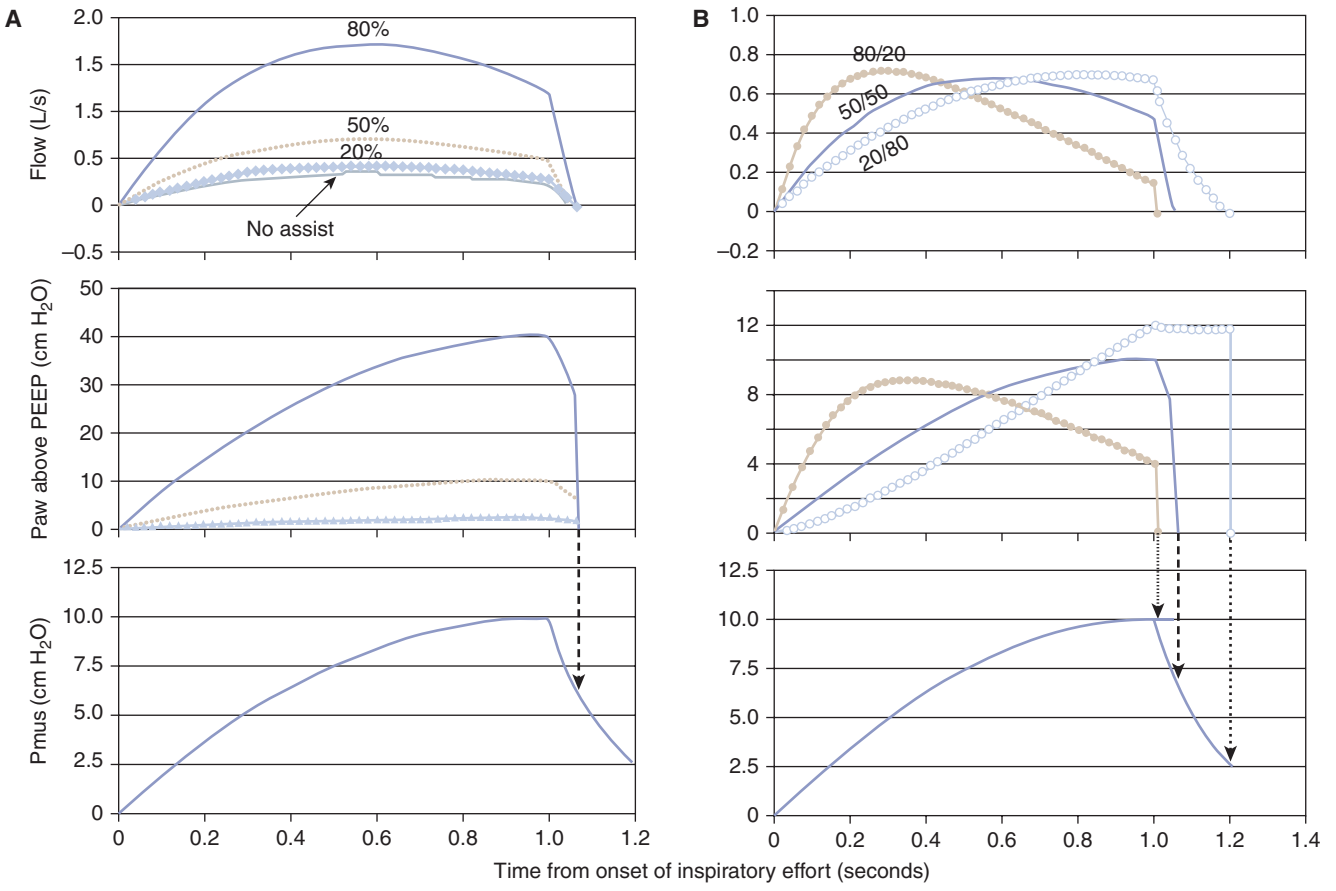

FIGURE 12-3 Model simulation showing the impact of using equal (A) versus unequal (B) percent assist for the flow and volume components. **A.** Three assist levels are shown: 20%, 50%, and 80%. When the same percent assist is applied to both components, the shape of the assist (airway pressure [*Paw*]) is identical to that of muscle pressure (*Pmus*), but the proportionality is different (Paw/Pmus = 0.25, 1.0, and 4.0, respectively). Note also that flow reaches zero (end of mechanical inspiration) at the same time during the declining phase of *Pmus* at all assist levels, including the no-assist situation (*top panel*). **B.** Flow assist is 80% of resistance, and volume assist is 20% of elastance (*solid dots*). Note that the assist (*Paw*) is more aggressive early in inspiration and terminates sooner relative to the balanced assist (*50/50 line*). A relatively greater volume assist (*open circles*) offers less assist early while cycling off is delayed.

values for FA and VA), proportionality between Paw and Pmus is no longer constant, and the shapes of the two waveforms differ (Fig. 12-3B).

PHYSIOLOGIC EFFECTS

Relevant Physiologic Principles

These principles are discussed first because they not only help to explain PAV's reported effects, but also make it possible to gain useful insights from a patient's responses to this mode; reference 3 provides more details. Responses to PAV may be mediated by changes in blood-gas tensions (chemical factors) or through modification of nonchemical sources of respiratory drive. Chemical responses are highly predictable, whereas the others are not. What happens, therefore, depends on what sources of respiratory drive are operative at the time of application.

SOURCES OF RESPIRATORY DRIVE

During sleep and anesthesia, chemical factors are the sole source of respiratory drive; artificially reducing the partial pressure of carbon dioxide (P_{CO_2}) under these conditions abolishes respiratory efforts.[4–6] Furthermore, in these states, respiratory muscle responses to changes in load are mediated exclusively via changes in blood-gas tensions.[7] Conversely, in alert individuals, other sources of respiratory drive exist; it is very difficult to produce apnea by assisted ventilation despite marked hypocapnia.[8–11] These drive inputs, collectively called the *consciousness factor,*[4] presumably arise from behavioral centers and from respiratory mechanisms that operate only during consciousness (e.g., nonchemical load-compensatory mechanisms[7]). Patients who require mechanical ventilation cover a wide spectrum of levels of consciousness. Therefore, it is difficult to make general conclusions about their drive inputs. The next few sections describe what should happen in response to PAV if respiratory output were driven solely by

chemical factors. Deviation from this expected behavior then might be attributed to nonchemical factors.

DETERMINANTS OF V_E AND Pa_{CO_2} IN THE ABSENCE OF NONCHEMICAL DRIVE SOURCES

Without Assist. A steady state in P_{CO_2} and minute ventilation ($\dot{V}_E$) can occur only if pulmonary carbon dioxide (CO_2) removal (the product of alveolar ventilation [$\dot{V}_E$] and alveolar CO_2 concentration [$F_{A_{CO_2}}$]) equals the CO_2 produced by the tissues ($\dot{V}_{CO_2}$). At a given $\dot{V}_{CO_2}$, if ventilation is increased artificially, $F_{A_{CO_2}}$, and hence Pa_{CO_2}, must decrease before a steady state is reached. Accordingly, at a given $\dot{V}_{CO_2}$, there is an inverse relationship between $\dot{V}_E$ and Pa_{CO_2} in the steady state—the metabolic hyperbola.[12] The actual equation is $Pa_{CO_2} = 0.86\ [\dot{V}_{CO_2}/\dot{V}_E(1 - V_D/V_T)]$,[12] where V_D/V_T is the dead-space-to-tidal-volume ratio. Figure 12-4A illustrates this relationship.

Ventilation increases progressively as a function of P_{CO_2}.[13] The slope of the response depends on the sensitivity of chemoreceptors (the sensory arm) and the effectiveness of the motor arm in generating ventilation. Thus, for a given chemoreceptor response, ventilatory response is less if respiratory muscles are weaker or mechanics are abnormal. Without nonchemical drive sources, there is a Pa_{CO_2} below which apnea develops,[4–6] the apneic threshold (AT; see Fig. 12-4).

Four subjects with different disorders are illustrated in Figure 12-4A. For each subject, there is only one possible steady state, namely, the point of intersection of the CO_2 response line and the hyperbola.[13] At this point, pulmonary CO_2 elimination equals tissue CO_2 production.

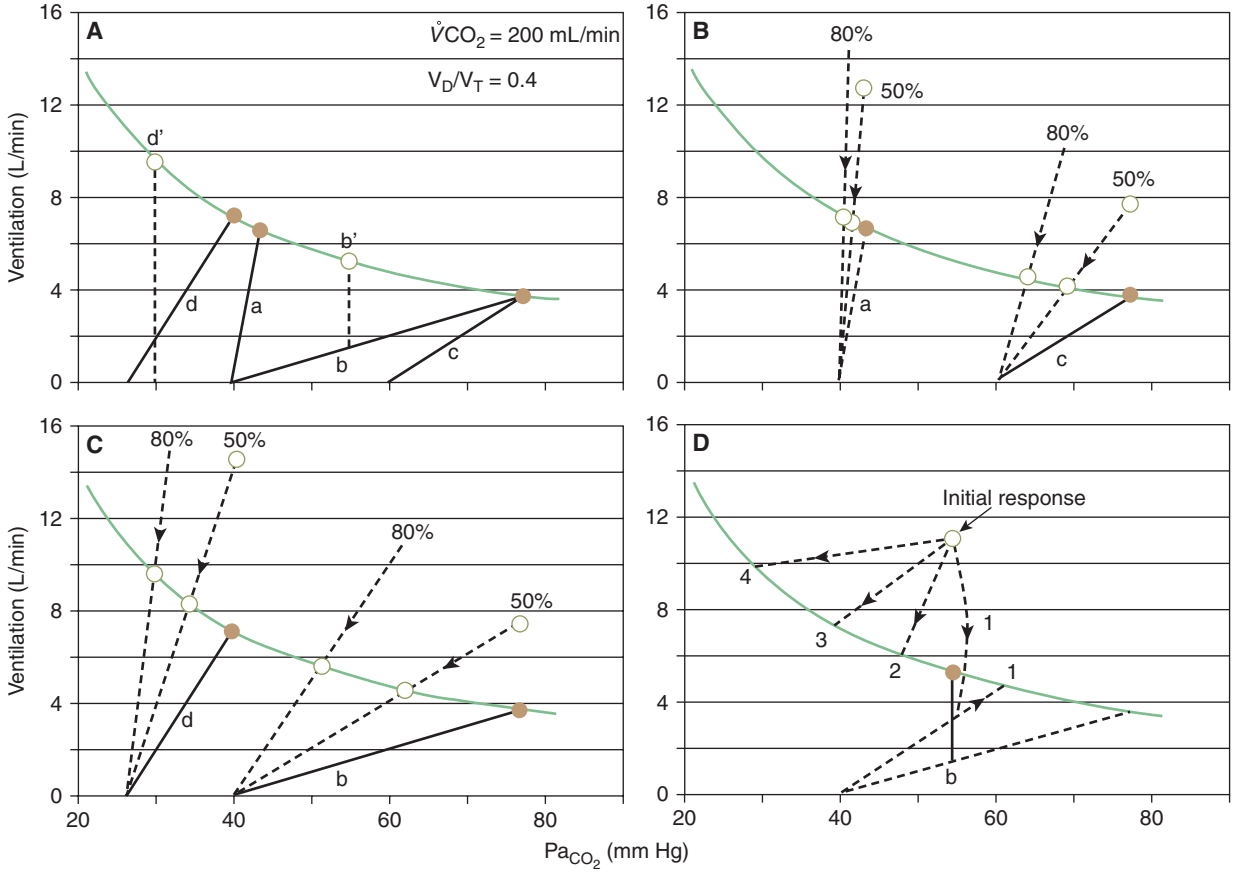

FIGURE 12-4 Effect of proportional assist on steady-state ventilation ($\dot{V}_E$) and Pa_{CO_2}. A metabolic hyperbola is shown for a subject with CO_2 production ($\dot{V}_{CO_2}$) of 200 mL/min and a dead-space-to-tidal-volume ratio (V_D/V_T) of 0.4. **A.** Unassisted breathing. The ventilatory responses to CO_2 in four subjects are shown: (*a*) normal, (*b*) acute hypercapnic failure, (*c*) chronic hypercapnic failure, and (*d*) acute nonhypercapnic failure with metabolic acidosis. In each case, the x intercept of the ventilatory response is the apneic threshold. The apneic threshold is shifted up in subject *c* and down in subject *d*. The intersection of ventilatory response line and the hyperbola gives steady-state values for $\dot{V}_E$ and Pa_{CO_2}. *Vertical dotted lines* represent additional nonchemical inputs that cause ventilation to be higher and Pa_{CO_2} to be lower than in their absence. **B** and **C.** Effect of 50% and 80% assist in the four subjects. In each case the ventilatory response slope doubles with 50% assist and increases fivefold at 80%. Open circles off the hyperbola are immediate responses not consistent with steady state. Open circles on the hyperbola are the steady-state values with assist. Note that the magnitude of change in $\dot{V}_E$ and Pa_{CO_2} is a function of the difference between unassisted Pa_{CO_2} (*solid circle*) and the apneic threshold. **D.** Response to proportional assist in the presence of nonchemical input (*vertical solid line*). Note that the response is highly unpredictable (see text).

Line *a* represents a normal subject. Ventilatory response is normal (2.2 L/min/mm Hg), and AT is 40 mm Hg. The intersection point is at a Pa_{CO_2} of 43 mm Hg and a $\dot{V}_E$ of 6.6 L/min. The difference between unassisted (no assist [NA]) steady-state P_{CO_2} and AT (i.e., $\Delta P_{CO_2, NA\text{-}AT}$) is very small (3 mm Hg). Line *b* represents a patient with severe acute hypercapnic respiratory failure. AT is the same, but the ventilatory response to CO_2 is greatly depressed because of abnormal mechanics. The intersection point is 76 mm Hg at a $\dot{V}_E$ of 3.8 L/min. $\Delta P_{CO_2, NA\text{-}AT}$ is very large (36 mm Hg). Line *c* describes a patient with chronic respiratory failure. Ventilatory response to CO_2 is depressed because of abnormal mechanics and/or weak respiratory muscles. In this case, however, AT is higher. $\Delta P_{CO_2, NA\text{-}AT}$ is larger than normal (16 mm Hg), but for the same steady-state Pa_{CO_2}, it is lower than in the patient represented by line *b*. Line *d* represents a patient with a reduced ventilatory response to CO_2 (0.6 L/min/mm Hg) because of abnormal mechanics or weak muscles but in whom the apneic threshold is low, for example, because of concomitant metabolic acidosis.[14] Steady-state P_{CO_2} and $\dot{V}_E$ are near normal, but $\Delta P_{CO_2, NA\text{-}AT}$ is large.

Expected Response to Proportional-Assist Ventilation Application. With PAV, respiratory motor output is amplified by an amount that is related to percent assist (see Fig. 12-3A). Within the linear range of the pressure-volume and pressure-flow relationships, the amplification of pressure results in a corresponding amplification of ventilation (see Fig. 12-3A). Thus, the net effect of PAV is to increase the slope of the ventilatory response to CO_2 (as well as to the partial pressure of oxygen [P_{O_2}] and pH). For simplicity, we will assume that P_{CO_2} is the only stimulus and that resistance and elastance are constant in the tidal volume range. Under these conditions, at 50% assist, delivered assist equals Pmus, and the combined pressure (patient + ventilator) is twice Pmus. Accordingly, the slope of the CO_2 response is doubled. At 80% assist, Paw is four times Pmus (see Fig. 12-3A), and pressure output is amplified by a factor of five. The ventilatory response should increase nearly fivefold, and so on.

In the normal subject (line *a*), 50% assist doubles the CO_2 response (see Fig. 12-4B). $\dot{V}_E$ immediately doubles (*upper open circle*). Pulmonary CO_2 output now exceeds $\dot{V}_{CO_2} \cdot Pa_{CO_2}$ falls. Respiratory efforts decrease, and $\dot{V}_E$ follows along the new CO_2 response line until the metabolic hyperbola. A steady state is now possible. The same would happen at higher percent assist. Because steady-state values must be above the AT, and $\Delta P_{CO_2, NA\text{-}AT}$ is very small, $\dot{V}_E$ and Pa_{CO_2} cannot change much. Furthermore, because $\dot{V}_E$ hardly changes, virtually all the assist (Paw) is used to reduce respiratory motor output, and percent reduction in Pmus is similar to percent assist.

A similar analysis for the patient with chronic respiratory failure (line *c* in Fig. 12-4B) shows that at 50% assist, Pa_{CO_2} decreases by 7 mm Hg and $\dot{V}_E$ increases by 10%, whereas at 80% assist, Pa_{CO_2} decreases by 13 mm Hg and $\dot{V}_E$ increases by 20%. Because $\dot{V}_E$ increased significantly, the decrease in respiratory muscle output (Pmus) is less than percent assist. For example, at 50% assist, Pmus is contributing 50% to a higher $\dot{V}_E$ (110%). The decrease in Pmus is 45% instead of 50%. Because the difference between Pa_{CO_2} at 80% assist and AT is now very small, increasing assist beyond 80% would have little further effect even though Pa_{CO_2} is still high. Thus, when AT is high, it is not possible to acutely normalize Pa_{CO_2} using PAV (or any other strictly assist mode).

In the patient with severe acute hypercapnic failure (line *b* in Fig. 12-4C), the changes are even greater. At 50% and 80% assist, Pa_{CO_2} decreases by 14 and 25 mm Hg, respectively, and $\dot{V}_E$ increases by 23% and 50%. Even at 80% assist, the difference between Pa_{CO_2} and AT is still large, and further reduction in Pa_{CO_2} is possible. Because $\dot{V}_E$ increases substantially, the decrease in Pmus is much less than percent assist (39% and 70%, for the 50% and 80% assist, respectively).

Finally, in the patient represented by line *d* in Figure 12-4C, increasing PAV assist results in progressive hypocapnia. By normalizing mechanics, the effect of the concomitant metabolic acidosis is now exposed.

In summary, *in the absence of nonchemical drive sources*, whether and by how much ventilation and Pa_{CO_2} change following institution of a given percent assist are determined by the unassisted ventilatory response to CO_2, the apneic threshold, and the position of the metabolic hyperbola. These determine the difference between unassisted Pa_{CO_2} and AT. Because the more $\dot{V}_E$ increases, the less Pmus decreases, the same three factors determine the extent to which the assist is used to increase ventilation versus decrease muscle output.

EFFECT OF NONCHEMICAL DRIVES ON RESPONSE TO PROPORTIONAL-ASSIST VENTILATION

The action of nonchemical drive inputs can be viewed as additive with chemical drive. They cause ventilation to be higher at a given Pa_{CO_2} than if chemical drive were the sole source (points *b′* and *d′* in Fig. 12-4A). Total drive is made up of a CO_2-sensitive component and a component that reflects consciousness-related reflexes and unpredictable behavioral influences.

Figure 12-4D illustrates how these inputs may modify the response to PAV. Without nonchemical influences, Pa_{CO_2} would be 76 mm Hg. Because of the nonchemical input (*solid vertical line*), however, steady-state $\dot{V}_E$ is 5.5 L/min at a Pa_{CO_2} of 55 mm Hg. A 50% assist results in an immediate increase in $\dot{V}_E$ to 11 L/min (both components are amplified). Pa_{CO_2} must fall. What happens then depends on the response of the nonchemical component. At one extreme, it may disappear (e.g., the patient may fall asleep when assisted). $\dot{V}_E$ would fall to the new CO_2 response line (*diagonal dashed line*). Should $\dot{V}_E$ at this point be below the hyperbola, Pa_{CO_2} and $\dot{V}_E$ will rise along the CO_2 response line, reaching the hyperbola at point 1. Here the assist is followed by an increase in Pa_{CO_2}, but the patient is working

much less. If the nonchemical stimulus remains the same, Pa_{CO_2} and $\dot{V}_E$ will decrease along a path parallel to the CO_2 response line, meeting the hyperbola at point 3. Here, there is no longer a CO_2 stimulus, and ventilation is sustained by the twice-amplified nonchemical influence. An intermediate value (point 2) may result if the nonchemical influence partially decreases. Finally, at the other extreme, the patient may become agitated with the assist, increasing the nonchemical stimulus, and this, when amplified, may reduce Pa_{CO_2} to very low levels (point 4). It is clear that with nonchemical stimuli (alert individuals), the ventilatory response to PAV is theoretically unpredictable.

Reported Physiologic Responses

RESPIRATORY MUSCLE OUTPUT

PAV resulted in significant reduction in muscle output in all studies where this was tested.[15–30] Typically, Pmus decreased by 30% to 45% at 50% assist and by 55% to 70% at 80% assist. The less-than-expected reduction is caused by (a) differences between assumed and actual E and R (see "Accuracy and Stability of Respiratory Mechanics Values" below), (b) imperfect delivery by the ventilator (see "Ventilator Response Time" below), (c) dynamic hyperinflation (see "Dynamic Hyperinflation" below) or nonlinearity in the pressure–volume relationship (see "Nonlinearity in the Pressure–Volume Relationship within the Tidal Volume Range" below), and (d) an associated increase in $\dot{V}_E$ (see "Ventilation and Partial Pressure of Carbon Dioxide" below). As indicated earlier, when some of the assist is used to increase $\dot{V}_E$, less is used to reduce muscle output.

VENTILATION AND PARTIAL PRESSURE OF CARBON DIOXIDE

Application of PAV to normal sleeping subjects results in an immediate increase in tidal volume (V_T) and $\dot{V}_E$, which decrease over several breaths to near-baseline levels.[17] Steady-state responses are minimal,[6,17] and the decrease in end-tidal CO_2 tension ($P_{ET}CO_2$) is very modest (approximately 3 mm Hg[6,17]). These results are consistent with a small difference between unassisted Pa_{CO_2} and AT secondary to a normal ventilatory response to CO_2 (subject represented by line *a* in Fig. 12-4B).

By contrast, in experienced, awake resting normal subjects, PAV results in an important increase in $\dot{V}_E$ and a more pronounced reduction in Pa_{CO_2}, and the decrease in respiratory muscle output is only modest.[18] Pa_{CO_2} generally decreases below the apneic threshold (e.g., 30 ± 5 mm Hg[18]), reflecting the presence of nonchemical drive inputs that fail to be eliminated. PAV applied to inexperienced, awake subjects is followed by unpredictable responses extending to severe hyperventilation (personal observations), reflecting erratic behavioral responses.

When PAV is applied to normal subjects during steady exercise[31] or during inhalation of CO_2-enriched air,[28] there is little change in ventilation. Thus, during ventilatory stimulation the assist is primarily utilized to reduce respiratory muscle output rather than to increase ventilation. Georgopoulos et al[32] measured Pmus during CO_2 rebreathing with and without PAV unloading. They found that Pmus was the same when measurements were compared at the same end-tidal P_{CO_2}. Thus, it appears that during exercise-induced or CO_2-induced ventilatory stimulation the downregulation of Pmus, at the same exercise level or the same fraction of inspired carbon dioxide (FI_{CO_2}), is mediated by small reductions in systemic P_{CO_2}.

There are numerous reports on the changes in $\dot{V}_E$ and Pa_{CO_2} with PAV in patients with respiratory failure.[15,16,19–26,33–39] Responses ranged from virtually no change or even a decrease in $\dot{V}_E$ as assist increased[33–36] to large increases in $\dot{V}_E$ and decreases in Pa_{CO_2}.[16,19,25,37] These differences can be explained readily if one considers the experimental circumstances of the various studies or patients.

1. *Intubated ventilator-dependent patients with normocapnia.* It is clearly not possible to establish steady-state values of $\dot{V}_E$ and Pa_{CO_2} during unassisted breathing in these patients as they rapidly develop distress. The effect of PAV is, accordingly, determined over a range of assist above a minimum value (e.g., 80% vs. 40%). Furthermore, in such patients, Pa_{CO_2} at the minimum tolerable assist is normal. All such studies demonstrated very little change or even a small decrease in $\dot{V}_E$ as assist increased.[33–36] Pa_{CO_2} decreased, but the change was small (2 to 4 mm Hg). These patients, therefore, behave like the subject represented by line *a* in Figure 12-4B, who has no nonchemical inputs and a small $\Delta P_{CO_2, NA\text{-}AT}$. This state, however, is reached only at some finite assist. It therefore would appear that these patients become comfortable only when their Pa_{CO_2} is a few millimeters of mercury above AT. Under these conditions, $\dot{V}_E$ cannot increase further by PAV application (Figure 12-4B, line *a*); the extra assist is used simply to decrease muscle output. The decrease in $\dot{V}_E$ observed in some cases[34,36] is caused by a reduction in V_D/V_T and/or $\dot{V}_{CO_2}$ (secondary to decreased respiratory muscle work) because in all such cases, Pa_{CO_2} was lower even though $\dot{V}_E$ was lower.[34,36]

   The preceding observations lead to an interesting conclusion: Ventilator-dependent patients who show little change in $\dot{V}_E$ and Pa_{CO_2} over a relatively wide PAV assist do not tolerate a Pa_{CO_2} that is much above AT. This indicates a high degree of chemosensitivity that likely contributes to their ventilator dependence. *Chemosensitivity,* as used here, does not refer to ventilatory responses (which are affected by mechanics and muscle strength) but to central effects of Pa_{CO_2} on respiratory sensation and muscle activation.
2. *Chronic hypercapnia with and without acute exacerbation.* In virtually all reported studies, $\dot{V}_E$ and Pa_{CO_2} on PAV were compared with values obtained during a period of

unassisted breathing.[16,19–21,23,25,26,40] Unlike the preceding group, there always was a significant increase in $\dot{V}_E$ and a decrease in Pa_{CO_2}. The changes were modest, however (approximately 25% increase in $\dot{V}_E$ and a 3- to 6-mm Hg decrease in Pa_{CO_2}). Such a response is consistent with a somewhat larger difference between AT and unassisted P_{CO_2} (subject represented by line *c* in Fig. 12-4B). Pa_{CO_2} remained abnormally high in all cases, consistent with a high AT. The changes in $\dot{V}_E$ and Pa_{CO_2} likely would have been greater if the hypoxic stimulus did not change. In all but one study,[19] Pa_{O_2} was quite low during unassisted breathing and improved with PAV. Because a higher Pa_{O_2} decreases the ventilatory response to CO_2,[13] an increase in Pa_{O_2} mitigates the increase in CO_2 response produced by PAV, resulting in a smaller increase in ventilatory response. The assist provided in this case is used preferentially to decrease muscle output as opposed to increasing $\dot{V}_E$. In one study,[19] the hypoxic drive was negligible at baseline (Pa_{O_2} = 99.5 mm Hg). Here, the increase in $\dot{V}_E$ was much greater (38%[19]). Although the changes in Pa_{CO_2} and Pa_{O_2} undoubtedly contributed to the reduction in respiratory muscle output, most of these patients were alert, so a reduction in nonchemical inputs may have been partly responsible.

3. *Acute hypercapnic failure.* Gay et al[38] reported an average 8 mm Hg decrease in Pa_{CO_2} (60 to 52 mm Hg) within a half hour of instituting noninvasive PAV. Likewise, in a study by Busterholtz et al on patients with acute cardiogenic pulmonary edema, Pa_{CO_2} decreased from 51 ± 25 to 41 ± 25 mm Hg and Pa_{O_2} increased from 66 ± 18 to 130 ± 30 mm Hg within 30 minutes of applying PAV.[41] Considering that not all patients in these two studies were hypercapnic and that the nonhypercapnic patients likely did not contribute to the average decrease (see 4 below), the decrease in Pa_{CO_2} in the hypercapnic group must have been greater. In another study,[37] there were four patients with acute hypercapnic failure not associated with central depression. In them, Pa_{CO_2} declined 17 mm Hg on average (66 to 49 mm Hg) within a half hour of instituting PAV. These observations suggest that patients with acute hypercapnia secondary to severe acute mechanical abnormalities do sustain large increases in $\dot{V}_E$ and reductions in Pa_{CO_2} on institution of PAV (see line *b*, Fig. 12-4C). Interestingly, Pa_{CO_2} remained above normal (approximately 50 mm Hg) in some patients for a few hours.[37] It is possible that the apneic threshold increased somewhat during the preceding period of severe hypercapnia.
4. *Acute hypoxemic failure.* Information about this group is scant. Although patients were included in three previous reports,[37–39] only in one study were the results of the normocapnic group (four patients) separated from those of hypercapnic patients.[37] In these four patients, Pa_{CO_2} did not change despite distress decreasing dramatically. The likely explanation for failure of Pa_{CO_2} to decrease is that respiratory muscle output to a large extent was related to nonchemical inputs, which decreased substantially on unloading (pathway 1 in Fig. 12-4D).

RESPIRATORY RATE AND BREATHING PATTERN

With one exception,[16] when there was no clinical distress at the lowest level of assist, application of PAV or further increases in percent assist did not result in appreciable changes in ventilator rate (i.e., >2 to 3 breaths/min). This applied to normal sleeping subjects,[6,17] intensive care unit (ICU) patients in whom percent assist was changed over a wide range above a comfortable level,[33–36] and ambulatory patients with chronic respiratory failure in whom the lowest level was spontaneous breathing.[19,20,24–26,40] In the only exception,[16] respiratory rate (RR) deceased substantially when PAV was applied, but in this case there were clear signs of runaway (i.e., patient was no longer in the PAV mode).

In patients with acute exacerbation of chronic obstructive pulmonary disease (COPD), RR on PAV was lower than during spontaneous breathing (3 to 5 breaths/min[21,23]). The pH, however, was low at baseline, and some degree of distress may have been present then. When PAV is applied to patients with clear respiratory distress, RR decreases dramatically along with relief of distress.[37–39]

From these observations it is clear that PAV does not per se change RR. RR changes only when PAV relieves respiratory distress. In physiologic studies in which respiratory drive is deliberately increased, RR does not increase until moderate levels of stimulation.[18,42] This applies whether stimulation is produced by hypercapnia, hypoxemia, acidosis, or an increase in metabolic rate.[43] Thus, a change in RR with assist level indicates that respiratory drive is in a range where RR is sensitive to drive and hence probably excessive, whereas failure of RR to change over a range of PAV assist indicates that respiratory drive is only modest over this range. There are two important clinical implications to these observations on PAV:

1. Failure of RR to change over a range of PAV assist indicates that respiratory drive is only modest over this range and that the RR observed in this range is the undistressed value preferred by the patient's control system. Importantly, undistressed RR, so defined, ranges from 12 to 46 breaths/min.[33,34] That undistressed RR varies widely among patients is consistent with the wide range in normal subjects (8 to 25 breaths/min).[44] The main difference between ICU patients and normal subjects is that the average undistressed rate is 10 breaths/min higher.[33] A number of factors may contribute to this, including body temperature, irritation of tracheal receptors by the endotracheal tube, disease-related effects on pulmonary and other receptors, neuropathology, and drug effects.[33]
2. Because the undistressed RR can be quite low, a change in RR as assist level is changed is more important than absolute RR at the low assist. For example, an increase from 20 to 25 breaths/min may indicate distress, although

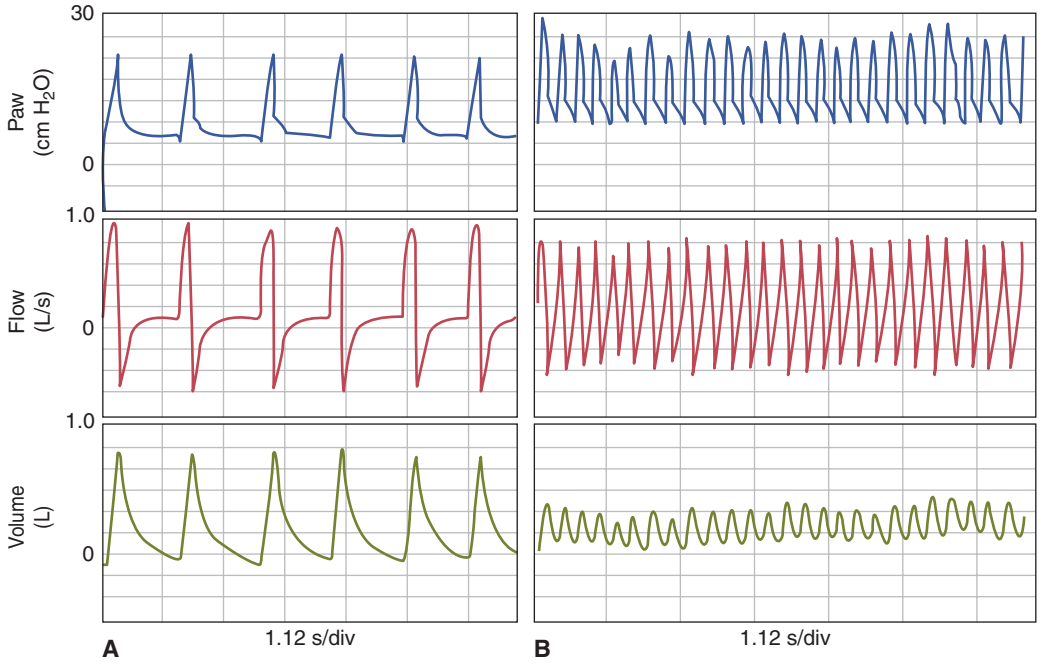

FIGURE 12-5 Tracings from two patients on high PAV assist showing extremes of undistressed breathing pattern. *Paw*, airway pressure.

25 breaths/min is not usually considered a sign of distress. By contrast, RR in excess of the usual cutoff of 35 breaths/min need not reflect distress.

Tidal volume responses mirror the $\dot{V}_E$ responses and obviously share the same mechanisms (see "Ventilation and Partial Pressure of Carbon Dioxide" above). It is important to note that in normocapnic patients, once a distress-free assist level is reached, further increases have little effect on V_T.[33,34] Accordingly, every patient has a preferred or target V_T that cannot be exceeded with more PAV assist. As with normal subjects,[44] the preferred V_T varies widely among patients (4 to 15 mL/kg[33,34]).

PAV has made it possible to determine the undistressed breathing pattern in ICU patients. This proved quite variable. Figure 12-5 shows two extremes. With this wide range, a one-size-fits-all strategy of mechanical ventilation (e.g., setting a target V_T) is clearly not ideal (see "Physiologic Consequences of Operational Differences" below).

Large breath-by-breath variability in V_T is characteristic of normal breathing, particularly in wakefulness.[45,46] Variability decreases in patients with abnormal mechanics.[47,48] Probably because PAV improves neuroventilatory coupling, breath-by-breath variability tends to be large in this mode (see, e.g., Fig. 12-1). Coefficients of variation of 25% or more are not unusual,[23,25,35–37] and spontaneous sighs may be frequent. As with normal subjects,[49] breathing variability on PAV is less in sleeping and obtunded patients (personal observations).

VENTILATORY INSTABILITY

The tendency for the respiratory system to become unstable is described by the so-called loop gain.[50–52] A value of 1 indicates that recurrent cycling will occur spontaneously (e.g., Cheyne-Stokes breathing). The lower the value, the more stable is the system. Ventilatory response to chemical stimuli is an important determinant of loop gain.[50–52] Because PAV increases ventilatory responses, we were concerned initially that it might precipitate periodic breathing.[1] This, however, did not materialize. Although PAV may aggravate preexisting Cheyne-Stokes breathing,[53] there are no reports of PAV-induced Cheyne-Stokes breathing in the usual ICU patient, and we have observed only a few in whom breathing became periodic on high PAV support.

The resistance to Cheyne-Stokes breathing was explained recently. Normal subjects require threefold to fourfold amplification of ventilatory responses to develop periodic breathing.[6,17,54] Thus, when respiratory muscles and mechanics are normal, native loop gain is less than 0.3. In the average ICU patient, respiratory muscle strength is 50% of normal,[55] resistance is four times normal (14 vs. 3 to 4 cm H_2O/L/s[56]), and elastance is two to three times normal (28 vs. 10 to 14 cm H_2O/L[57]). Collectively, these abnormalities should decrease ventilatory responses to 20% of the normal value. For PAV to induce periodic breathing in the average patient, it first must normalize ventilatory responses (i.e., a fivefold increase in the average patient) and then three to four times more, a greater than 10-fold amplification. This is very difficult to achieve because of technical and physiologic limitations (see "Limitations" below). Accordingly, if periodic breathing develops on PAV, it suggests that (a) respiratory muscles and mechanics are near normal, and the patient likely does not need ventilator support, and/or (b) the chemical control system is inherently unstable, and one should suspect disorders that result in Cheyne-Stokes breathing, chiefly heart failure.

A third condition that may precipitate periodic breathing is the runaway phenomenon (see below). Here, large tidal volumes may result, precipitating hypocapnia and recurrent central apneas. The pattern is unlike the crescendo–decrescendo Cheyne-Stokes breathing variety, however, and more like that produced by pressure support (several large breaths alternating with apnea[6,58]).

The ability of PAV to increase loop gain by measurable quantities is currently being used to study mechanisms of instability during sleep.[52,59]

RESPONSES DURING EXERCISE

Application of PAV during submaximal exercise in patients with severe COPD increased endurance time and reduced the rate of progression of dyspnea.[29,60–62] Patients with very severe COPD who received PAV during exercise in a rehabilitation program demonstrated greater improvement in unassisted exercise tolerance relative to a control group.[63] A beneficial effect of assist was not evident in mild COPD.[64] Application of PAV during submaximal exercise also increased endurance time and reduced dyspnea in patients with idiopathic pulmonary fibrosis[65] and in obese patients.[66]

Apart from its potential therapeutic role, PAV also has been used to examine the role of respiratory muscles in limiting exercise in normal subjects and in patients with COPD, with highly interesting results.[31,67–74]

COMPARISON WITH OTHER MODES

Operational Differences between Proportional-Assist Ventilation and Other Modes

With PAV, the assist (i.e., Paw) varies directly with the intensity of patient effort (see Fig. 12-1). By contrast, with pressure-support ventilation (PSV), the assist is the same breath after breath regardless of intensity of effort. With volume-controlled ventilation (VCV), assist varies inversely with effort (Fig. 12-6). This is so because flow and volume are preset. If the patient's contribution increases, the ventilator must deliver less assist (Paw), and vice versa. Otherwise, delivered flow and volume will deviate from set values. These different relations have been well documented.[18,22,75]

With PAV, the end of the ventilator cycle is synchronized automatically with the end of patient effort (see Fig. 12-1), whereas with other modes it is not. Although ventilator response delays tend to delay cycling off somewhat,[76] the effect is fairly trivial compared with the situation in other modes (see "Ventilator Response Time" below). In VCV, there is no relationship whatsoever; the patient determines the end of his effort, whereas the caregiver determines the end of the ventilator's cycle. Any synchrony is happenstance. The ventilator may continue inflation well after the end of effort, when patient wants to exhale (e.g., breath 1 in Fig. 12-6), or may cycle off, withdrawing support before the end of effort while patient is still trying to inhale (e.g., breath 4 in Fig. 12-6).

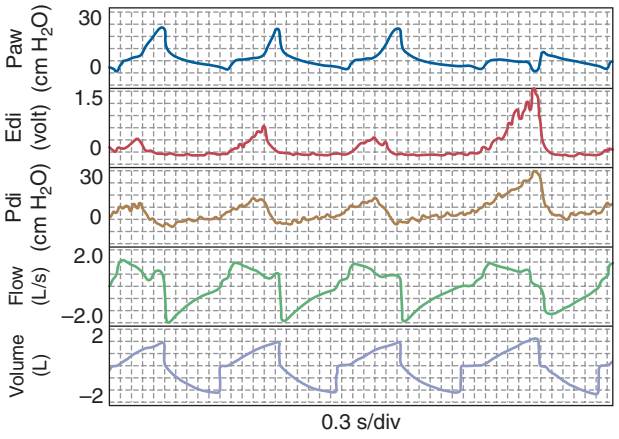

FIGURE 12-6 Tracings from a patient on volume-controlled ventilation. Note that ventilator cycles extend beyond inspiratory effort in the first three breaths while terminating during the effort in the last breath. Note also that patient received little or no assist when his effort was greatest (last breath). *Edi*, diaphragmatic activity; *Paw*, airway pressure; *Pdi*, diaphragmatic pressure.

With PSV, synchrony between the ends of the ventilator's and the patient's inspiratory phases may or may not occur depending on the patient's respiratory mechanics and the relation between PSV level and Pmus.[77,78] Ventilator cycles often extend well beyond inspiratory effort[34,79] or may be almost completely out of phase with them[79] (Fig. 12-7A). At times, inflation extends over two or more efforts (Fig. 12-8A).[34]

The operational characteristics of NAVA[80–82] are very similar to those of PAV in that the assist is proportional to instantaneous effort in both cases. Thus, in both cases the assist will increase when effort increases and vice versa, and in both cases the ventilator cycle will terminate soon after the end of inspiratory effort. The main difference is in the signal used to drive the ventilator: PAV uses an indirect noninvasive estimate of effort (calculated Pmus) whereas NAVA uses a direct estimate of diaphragmatic activity obtained from internally inserted esophageal electrodes. This gives NAVA an advantage with respect triggering in that with NAVA the assist can, theoretically, begin very soon after the onset of diaphragmatic activity in the presence of important dynamic hyperinflation or circuit leaks, whereas with PAV the assist will not start until flow becomes inspiratory, and triggering and assist may be adversely affected in the presence of significant leaks (see "Limitations" below). On the other hand, because the diaphragm participates in many nonrespiratory activities (such as postural changes and vomiting), control of airway pressure by diaphragmatic activity could result in undesirable large increases in airway pressure during such activities. For example, the diaphragm contracts vigorously during vomiting to increase abdominal pressure. This may be expected to cause a large increase in airway pressure in

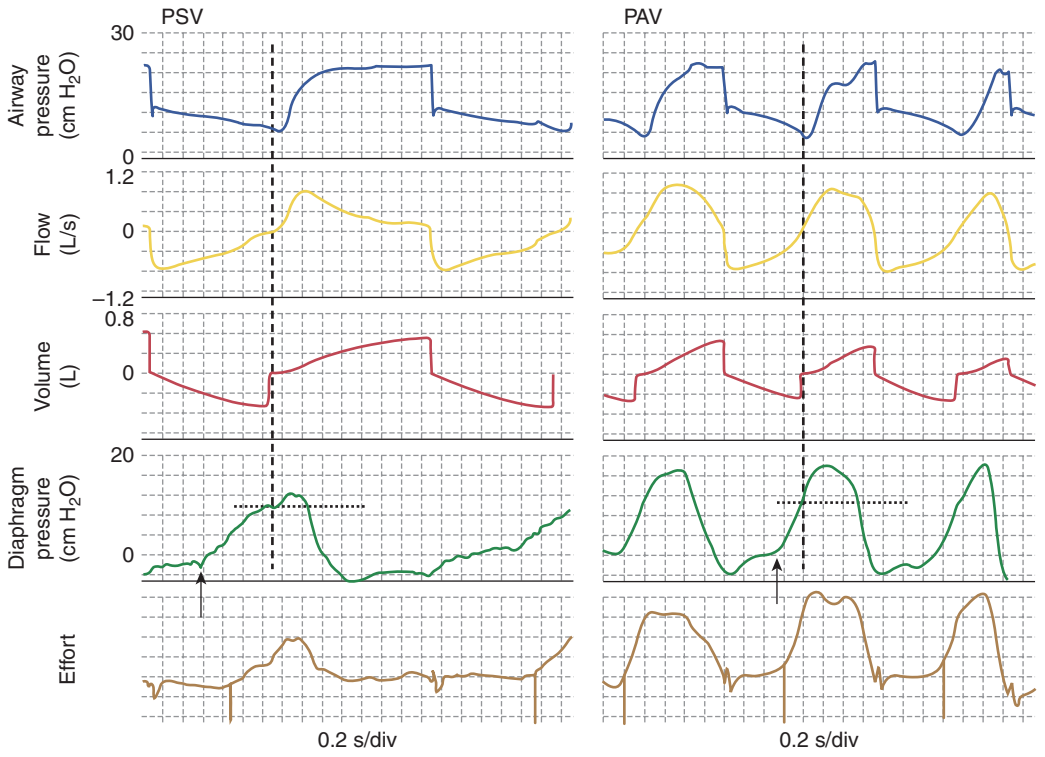

FIGURE 12-7 Comparison of pressure-support ventilation (PSV) and proportional-assist ventilation (PAV) in a patient with severe dynamic hyperinflation. With both modes, inspiratory muscles had to generate 10 cm H_2O before inspiratory flow could be generated and the ventilator triggered (*vertical dashed lines*). Note that in PSV, ventilator cycle extends well into neural expiration. There also were many ineffective efforts (not shown). This is not the case in PAV. Note also that diaphragmatic output is considerably higher in PAV. As a result, delay between onset of effort (*arrows*) and triggering is much less. In addition, respiratory rate is higher with PAV. With severe dynamic hyperinflation, it is difficult to maintain respiratory muscle output at a low level in PAV. See Figure 12-13 for transition from PSV to PAV in this patient. *Bottom tracing.* A semiquantitative effort signal generated without knowledge of respiratory mechanics[117] that can be used to identify onset and end of efforts noninvasively in real-time (*event marks*). Note that the onset of effort (*downgoing marks*) can be identified well before inspiratory flow crossing. If used for triggering, this essentially can eliminate the extra work associated with dynamic hyperinflation.

the case of NAVA. PAV, in contrast, is not susceptible to this problem because diaphragmatic descent and reduction in intrathoracic pressure are prevented by concurrent contraction of the expiratory muscles.

Physiologic Consequences of Operational Differences

The following sections deal with consequences as they relate to conventional assist modes (PSV and VCV). Because NAVA has similar operational characteristics, its consequences vis-a-vis conventional assist modes are expected to be similar (see Chapter 13 and reference 82 of this chapter). There are no studies in which NAVA and PAV have been compared directly so as to ascertain the clinical impact of NAVA's triggering advantage in the presence of dynamic hyperinflation and leaks.

RESPONSE TO DIFFERENT LEVELS OF ASSIST

Figure 12-9 illustrates what, theoretically, should happen when assist level is varied in different modes (see refs. 3 and 83 for more details). The response of RR to changes in Pa_{CO_2} near the AT is key to understanding these plots. As indicated earlier, RR is fairly constant over a range of Pa_{CO_2} above the AT. For example, average difference between spontaneous RR and RR just before apnea is less than 1 breath per minute.[6] At AT, breathing simply stops. There is no gradual reduction in RR.

The effect of different levels of PAV (see Fig. 12-9A) was discussed earlier (see Fig. 12-4). A steady state is possible at all assist levels, except in rare cases where chemical control is highly unstable (see "Ventilatory Instability" above). Once the AT is approached, it is not possible to increase $\dot{V}_E$ further.

The relationship between P_{CO_2} and ventilation during PSV is extremely complex.[3,34,77,83] For simplicity, it is shown as a parallel shift in the ventilatory response, reflecting the fact that the assist is independent of P_{CO_2}. Exactly what happens, however, to the slope of the ventilatory response is not terribly important here. What is important is that with PSV a minimum V_T is delivered once the ventilator is triggered. This minimum V_T is a function of PSV level and respiratory mechanics.[6,77] For example, in a patient with an elastance of 25 cm H_2O/L and a resistance of 12 cm H_2O/L/s, the minimum V_T at PSV of 7, 14, and 20 cm H_2O will be approximately 0.22, 0.43, and 0.64 L, respectively.[6,77] If the patient's RR near the AT is a conservative 16 breaths/min, and every

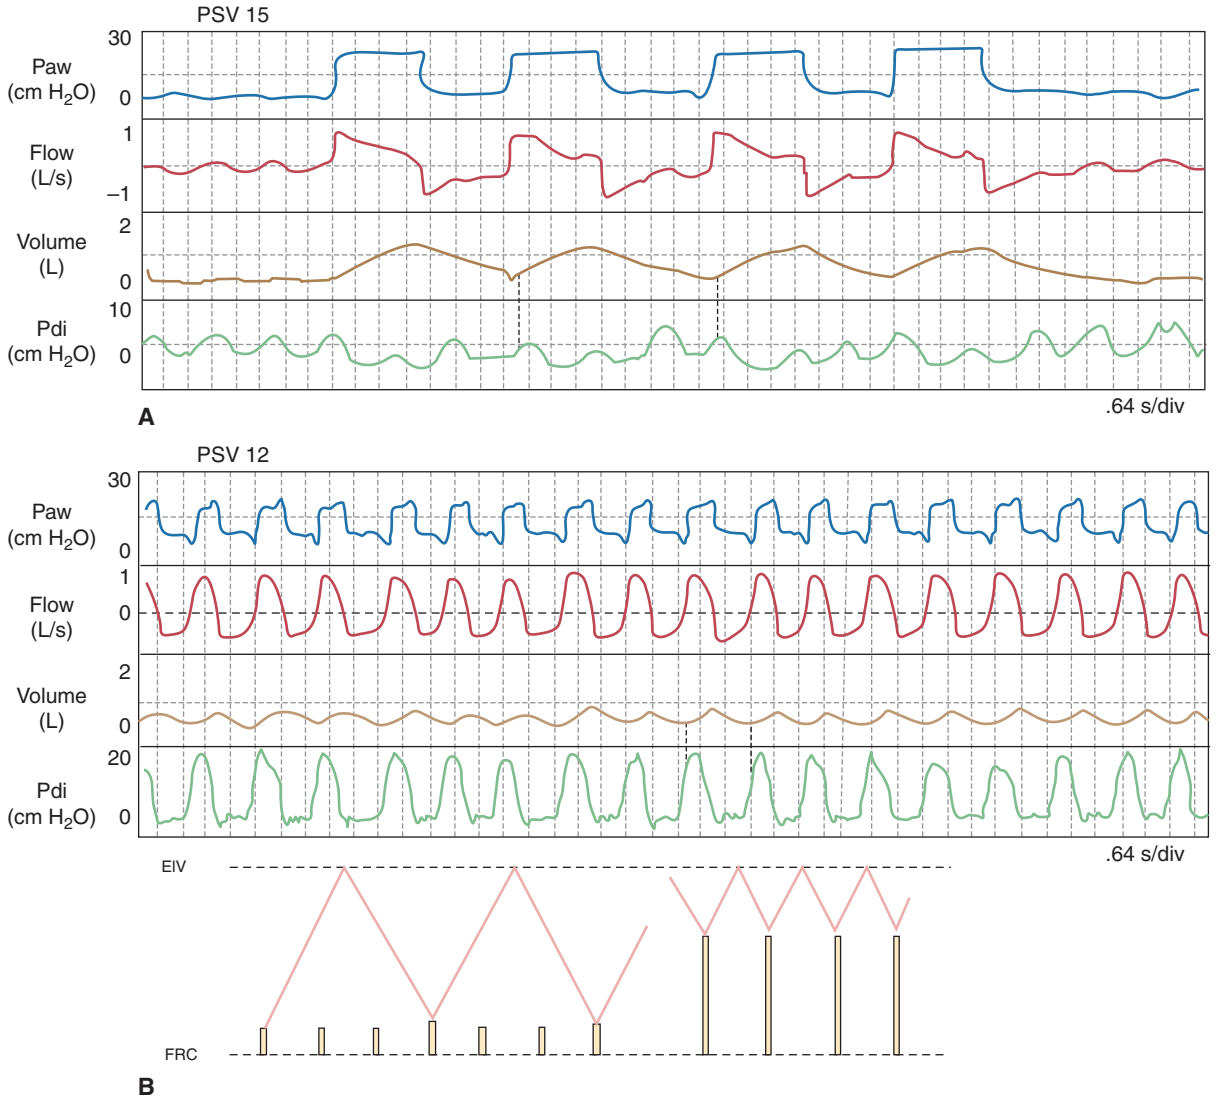

FIGURE 12-8 A dramatic example of a marked shift from slow, deep breathing (panel A) to very rapid, shallow breathing (panel B) following a small reduction in pressure support (PSV). The increase in respiratory rate was artifactual and related to improved synchrony (note that the rate of diaphragmatic efforts was unchanged). The small tidal volumes are related to dynamic hyperinflation (note that Pdi increases substantially before flow becomes inspiratory) (*vertical dotted lines*). Inset shows schematically the mechanism of shallow breathing. Height of *solid lines* represents effort amplitude. See text for additional details. *EIV*, end-inspiratory volume; *FRC*, functional residual capacity; *Paw*, airway pressure; *Pdi*, diaphragmatic pressure.

effort triggers the ventilator, minimum $\dot{V}_E$ near the AT will be 3.5, 6.9, and 10.2 L/min for the three levels, respectively (see Fig. 12-9). A higher minimum RR (range: 12 to 46 breaths/min; see "Respiratory Rate and Breathing Pattern" above) would increase minimum $\dot{V}_E$ correspondingly.

For the patient in Figure 12-9, applying PSV at level 1 will boost ventilation initially above the metabolic hyperbola. Pa_{CO_2} falls along the response line of that level. Because minimum $\dot{V}_E$ is below the hyperbola (*left end of line 1*), a steady state can be reached (*solid dot on line 1*). For level 2, a steady state still can be reached, but Pa_{CO_2} will be just above the AT, and efforts will be very feeble. At level 3, a steady state is not possible because minimum $\dot{V}_E$ is above the metabolic hyperbola. When Pa_{CO_2} is above the AT, $\dot{V}_E$ is above the hyperbola, and P_{CO_2} must fall. When it falls below the AT, $\dot{V}_E$ becomes zero. The only steady-state $\dot{V}_E$ is the open circle. This is not possible, however, if all efforts trigger the ventilator. For average $\dot{V}_E$ to equal $\dot{V}_E$ at the open circle, ventilator rate must decrease below the patient's minimum RR. This occurs in one of two ways depending on the time constant of the respiratory system (resistance/elastance [R/E]). If R/E is very short (e.g., severe, restrictive disease), ventilator cycles will not encroach on neural expiration,[77,78] allowing lung volume to return to FRC before the next effort. Here it is possible to continue triggering until the AT, and recurrent central apneas develop. When R/E is long, the ventilator cycle is also long[77,78] and extends into neural expiration. As efforts weaken, more and more efforts fail to trigger the ventilator. Here, ineffective efforts are scattered between triggered breaths. Depending on R/E, ineffective efforts may appear

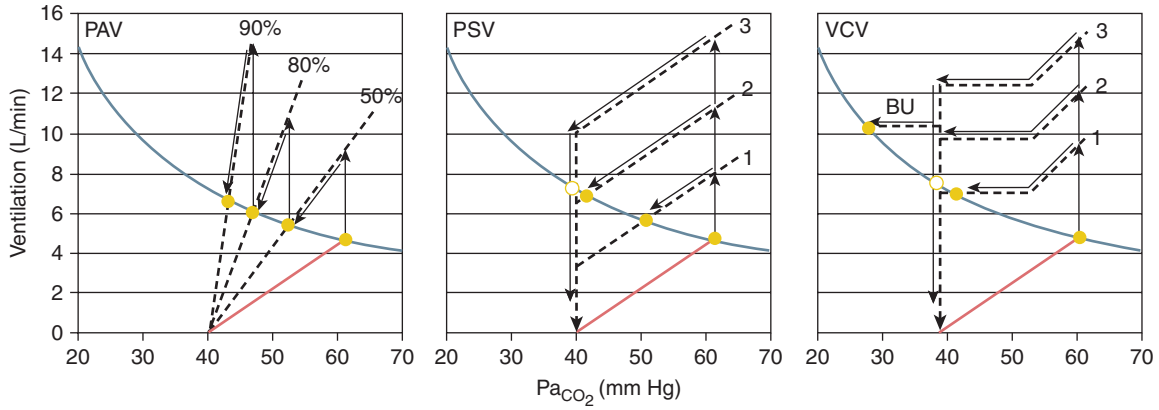

FIGURE 12-9 Responses to different levels of assist with proportional-assist (PAV), pressure-support (PSV), and volume-controlled ventilation (VCV). The ventilatory response to CO_2 is shown for three assist levels in each case. The format is as in Figure 12-4. Note that in PAV the ventilatory response line intersects the metabolic hyperbola at all levels of assist. A steady state thus is possible at all levels. In PSV and VCV, the response lines intersect the hyperbola over a limited range of assist. At higher levels, a steady state is not possible, and nonsynchrony must result (see text). In this simulation, respiratory rate is shown to increase when Pa_{CO_2} exceeds 53 mm Hg. This accounts for the increase in ventilation above this Pa_{CO_2} in VCV. *BU*, backup rate.

well before the AT. Because R/E is more commonly long than short, intermittent ineffective efforts are more common than recurrent central apneas.[34,84]

In summary, with neither PAV nor PSV is it possible to decrease average Pa_{CO_2} below the AT. What is different is that with PAV, V_T is independent of assist level near the AT, and ventilator cycles cannot extend substantially into neural expiration. Thus, a steady state can be reached at all levels without nonsynchrony.[34] With PSV, by contrast, V_T increases monotonically with assist. At some level the product $V_T \times$ minimum RR exceeds the $\dot{V}_E$ required for steady state, and nonsynchrony must occur. These differences have been demonstrated experimentally.[34]

With VCV, $\dot{V}_E$ is constant over the range where RR is independent of drive and is given by patient RR × set V_T. As set V_T increases, $\dot{V}_E$ increases and remains at that level as efforts decline (*horizontal lines, right panel,* Fig. 12-9). If steady-state Pa_{CO_2} associated with this fixed $\dot{V}_E$ is above the AT, a steady state with maintained synchrony can result (e.g., *line 1*). If not (*lines 2 and 3*), and there is no or minimal backup rate, ineffective efforts or recurrent central apneas must result (as with PSV), and nonsynchrony will increase as set V_T increases.[84] With a backup rate, once the AT is reached, $\dot{V}_E$ will decrease to set $V_T \times$ backup rate. If this $\dot{V}_E$ is below the hyperbola at the AT, periods in which the ventilator is triggered by the patient will alternate with periods in which it is self-triggered as Pa_{CO_2} oscillates about the AT. If backup $\dot{V}_E$ is above the hyperbola (line *BU* in Fig. 12-9), Pa_{CO_2} must fall further. Depending on ventilator settings, marked hypocapnia may develop.

In summary, with PSV and VCV there is a limited range of assist that is consistent with synchrony. Above this range, ineffective efforts or recurrent central apneas must develop. It is evident that the "appropriate" assist range depends on the metabolic hyperbola (a function of metabolic rate and V_D/V_T) and minimum patient RR near the AT (see Fig. 12-9). Because these may change with time, a suitable level may become unsuitable at another time. Several studies confirm that nonsynchrony is quite common with PSV and VCV[24,34,79,84] while being virtually nonexistent at all levels of PAV.[19,24,34] Ineffective efforts do occur at times during PAV, but they are very infrequent[34] and usually occur when a large breath (spontaneous sigh or runaway breath) is followed by a weak effort.

RESPONSE TO CHANGES IN VENTILATORY DEMAND

Figure 12-10 is a representative example of spontaneous changes in $\dot{V}_E$ over a 2-hour period. The changes are not trivial; the highest level was almost twice the lowest. This is not surprising because many influences that affect ventilatory demand can change in these patients, for example, pain, anxiety, sleep–wake cycles, metabolic rate, pH, and drugs. It is therefore useful to examine what happens with the three modes in response to such changes.

Figure 12-11 illustrates two metabolic hyperbolas, representing two metabolic rates. The unassisted ventilatory response (*solid line*) is identical and would be associated with a Pa_{CO_2} of 62 mm Hg. Initial ventilator settings with the three modes were adjusted to produce identical $\dot{V}_E$ (6 L/min) and Pa_{CO_2} (48 mm Hg) at the lower metabolic rate. Ventilatory demand increases by 50% (upper hyperbola). Efforts increase, but RR initially does not. With PAV, assist increases, and $\dot{V}_E$ increases along a relatively steep response line, reaching the higher hyperbola at a Pa_{CO_2} of 51 mm Hg. With PSV, assist is constant. As a result, the ventilatory response is no better than the unassisted slope. The higher hyperbola is reached at 57 mm Hg. With VCV, ventilation cannot increase until RR increases. Without

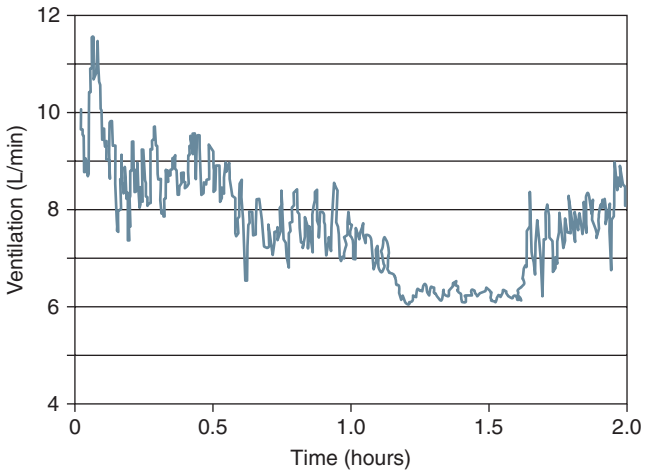

FIGURE 12-10 One-minute moving average of ventilation over a 2-hour period on PAV. Note large spontaneous changes in ventilatory demand.

tachypnea, the metabolic hyperbola is reached at a Pa_{CO_2} of 70 mm Hg.

It is clear that the likelihood of respiratory distress and tachypnea developing is higher with VCV and PSV. With VCV, there is the added problem that ventilator inspiratory time (T_I) does not change as patient respiratory cycle time (T_{TOT}) decreases. Less time remains for exhalation, promoting nonsynchrony.[84] Nonsynchrony occurring at a time of high respiratory drive may trigger anxiety. Of course, both PSV and VCV can be readjusted to provide adequate support at the higher demand. This level, however, will be excessive when ventilatory demand returns to the lower level.

The different responses to CO_2 challenge under the three modes were well illustrated in normal subjects.[18] In ventilator-dependent patients, Ranieri et al[75] showed that following addition of dead space during PAV, V_T increased with no change in RR (20.1 to 19.8 breaths/min). When added during PSV in the same patients, there was little change in V_T, and RR increased dramatically (from 16.4 to 33.2 breaths/min). By contrast, a recent repetition of this study[85] failed to demonstrate differences between PSV and PAV in the ventilatory, pressure-time product or transdiaphragmatic pressure responses to added dead space even though the magnitude of assist increased with PAV and not with PSV. There are several reasons to explain this negative result. Although both studies added the same amount of dead space (150 mL), the challenge was much greater in the Ranieri[75] study, as evidenced by a much greater increase in V_E (approximately equal to 13.5 vs. 2.1 L/min), Pa_{CO_2} (approximately equal to 19.0 vs. 2.0 mm Hg), and pressure-time product per minute (185 vs. 32.4 cm H_2O.s/min) on PSV of 10 cm H_2O. The reason for the large difference in challenge presented by the same addition of dead space is not clear. Nonetheless, with a minimal challenge, as was delivered in the study of Varelmann et al,[85] it is difficult to obtain significant responses given the noise in such studies (spontaneous changes in respiratory drive). It is worth noting that in the latter study,[85] Pa_{CO_2} increased more when dead space was added with PAV (5 mm Hg on PAV vs. 2 mm Hg on PSV) even though V_T and V_E increased more during PAV, albeit not significantly so. Thus, ventilatory demand was greater during added dead space on PAV than when it was added during PSV. Also, as pointed out by Mols et al[86] the two studies used different ventilators (Winnipeg Ventilator vs. Dräger Evita 4) with very different response characteristics.

Muscular exercise represents the most extreme form of ventilatory stimulation. The impact of PAV and PSV on exercise endurance and dyspnea in COPD patients was compared in one study.[61] PAV was found superior.

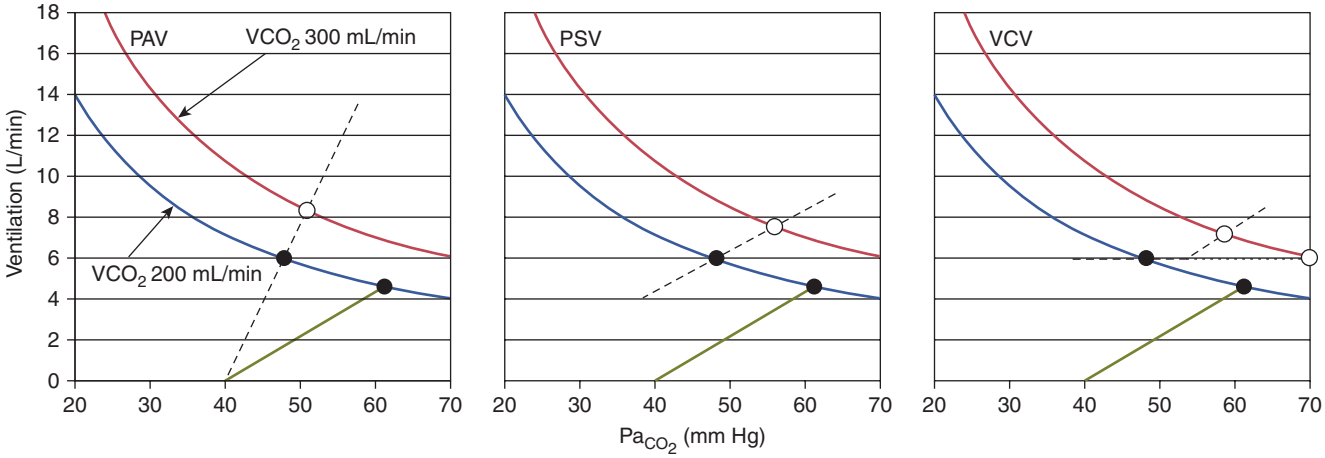

FIGURE 12-11 Responses to a 50% increase in ventilatory demand with proportional-assist (PAV), pressure-support (PSV), and volume-controlled ventilation (VCV). The unassisted ventilatory response to CO_2 is given by the *solid diagonal line* in each panel. The three modes were set during the low-demand period to produce the same ventilation and Pa_{CO_2} (*solid circles/dashed lines*). Because of the higher ventilatory-response slope on PAV, the new ventilation could be reached with a much smaller increase in Pa_{CO_2} (*open circles*). See text for more details.

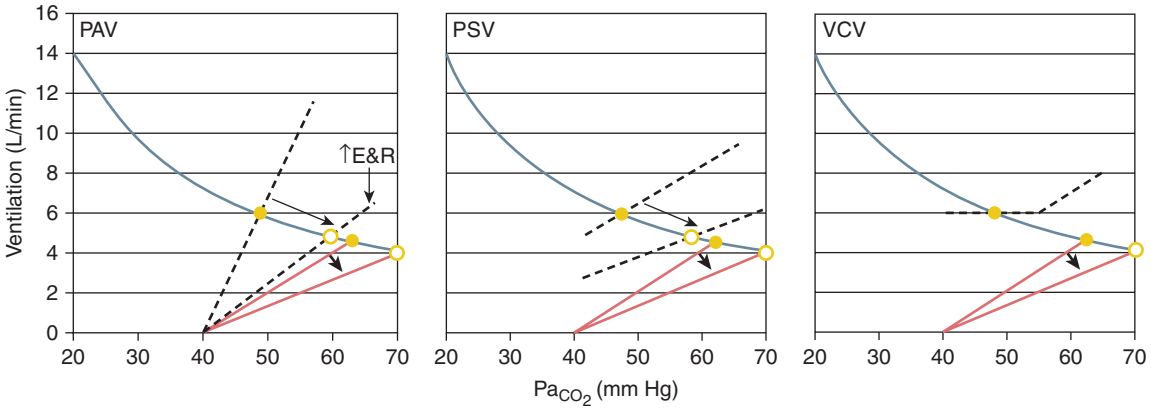

FIGURE 12-12 Responses to a 50% increase in elastance and resistance with proportional-assist (PAV), pressure-support (PSV), and volume-controlled ventilation (VCV). *Solid diagonal lines*: Unassisted ventilatory responses before and after the change in mechanics. *Dashed lines*: Ventilatory responses on assisted ventilation. All modes were set before the change to produce the same ventilation and Pa_{CO_2} (*solid circles/dashed lines*). As mechanics worsen, Pa_{CO_2} increases and ventilation decreases with PAV and PSV (*open circles*) but not with VCV.

RESPONSE TO CHANGES IN RESPIRATORY MECHANICS

Substantial changes in resistance (R) may occur from time to time.[56] Although similar information about elastance (E) is not available, there is every expectation that it also changes from time to time (e.g., secondary to changes in lung water, abdominal pressure, or atelectasis). Accordingly, it is important to consider the response to changes in mechanics.

Figure 12-12 illustrates the effect of a combined 50% increase in R and E. At a given Pmus, ventilation is inversely related to mechanical properties. Thus, a 50% increase in E and R reduces the unassisted ventilatory response to CO_2 to 67% of baseline.

An increase in R and E will reduce the slope of the ventilatory response under PAV for two reasons. First, percent assist is now lower. For example, if $\dot{V}_A$ were 70% E, and E increased by 50%, $\dot{V}_A$ would become 47% (70/150). This reduces the amplification factor (from 3.3 to 1.88 in this case; amplification factor = 100/[100 − percent assist]). Second, the slope of the ventilatory response that is being amplified also has decreased to 67% of the initial value. As a result, ventilatory response on PAV is now 38% of its initial value. $\dot{V}_E$ must fall, Pa_{CO_2} must rise, and distress may develop.

The situation is comparable with PSV. The already low ventilatory slope becomes even lower because the unassisted slope is now lower. Furthermore, the same pressure assist will be less effective in boosting V_T because of worse mechanics. As a result, the ventilatory response is displaced downward as well (e.g., Fig. 4 in ref. 22). A new steady state is reached at a lower $\dot{V}_E$ and higher Pa_{CO_2}. The changes in $\dot{V}_E$ and Pa_{CO_2} are comparable in the two modes.

By contrast, with VCV, a change in E and R will have no effect on ventilation. The ventilator will deliver the same V_T. Because there is no change in Pa_{CO_2}, there is no increase in effort. In this respect, therefore, VCV is superior to both PAV and PSV.

Grasso et al[22] compared responses to an increase in elastance with PAV and PSV. Surprisingly, they found that with PAV, V_T decreased less, RR increased less, and the increase in dyspnea was less. It is not clear why this was so. Regardless, the better results in this study were not expected and should not be viewed as intrinsic to PAV.

An improvement in mechanics also can create problems with PAV and PSV but not with VCV. If percent assist is high before the change, a reduction in R or E may cause the percent assist to exceed 100% of the new R or E, resulting in runaway. With PSV, improvement in mechanics at the same assist level will increase $\dot{V}_E$ and decrease Pa_{CO_2}. Asynchrony may appear.

In summary, on standard PAV, changes in mechanics may be followed by distress or excessive ventilator alarming (runaways). This emphasizes the need for using PAV systems equipped with algorithms that continuously monitor respiratory mechanics. This problem is mitigated by the fact that monitoring passive R and E continuously is possible in the PAV mode (see "Noninvasive Monitoring of Respiratory Mechanics, Pmus, and Work of Breathing" and "Commercially Available Proportional-Assist Ventilation Delivery Systems" below). Kondili et al[87] studied the response to changes in respiratory mechanics in ventilator-dependent patients using such a PAV delivery system (PAV+, Covidien). They found that the increase in all indices of respiratory effort was significantly less when the load was added during PAV+ than when added during PSV.

RESPIRATORY RATE IN DIFFERENT MODES

With all modes, patient RR will increase if assist is inadequate. Patient RR, however, is also sensitive to reflexes, independent of chemical drive. Continued inflation during neural expiration prolongs neural expiration and, by extension, reduces RR.[88–90] This reflex is less pronounced in ICU patients[90] than in alert patients[88,89] but is still quite evident. Its

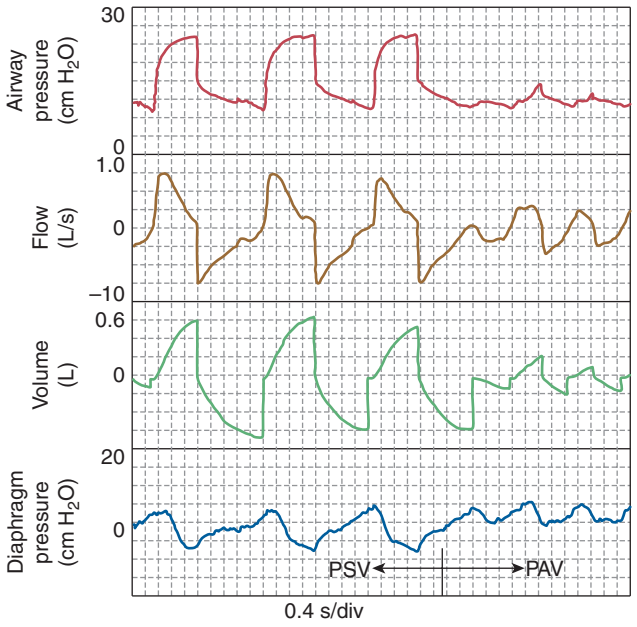

FIGURE 12-13 Transition from pressure-support ventilation (PSV) to PAV in the same patient as in Figure 12-7 with marked dynamic hyperinflation. Efforts were quite weak on PSV and barely succeeded in triggering the ventilator. On switching to PAV, the patient receives very little assist because, unlike PSV, assist cannot outlast inspiratory effort. Effort must increase in order to advance triggering and obtain adequate ventilation (see Fig. 12-7*B*). Note that respiratory rate increased suddenly on the switch. Because efforts were still quite weak and the response was immediate, the increase in rate was not caused by a high respiratory drive (i.e., distress) and almost certainly was reflexive in origin secondary to removal of inflation during neural expiration (see text).

gain varies widely among patients.[90] Figure 12-8 shows a very weak response. Note that patient RR was the same whether efforts occurred during inflation or deflation. In contrast, Figure 12-13 illustrates a strong response. Here, on PSV, ventilator cycle extended well into neural expiratory time. When PSV was discontinued, there was a marked increase in patient RR (from 20 to 33 breaths/min). This cannot represent distress because it occurred immediately, and diaphragmatic swings were still very low (approximately 5 cm H_2O). Thus, with PSV, nonsynchrony may reduce patient RR for reasons that have little to do with relieving distress. As a corollary, reduction in asynchrony, as would occur if PSV levels were reduced,[34,77] may result in acceleration of patient RR that is unrelated to distress. This is not a problem with PAV because the ends of patient and ventilator inspiratory phases are synchronized. Therefore, changes in RR on PAV reflect level of distress more reliably.

TIDAL VOLUME IN DIFFERENT MODES

As indicated earlier (under "Respiratory Rate and Breathing Pattern"), with PAV, V_T is determined by the patient, and the preferred V_T ranges from 4 to 15 mL/kg, with an average of 7 mL/kg.[33,34] With VCV, V_T is set without knowledge of the patient's preferred V_T. PSV is also usually adjusted to yield a given V_T. In either case, the set V_T almost always will be larger than necessary. For example, if V_T is set to 10 mL/kg, it will be greater than preferred V_T in most patients. In the others, it will be inadequate. If one individualizes the assist to comfort level, V_T still will be higher than with PAV for two reasons: first, when V_T is titrated to the lowest level consistent with comfort, the chosen V_T is greater than the average V_T during spontaneous breathing.[8,91] Second, if V_T or PSV level is set to comfort level at a given point, a change in ventilatory demand (see, e.g., Figs. 12-10 and 12-11) will cause it to become either excessive or too little later. If it becomes excessive, it will not be adjusted down. If it becomes inadequate (increase in demand), however, it will be increased and remain at the high level after, when demand decreases again. On average, V_T will be larger than if it were allowed to vary with demand (i.e., PAV).

Another peculiarity unique to PSV is that dynamic hyperinflation may cause tidal volume to be inversely related to inspiratory effort (see, e.g., Fig. 12-8). This is so because at a given PSV, the end-inspiratory volume, relative to passive FRC, at which the ventilator cycles off, in the absence of effort (Vth), is fixed.[77] A stronger effort will trigger the ventilator at a higher volume relative to FRC, leaving less difference between the onset of the breath and Vth (see inset of Fig. 12-8). With high PSV, it is possible to reduce chemical drive to very near the AT, resulting in very weak efforts (see, e.g., Fig. 12-8A). Triggering then can occur only when volume is very close to FRC. When a breath is triggered, volume must increase by a large amount before the ventilator cycles off. Large protracted V_Ts result (see Fig. 12-8A). If efforts increase, either spontaneously or after reducing PSV level, breaths can be triggered at a higher volume and hence closer to Vth. A small V_T will cause Vth to be reached. Once effort ceases, flow decreases to the cycling-off threshold, and the ventilator cycle ends. Synchrony is reestablished, but breathing becomes faster and shallower (see Fig. 12-8). Thus, paradoxically, under these conditions V_T is largest when effort is weakest, and changes in V_T no longer reflect effort.

This scenario can never happen with PAV in part because in the presence of dynamic hyperinflation it is not possible to reduce efforts to the very low levels that can be reached with high-level PSV (see "Dynamic Hyperinflation" below) and in part because the inflation cycle ends when patient effort ceases regardless of the end-inspiratory volume reached.

COMFORT

Comfort, of course, cannot be compared in obtunded patients. Whenever PSV and PAV were compared in alert patients with respiratory distress, however, PAV was preferred.[23,38,39]

HEMODYNAMIC EFFECTS

Mechanical ventilation has complex effects on the circulation (see Chapter 36). Data comparing hemodynamics on PAV with other modes are very limited. Patrick et al[92] found

that cardiac output was 22% higher during PAV than during VCV in eight patients with septic shock (see Fig. 14-9 in ref. 93). Blood pressure also was higher. These results likely were secondary to lower airway pressure, and hence mean intrathoracic pressure, during PAV promoting higher venous return. Kondili et al[94] compared hemodynamics on PAV and PSV when mean airway pressure was matched in the two modes. Cardiac index was slightly but significantly higher during PAV. There is no information on the effect of PAV versus other modes in patients with left-ventricular dysfunction. Such information is needed because, in theory, a lower intrathoracic pressure may not be helpful in these patients (higher afterload).

Clinical Consequences of the Physiologic Differences

PATIENT MANAGEMENT ISSUES

Noninvasive Monitoring of Respiratory Mechanics, Pmus, and Work of Breathing. PAV has unique features that allow estimation of passive mechanics noninvasively.[56,57] In PAV, end of ventilator cycle occurs during the declining phase of inspiratory Pmus (see Figs. 12-1 and 12-14A). A brief end-inspiratory occlusion coincides with the terminal part of the declining phase and the decline of Pmus after the occlusion presents as a rise in airway pressure during the first part of occlusion (Fig. 12-14A). This phase ends shortly after the onset of occlusion, and its end is readily recognizable as the rise in airway pressure stops (Fig. 12-14A).[57] Paw at the end of this phase provides the passive recoil pressure associated with occluded volume. This is not the case with VCV or PSV because the end of the ventilator cycle may occur during an active inspiratory or expiratory phase. This approach has been validated,[57] and an automated version was included in new 840 PAV+ software (Covidien). A multicenter study confirmed its reliability ($r^2 = 0.92$ compared with elastance measured concurrently by esophageal catheter[95]). A more recent study found a significant correlation between elastance measured on controlled mechanical ventilation and that measured during PAV.[96] There was, however, much scatter. This can be explained by the fact that, unlike the previous study,[95] the two measurements were separated by hours and were obtained with different modes and breathing patterns.

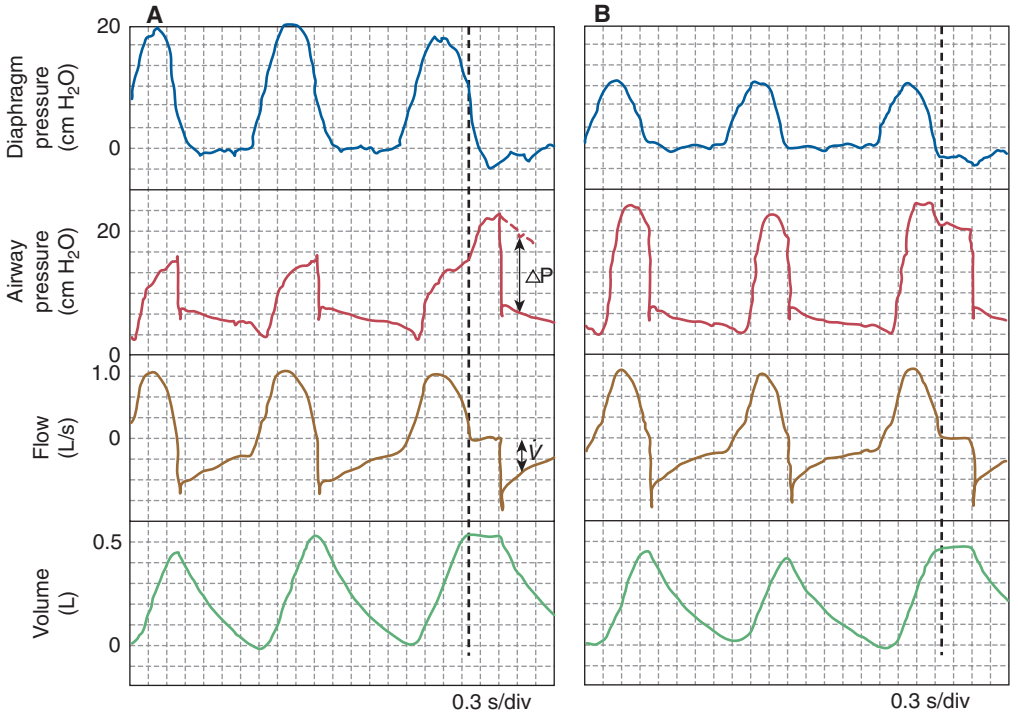

FIGURE 12-14 Tracings from a patient on the 840 PAV+ option (Covidien) illustrating the random brief end-inspiratory occlusions. **A.** Forty percent assist. **B.** Eighty percent assist. Note the minimal change in breathing pattern and lower amplitude of diaphragmatic pressure swings. Airway pressure rises early during the occlusion in panel A, reflecting the fact the inspiratory phase ended during the declining phase of inspiratory pressure (*vertical dashed line*). During occlusion, airway pressure is inversely related to muscle pressure. By the end of occlusion, airway pressure had plateaued, corresponding to inspiratory pressure reaching its baseline level. In panel B, there is no rising phase during the occlusion because inspiratory pressure had returned to baseline already; at high assist, the inspiratory phase tends to end at a later point on the declining phase.[76] Note that airway pressure is approximately the same at end occlusion in both cases. Elastance is determined from ([end-occlusion pressure – positive end-expiratory pressure]/V_T). Expiratory resistance is determined from flow early in expiration and ΔP (the difference between airway pressure and elastic recoil at the same point). Elastic recoil is obtained from end-occlusion pressure minus an amount corresponding to the volume expired and elastance (*dotted line*).

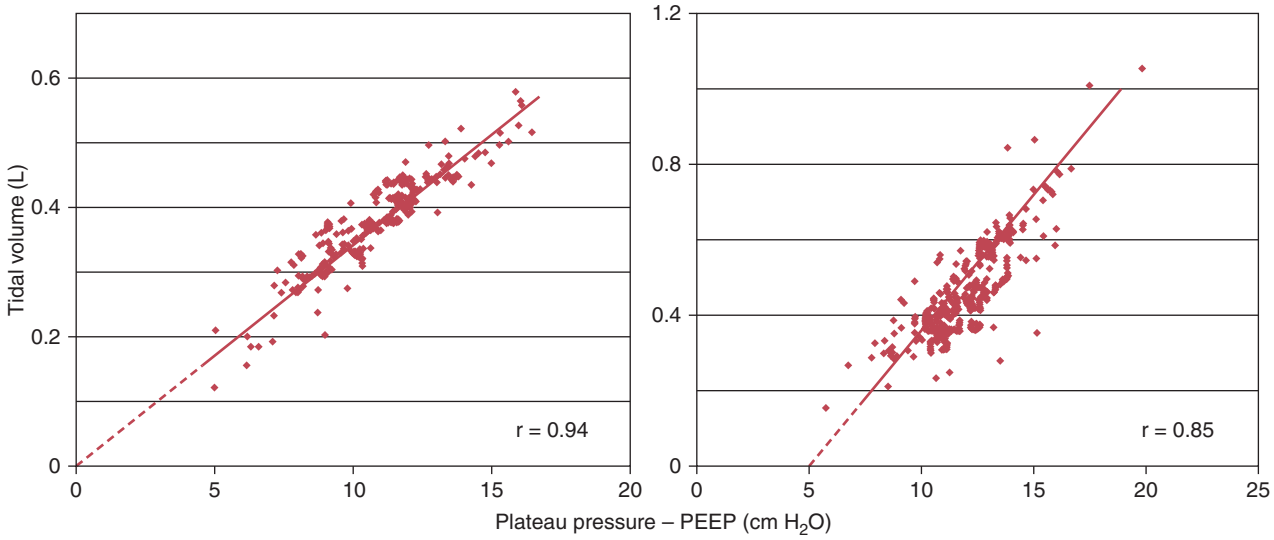

FIGURE 12-15 Relationship between occlusion pressure and tidal volume. Data collected over approximately an hour of recording with randomly applied occlusions. The range of volumes was the result of spontaneous tidal volume variability. In both cases, a highly significant correlation was obtained. **A.** Pressure intercept not different from positive end-expiratory pressure (PEEP), indicating no dynamic hyperinflation. **B.** Patient with dynamic hyperinflation. Note the positive intercept.

Because V_T is usually variable on PAV, random end-inspiratory occlusions frequently produce a wide range of V_Ts and plateau pressures from which confident estimates of the slope and pressure intercept can be obtained (Fig. 12-15). A positive intercept indicates either dynamic hyperinflation or a respiratory system that is stiffer in the lower part of tidal ventilation (see "Nonlinearity in the Pressure-Volume Relationship within the Tidal Volume Range" below). Because both abnormalities respond to increasing positive end-expiratory pressure (PEEP), changes in intercept can be used to set the PEEP level associated with best elastance. This process (display of plateau pressure vs. V_T) can obviously be incorporated in PAV delivery systems to help with the management of dynamic hyperinflation.

Because Paw at the end of brief occlusions reflects passive recoil at end inspiration, it is possible to estimate passive *expiratory* resistance[97] (see Fig. 12-14A). This approach was incorporated in the 840 PAV+ option (Covidien). Its main limitation is that expiratory resistance in the PAV+ option is measured around the time of peak expiratory flow. Although this is acceptable in patients without severe COPD, it results in *underestimation* of resistance in COPD patients who display a sharp expiratory flow spike in early expiration (see, e.g., Fig. 12-5A). This early flow spike incorporates a large component derived from central airway collapse at the beginning of expiration and does not reflect the flow of air from the alveoli.[98,99] Because alveolar flow is overestimated at this point, and flow is the denominator of the resistance equation, resistance can be markedly underestimated in the presence of this artifact. On the other hand, if the early expiratory flow spike is avoided, and resistance is measured later in expiration, resistance may be overestimated because of flow limitation. Thus, in the presence of severe expiratory flow limitation with an early flow spike, adjustment of PAV assist using an expiratory resistance value is not recommended. An alternate method that estimates inspiratory resistance from brief pressure pulses during inspiration has been described and validated.[56]

Apart from overcoming the major practical limitation to implementing PAV, namely, knowing passive mechanics, continuous monitoring of passive R and E should help in monitoring disease progression and in the timely identification of complications (e.g., changes in lung water, accumulation of secretions, and bronchospasm). If a patient's condition deteriorates, it should be possible to sort out what happened to mechanics by observing recent trends in R and E. Furthermore, when R and E are known, it is possible to calculate patient-generated pressure (Pmus) and work of breathing in real time. Real-time estimates of Pmus can be used to trigger the ventilator, thereby eliminating the major remaining technical problem with PAV, namely delayed triggering in the presence of severe hyperinflation.

Improved Reliability of Ventilator Rate as a Measure of Distress and Weaning Failure. As indicated earlier (under "Physiologic Consequences of Operational Differences"), an increase in ventilator rate is not specific to distress in PSV and VCV. In either mode, a simple increase in effort, occurring spontaneously or as result of reduction in assist, may decrease ineffective efforts and result in an artifactual, sometimes dramatic increase in ventilator rate (see Fig. 12-8). Although this artifact can be identified from flow and Paw tracings,[34] considerable expertise is required. Furthermore, even if true RR is counted and found to have increased, the

increase may be reflexive and not secondary to true distress (see "Respiratory Rate in Different Modes" above). With PAV, ineffective efforts are very rare, and inflation extends minimally into neural expiration. Accordingly, ventilator rate faithfully reflects patient rate.[20,34,96] When it increases, distress can be inferred more reliably. Because a substantial increase in ventilator rate following a reduction in assist is used commonly to infer continued ventilator dependence, this feature of PAV should reduce false weaning failure verdicts.

The occurrence of an absolute RR of more than 35 breaths/min during a weaning trial is used commonly as a sign of weaning failure.[102,103] Yet some patients breathe at rates greater than 35 breaths/min, even when assist is very high and efforts are very weak (see Fig. 12-8A).[34,100] Thus, in some patients, a high absolute RR need not indicate distress. PAV can be used to determine whether absolute tachypnea observed during a weaning trial is distress-related. Failure of RR to decrease as PAV assist is increased to high levels would indicate that tachypnea is not distress-related (see "Respiratory Rate and Breathing Pattern" above). Such a test would not be feasible with other modes because in such patients (high intrinsic RR), ventilator or even patient rate invariably will decrease as assist increases because of nonsynchrony. It remains to be determined, however, whether tachypnea that is not relieved by ventilator support is a reason to continue mechanical ventilation.

Choice of Ventilator Settings. With VCV and PSV, one does not know what is appropriate for each patient. Given what we know now about variability in undistressed (preferred) breathing pattern and time-to-time changes in demand, no general guidelines will be suitable for all patients; in most cases, the assist delivered will exceed what is necessary (see "Tidal Volume in Different Modes" above). With PAV, there is no uncertainty about what the patient wants or needs or how to set the level of assist. There is only one variable to consider (percent assist), and when percent assist is increased to a point where V_T and RR no longer respond to further increases, the values observed are what the patient needs.

This apparent simplicity of setting PAV was mitigated early on by a number of practical limitations, which proved problematic when simple PAV delivery systems were used (see "Limitations" below). These included the need to measure respiratory mechanics frequently and frequent alarming when the patient takes a large tidal volume or during runaways. To compound matters, troubleshooting these problems requires considerable expertise. These problems have now been largely overcome through introduction of methods for continuous monitoring of respiratory mechanics during PAV application, modification of alarm systems to allow for the spontaneous variability of tidal volume during PAV, and measures to avoid and limit runaways. A recent study[101] on critically ill patients compared the number of interventions (ventilator settings and sedatives, analgesics and vasoactive medication dose manipulations) when patients were on PSV with the number while using a PAV system equipped with the above features (PAV+, Covidien). The number of interventions was significantly less on PAV+.

CLINICAL OUTCOME

It is reasonable to inquire as to whether the physiologic advantages of PAV translate into better clinical outcome. Unfortunately, information about outcomes is very scanty. This is so chiefly because, until very recently, available ICU ventilators (Winnipeg ventilator and Dräeger Evita) were not equipped with means to provide smooth, nuisance-free PAV delivery over the extended periods required for outcome studies. It is hoped that with newly available systems such studies will be carried out. In the meantime, one is limited to speculation about how physiologic advantages may improve outcome.

Noninvasive Ventilation. Two studies compared outcomes with PSV and PAV in acute respiratory failure.[38,39] Both found greater comfort and acceptance rate and a lower incidence of facial ulcers and conjunctivitis with PAV. One study found faster improvement in respiratory rate and Pa_{CO_2} with PAV.[38] Neither study found a difference in intubation rate. Both studies, however, were seriously underpowered in this respect. When faced with a choice between severe distress and a somewhat uncomfortable way to relieve it, most people will opt for relief of dyspnea. Thus, nonacceptance rate with PSV is low (15% vs. 3% in PAV[39]). Furthermore, intubation rate in such patients is also low (approximately 20% to 30%[38,39]). It is estimated that more than 1000 patients are required to determine whether a new intervention reduces rate of intubation.[39] Rusterholtz et al randomized thirty-eight patients with acute cardiogenic pulmonary edema to receive noninvasive PAV or continuous positive airway pressure.[41] They found no difference in failure rate (seven in each group) as defined by the onset of predefined intubation criteria, severe arrhythmias, or patient refusal. Again, the study size is insufficient to establish differences in clinical outcome.

Clinical Outcome in the Intensive Care Unit Setting. PAV may improve clinical outcome in a number of ways:

1. *Sedative use.* Most ICU patients are heavily sedated if they are not spontaneously unconscious. Sedatives may affect clinical outcome adversely.[104,105] It is not clear to what extent patient–ventilator interactions contribute to need for sedation. To the extent that they may, PAV may result in less sedative use and reduction in sedation-related complications.
2. *Impact on sleep.* Poor patient–ventilator interaction may affect sleep adversely in the ICU.[58,106] Sleep deprivation may increase blood pressure, depress immune function, and promote a negative nitrogen balance, actions that can affect morbidity adversely (for review, see ref. 106). By improving patient–ventilator interaction, PAV may help to reduce these complications. Bosma et al[107] monitored sleep for two consecutive nights in thirteen patients in the

weaning phase. PAV and PSV were each used on one night and the order was randomized. The number of arousals and awakenings per hour of sleep was significantly lower on PAV and there was significantly more slow wave (deep) and rapid eye movement sleep. Interestingly, the number of arousals correlated with number of asynchrony events, which was greater with PSV.

3. *Barotrauma and ventilator-induced lung injury.* Excessive lung distension may result in further lung injury (see Chapter 44) and possibly multisystem organ failure[108] (see Chapter 42). There are a number of reasons why V_T will, on average, be smaller in PAV (see "Tidal Volume in Different Modes" above). Furthermore, neural reflexes terminate inspiratory muscle activity if lung distension exceeds a certain threshold that is well below physiologic total lung capacity (TLC) (e.g., Hering-Breuer reflex). For example, when tidal expansion approaches TLC during exercise, further increases in ventilation are achieved automatically via increases in RR.[109] Because the assist terminates automatically with PAV when respiratory muscles are inhibited, overdistension beyond physiologic TLC (transpulmonary pressure approximately equal to 40 cm H_2O) is virtually impossible (except in patients with denervated lungs, such as after bilateral transplantation). Figure 12-16 shows average plateau pressure on PAV in forty-eight patients with a wide range of elastance. Plateau pressure was less than 30 cm H_2O above PEEP in all, and less than 20 cm H_2O above PEEP in all but four. These findings were confirmed in another recent study.[96] Considering that plateau pressure also includes chest wall recoil, lung distension was even less. It is reasonable to expect that this behavior will reduce barotrauma. It also may make it possible to achieve the objectives of permissive hypercapnia (small V_T) without the need for sedation or even hypercapnia (because RR increases automatically as end-inspiratory volume approaches TLC).

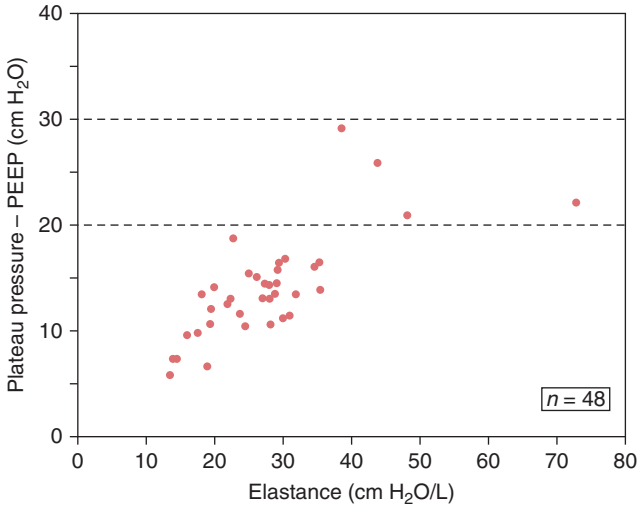

FIGURE 12-16 Average plateau pressure (minus PEEP) in forty-eight patients with a wide range of elastance.

4. *Weaning.* The greater reliability of ventilator rate as a measure of distress (see "Improved Reliability of Ventilator Rate as a Measure of Distress and Weaning Failure" above) should decrease instances of false ventilator dependence. Tachypnea as the sole reason for a declaration of weaning failure accounted for 37% of all weaning failures in two large trials[102,103] (A. Esteban, personal communication). It is tempting to speculate that some of these patients were not ventilator-dependent, so their identification under PAV will reduce ventilator time.

   With PSV and VCV, Pa_{CO_2} may decrease to very near the AT, resulting in extremely weak efforts, particularly during periods of reduced demand (see "Physiologic Consequences of Operational Differences" above). With VCV in the assist-control mode, it is also possible to produce protracted apnea. With PAV, a modest to moderate level of activation is present at all times, including during sleep. The likelihood of disuse atrophy of respiratory muscles (see Chapter 43) may be less, and this may facilitate weaning.

   Most ineffective efforts occur during mechanical expiration. Accordingly, the inspiratory muscles are being lengthened during their activation. This type of contraction has been associated with muscle injury.[110,111] Because ineffective efforts are very common with PSV and VCV[84] but not with PAV, this type of injury may be mitigated.

5. Continuous noninvasive monitoring of passive mechanics, made possible by PAV, may lead to better PEEP management and early detection and management of complications.

   To date there has been only one study that compared clinical outcome with PSV and PAV in critically ill ventilated patients.[96] Xirouchaki et al[96] randomized 208 critically ill patients, mechanically ventilated on controlled modes for at least 36 hours, to receive either PSV (n = 100) or PAV + (n = 108). Specific written algorithms were used to adjust the ventilator settings in each mode. The patients were observed for 48 hours following transition from controlled ventilation unless they met predefined criteria either for switching back to controlled modes (failure criteria) or for breathing without ventilator assistance. Failure rate was significantly lower with PAV+ (11.1% vs. 22.0%, P = 0.040, odds ratio [OR] 0.443, 95% confidence interval [CI] 0.206 to 0.952) and the proportion of patients exhibiting major dyssynchronies was also significantly lower (5.6% vs. 29.0%, P < 0.001).

COMMERCIALLY AVAILABLE PROPORTIONAL-ASSIST VENTILATION DELIVERY SYSTEMS

The BiPAP Vision (Respironics) is the only ventilator currently suitable for noninvasive use. The Vision is equipped with leak-compensation algorithms. It also has excellent response characteristics and trigger sensitivity and has

performed very well in several clinical trials.[21,23,38,39] The Vision offers pathology-specific default startup settings as well as custom settings.

Until recently, the Evita ventilator (Dräeger) was the only commercial ICU ventilator capable of delivering PAV. It is a basic PAV system with no capability to monitor passive mechanics in real time and with standard alarms. As indicated earlier, such basic systems (including the Winnipeg ventilator) have proven difficult to use except by experts and for short periods.

Covidien's 840 ventilator currently has a PAV+ option. The ventilator monitors mechanics continuously by applying random brief end-inspiratory occlusions (see Fig. 12-14). The results have been validated.[95] In addition, algorithms were added to limit the maximum elastic assist to a set level and the alarms were modified to allow for pressure and volume limits to be reached occasionally without the alarms sounding off. With this option, the maximum possible airway pressure, including PEEP, is 35 cm H_2O. This may be a limitation in a few patients receiving high levels of PEEP whose resistance is also high. Another limitation is that the resistance used to adjust the flow assist during inspiration is measured around peak expiratory flow. In the presence of an early expiratory flow spike (as in very severe COPD), this measurement can greatly underestimate the patient's true resistance and result in underassist (see "Noninvasive Monitoring of Respiratory Mechanics, Pmus, and Work of Breathing" above).

LIMITATIONS

The following mechanisms may result in excessive sounding of alarms and occasional instances in which patients are in distress despite a high percent assist. Fortunately, the underlying reasons for these difficulties are well understood, and auxiliary algorithms have become available that should mitigate most, if not all, of these problems.

Runaway Phenomenon

Despite its ominous-sounding name, the runaway presents no danger in modern ventilators with properly set pressure and/or volume limits. It is simply a nuisance in that, when it happens, it can trigger alarms, which can be annoying to staff and may promote anxiety in alert patients. Nonetheless, it is important to understand its mechanism and recognize its features, as this will be useful in managing PAV in patients who require a very high level of assist. The nuisance factor is much reduced in delivery systems with smart alarms, which allow for pressure and volume limits to be reached occasionally without the alarms sounding off.

Runaway occurs when the volume assist component (%assist [estimated V × estimated E]) exceeds the actual elastic recoil pressure of the respiratory system (actual V × actual E) and/or the flow assist component of the assist (percent assist [flow × estimated R]) exceeds the actual pressure dissipated against respiratory resistance (actual flow × actual R). In modern PAV delivery systems in which the percent assist is used to adjust PAV, the percent assist cannot exceed 100. Thus, runaway occurs when flow and its integral, volume, are overestimated (e.g., uncompensated leaks) and/or estimated E and/or estimated R are greater than the actual values.

The runaway pattern depends on whether the resistive or elastic component is overassisted. With elastic overassist, the elastic pressure provided exceeds actual elastic pressure by an amount that increases as a function of volume. If flow is not overassisted, the resistive pressure provided is less than actual resistive pressure by an amount that is related to flow. So long as excess elastic pressure is less than the deficit in resistive pressure, a runaway does not occur because total applied pressure (Paw) is less than the sum of actual resistive and elastic pressures. Runaway occurs when excess elastic pressure cannot be absorbed by the deficit (or reserve) in resistive pressure.

With elastic overassist, excess elastic pressure increases progressively during inspiration because volume rises throughout. By contrast, reflecting flow pattern, deficit/reserve in resistive pressure is highest in early and middle inspiration and decreases later. The point at which elastic overassist will exceed the reserve in resistive pressure (i.e., runaway) necessarily will occur late in inspiration. When VA is just greater than E, the runaway will occur at the very end of the inspiratory phase when flow is near zero (Fig. 12-17A). This fact has been put to use to measure actual patient E in sleeping or obtunded patients.[6,17,93] VA is dialed up in small steps until the characteristic runaway pattern appears (Fig. 12-17B). At this point, VA is just greater than E. The more the elastic overassist, the sooner, in the inspiratory phase, runaway will develop (Fig. 12-17). Likewise, runaway occurs earlier if the difference between actual R and percent assist × estimated R is small because the deficit in resistive pressure will be less and more readily overcome by excess elastic pressure.

Once a runaway develops as a result of elastic overassist pressure and volume will continue to rise beyond the end of inspiratory effort (see Fig. 12-17B) until the cycle is stopped by (a) a set pressure or volume limit, or (b) volume approaching the stiffer upper part of the pressure–volume curve of the respiratory system (Fig. 12-18A). The latter results in a progressive increase in actual elastance that cancels the overassist. Thus, the nonlinearity of the pressure–volume relationship of the respiratory system acts as natural protection against excessive overdistension.

By analogy, with resistive overassist, runaway will occur when the excess resistive pressure provided by the ventilator exceeds the deficit/reserve in applied elastic pressure. This point invariably will occur at the very beginning of inspiration, where volume, and hence elastic assist, is near zero, and there is no possibility for the elastic deficit/reserve to absorb the excess resistive pressure.

The pattern of flow runaway depends on whether the pressure-flow relation is linear (Fig. 12-19). A linear

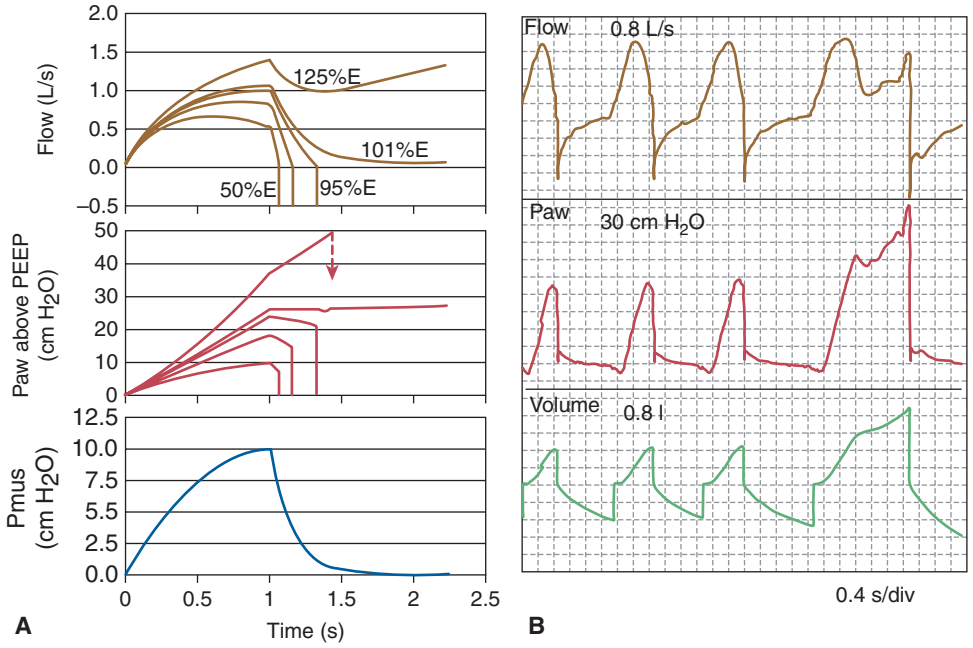

FIGURE 12-17 Runaway. **A.** Model simulation of effect of increasing percent of elastance used for volume assist (VA). Note that as soon as VA exceeds elastance (101% E), flow fails to return to zero at the end of inspiratory phase. At higher levels, the runaway begins earlier, and flow and pressure increase progressively until the cycle is terminated by a physiologic or ventilator limit. **B.** Patient with COPD and moderate dynamic hyperinflation, 90% assist. Note the spontaneous occurrence of a runaway breath (last breath). The pattern is intermediate between the 101% and 125% in the *left panel*. Note that in the breath preceding the runaway, exhaled volume exceeded inhaled volume, suggesting less dynamic hyperinflation at the beginning of the runaway breath. See text for more details. The runaway breath was terminated by the ventilator's high-pressure limit.

pressure-flow relation occurs when breathing via the mouth, thereby excluding the nonlinear nasal pressure-flow relation, or when the nonlinear relation of the endotracheal tube is offset independently by automatic tube compensation (ATC). Here, as flow assist just exceeds actual resistive pressure, there is a very rapid increase in flow and pressure that can be aborted only by a ventilator limit (see Fig. 12-19A). The inflation phase is very brief. By contrast, when the pressure-flow relation is nonlinear, there is no discrete change as FA exceeds R. Rather, change is gradual and consists of a progressive shift in peak flow to earlier points in inspiration (see Fig. 12-19B). Flow pattern at high levels of overassist resembles that of PSV. The rapid increase in flow early in inspiration may truncate the breath, however, and sound an alarm if peak pressure limit is reached.

The development of algorithms to continuously monitor mechanics and their incorporation in commercial PAV delivery systems has greatly reduced this problem when such systems are used.

Runaways need not occur on every breath (see, e.g., Fig. 12-17). Because true elastance (E) may vary breath by breath (see "Dynamic Hyperinflation" and "Nonlinearity in the Pressure–Volume Relationship within the Tidal Volume Range" above), estimated E may exceed actual E in some breaths, even though it is less than average E. Assume that average E, determined from a number of end-inspiratory occlusions, is 30 cm H_2O/L, with a range of 24 to 36 cm H_2O/L. At 90% assist (i.e., 27 cm H_2O/L), some breaths may develop runaway. The higher the percent assist, the more frequent are the runaways.

Accuracy and Stability of Respiratory Mechanics Values

Knowledge of R and E is not necessary in noninvasive applications. Feedback from the alert patient ensures that VA and FA are appropriate. In the usually obtunded ICU patient, subjective feedback is not possible, and setting PAV properly requires knowledge of passive mechanics. This has created problems for two reasons: first, measuring passive mechanics in the usual way (under sedation, hyperventilation, and/or paralysis) is cumbersome, requires expertise, cannot be done frequently, and the results may not reflect the E and R values on PAV (because of differences in V_T, flow rate, dynamic hyperinflation, and so on). Second, passive mechanics frequently change (see "Response to Changes in Respiratory Mechanics" above). Values that are accurate at one point may become inaccurate later.

When differences between actual and assumed R and E values are small (e.g., <25%) and percent assist is not high, the impact is operationally insignificant. For example, with a 20% error at 50% assist, actual assist will be 40% or 60% depending on the direction of the error. Either value is

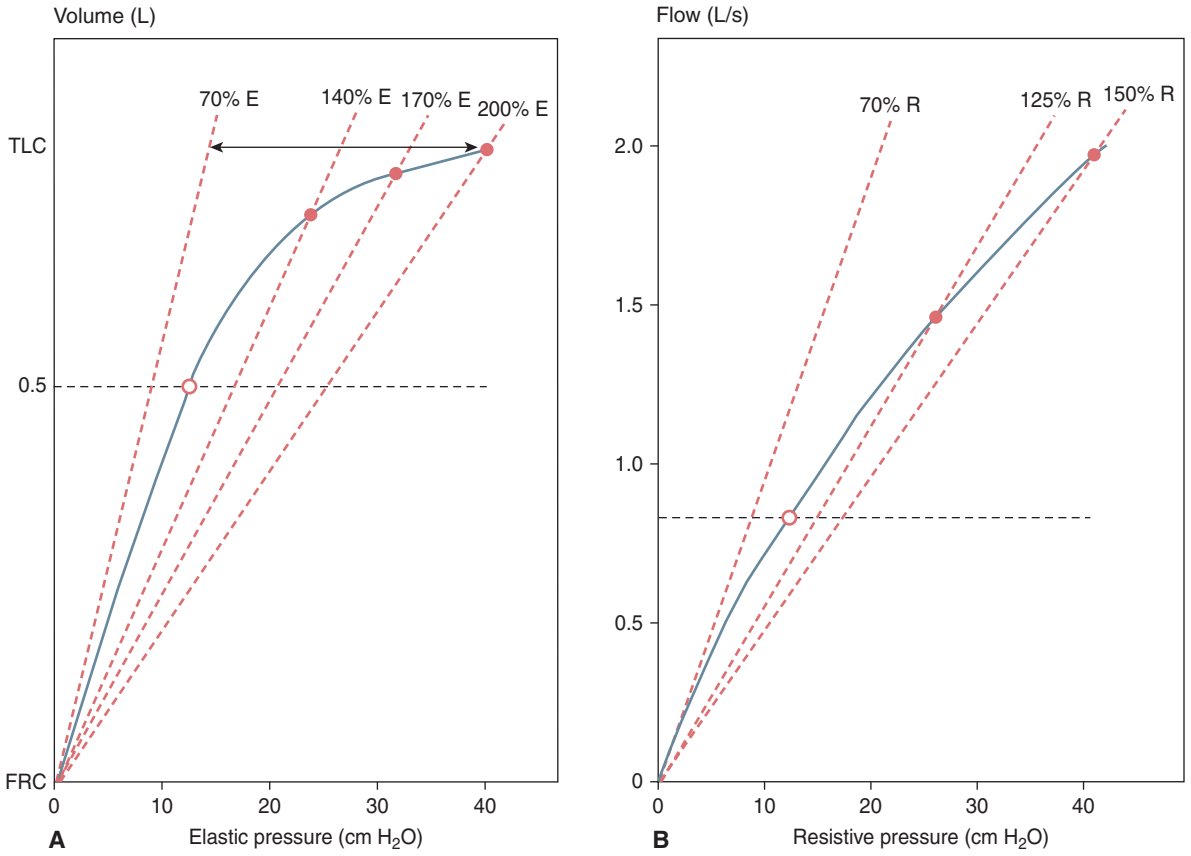

FIGURE 12-18 Physiologic limits to runaway. **A.** Typical pressure–volume curve in an average ventilated patient. Elastance (E) at a tidal volume (V_T) of 0.5 L (the average V_T on PAV in this case) is 25 cm H_2O/L (*open circle*). *Left diagonal line*: Volume assist = 70% E. The elastic pressure delivered by the ventilator is less than elastic recoil at all volumes (no runaway). The next three diagonal lines represent progressively increasing overassist. An excess elastic pressure is delivered in the spontaneous tidal volume range (horizontal distance between diagonal lines and pressure–volume line), forcing a volume runaway. Because of the stiffening of the system near TLC, however, excess pressure decreases as volume increases. Runaway ends when the diagonal line meets the pressure–volume line because there is no longer an excess pressure. Note that even with a marked overassist (200% E), runaway stops at an elastic pressure of 40 cm H_2O, corresponding to a physiologic TLC value. **B.** Typical pressure-flow relationship in an average patient (airway resistance is 10 cm H_2O/L/s with a no. 8 endotracheal tube). Total resistance at a flow of 0.8 L/s is 15 cm H_2O/L/s. A flow assist in excess of this value will cause a flow runaway (*right two diagonal lines*). Because the pressure-flow relationship is not linear, excess resistive pressure decreases as flow increases. Flow runaway stops when the diagonal line meets the pressure-flow line. Excessive overdistension of the lung is also mitigated in this case by nonlinearity of the pressure–volume curve. Note that if VA is less than E (*left diagonal line, panel A*), the deficit in elastic pressure increases dramatically near TLC (*horizontal arrow, panel A*). This helps offset the excess resistive pressure and aborts the flow runaway below physiologic TLC. *FRC*, functional residual capacity; *TLC*, total lung capacity.

consistent with proper functioning, and if the assist is insufficient, there is room to increase it. By contrast, with a 50% error at 80% assist, actual assist will be 40% or 120%. In the former case, assist may be insufficient, resulting in distress when the patient is "supposedly" receiving high assist, and there is little room for further increases. In the latter case, runaway will develop, with frequent sounding of the alarms, even though it should not happen (percent assist <100). In my opinion, the discrepancy between assumed and actual R and E is the most important source of implementation difficulties. Fortunately, this has now been largely resolved (see "Noninvasive Monitoring of Respiratory Mechanics, Pmus, and Work of Breathing," and "Commercially Available Proportional-Assist Ventilation Delivery Systems" above).

Leaks

Leaks affect PAV delivery in much the same way as overestimation of E and R does. For example, if half the gas leaving the ventilator leaks out, assist will be twice that intended, or analogous to 100% overestimation of E and R. Thus, the magnitude of overestimation is related directly to the magnitude of the leak. As in the case of overestimation of E and R (see preceding section), a small leak will not have much impact if percent assist is low or moderate and will cause runaway if assist is high. Large leaks would result in runaway at all but the lowest assist levels.

In noninvasive applications, leaks can be huge. For this reason, noninvasive PAV delivery systems must be equipped

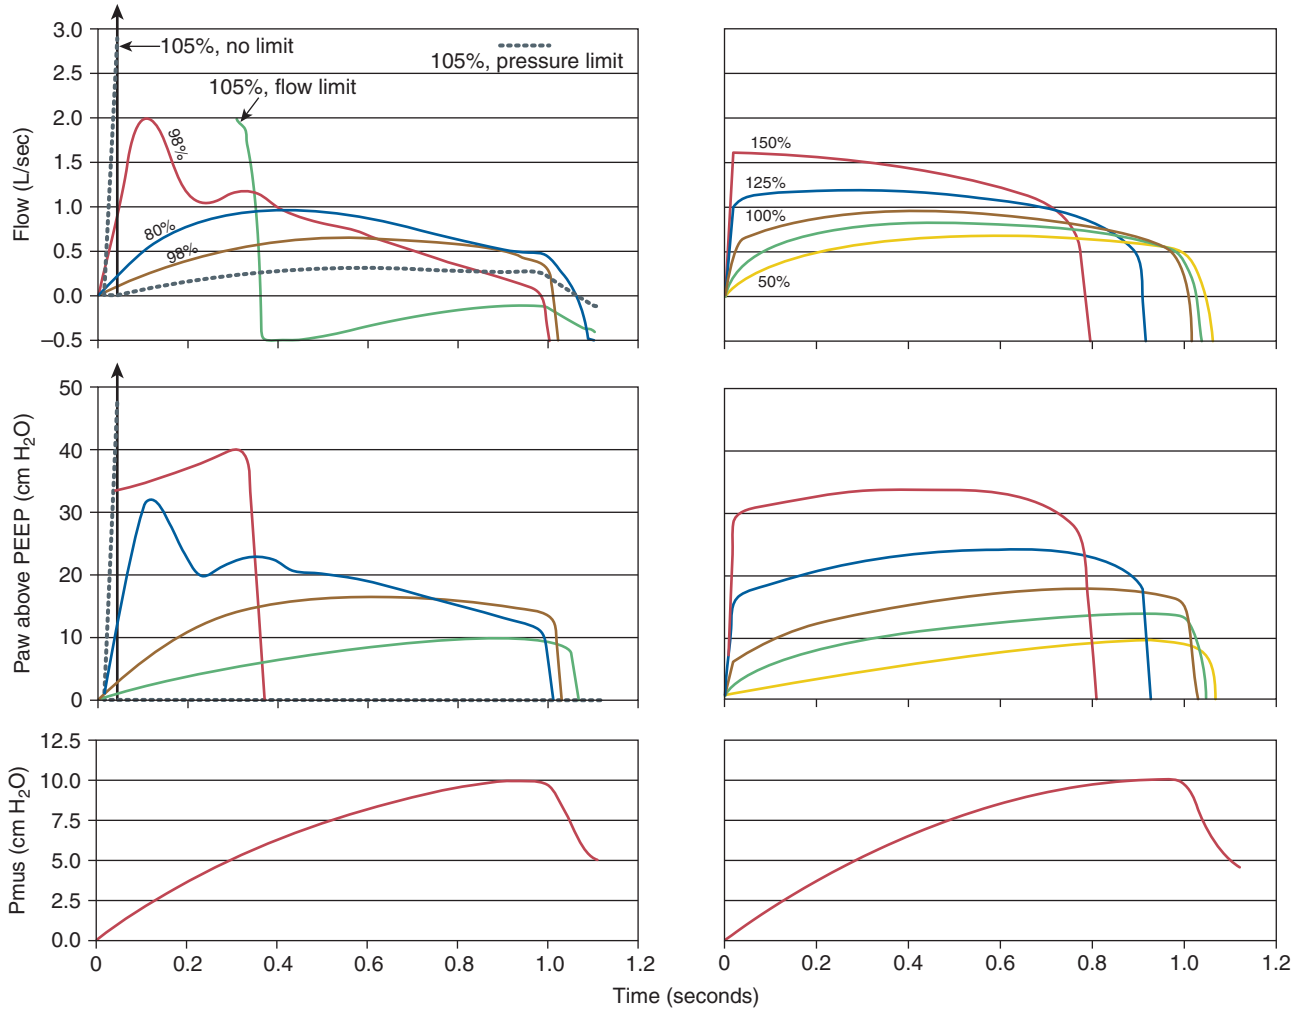

FIGURE 12-19 Patterns of flow runaway. Percent denotes ratio of flow assist to resistance at a reference flow (0.5 L/s in panel B). **A.** Linear pressure-flow relationship. FA is increased in steps beginning with 50% R. As the assist approaches 100% R, some oscillations become apparent. At just above 100% R, there is a sudden change in response. Without any ventilator limits, flow and pressure increase very rapidly to extremely high levels at the beginning of inspiration. Termination of runaway depends on ventilator limits. With activation of peak-pressure limit, the cycle is aborted rapidly. If the maximum flow capability of the ventilator (e.g., 2 L/s) is reached before the peak-pressure limit, the cycle continues a while more at the maximum flow and then self-terminates rapidly. With a constant resistance, therefore, transition of assist to above 100% is abrupt. **B.** Nonlinear pressure-flow relationship (e.g., in the presence of an endotracheal tube). Runaway is blunted by the increasing resistance at higher flow (see Fig. 12-18B). There is no clear change in response at 100% assist. Rather, change is gradual and consists of a progressive shift in peak flow to earlier points in inspiration. *Paw*, airway pressure; *Pmus*; respiratory muscle pressure.

with leak-compensation algorithms. In the ICU setting, leaks are usually very small, except in bronchocutaneous fistulas. Nonetheless, checking for leaks should be undertaken if alarms begin sounding excessively when they did not before.

Inclusion of automatic mechanics in PAV delivery systems essentially should eliminate leak-related problems. Thus, when a leak exists, the end-inspiratory occlusion technique (see Fig. 12-14) will underestimate E by an amount corresponding to the leak (provided inspired volume is used to compute E). This should offset the error at the ventilator level. Likewise, the pulse technique (resistance)[56] will underestimate inspiratory resistance in the presence of leaks, thereby offsetting the pressure-delivery error at the ventilator level.

Dynamic Hyperinflation

Dynamic hyperinflation (DH) presents occasional implementation difficulties, particularly when severe and associated with marked respiratory muscle weakness. Thus:

1. By definition, DH means that elastic recoil pressure is greater than zero at inspiratory onset. Inspiratory muscles must generate enough pressure to offset this elastic recoil before the ventilator is triggered (see, e.g., Figs. 12-7 and 12-8). Therefore, by the time the ventilator is triggered, a finite fraction of the patient's inspiratory phase will have elapsed. This delay is a function of magnitude of DH and the rate of rise of Pmus (see Fig. 12-7).

When DH is large (e.g., 10 cm H_2O in Fig. 12-7A) and the rate of rise of Pmus is low, triggering may not occur until near the end of inspiratory effort (see, e.g., Fig. 12-7A). In PSV and VCV, once triggering occurs, a substantial breath will be delivered. Although volume delivery will be almost entirely during the patient's expiratory phase, adequate ventilation nonetheless will be delivered, making it possible for chemical drive to remain low. In PAV, the ventilator will provide support only for the remaining duration of inspiratory effort. When triggering is much delayed, the duration of support may be very brief, resulting in inadequate ventilation (see, e.g., Fig. 12-13). The only way the patient can receive reasonable ventilation is to increase the rate of rise of inspiratory effort in order to advance triggering (see, e.g., Fig. 12-7B). This will occur naturally at the expense of a higher chemical drive. When respiratory muscle reserve is high, the required increase in respiratory muscle output may be tolerated. When DH is very high and muscle reserve is quite low, distress may develop.

2. As illustrated in Figure 12-20, the effective assist received is less than the percent assist dialed in. This is so because the ventilator is unaware of the Pmus generated before triggering; the assist is applied only to that part of Pmus in excess of that required for triggering. Thus, not only does the patient have to generate more pressure to advance triggering, but the maximum percent assist that can be delivered effectively also is less. Distress may occur even at the highest possible assist.
3. Even if an assist level is found with which the patient is comfortable, runaway still may develop in occasional breaths, causing confusion (as percent assist is technically less that 100% E). The duration of expiration of spontaneous efforts can be quite variable. A breath preceded by a long expiratory time begins at a lower absolute volume (less DH). The same percent assist that was not associated with runaway when end-expiratory volume was higher may now cause runaway (see Fig. 12-17B). This can be appreciated by moving the VA line downward in Figure 12-20B. It will be noted that at some point

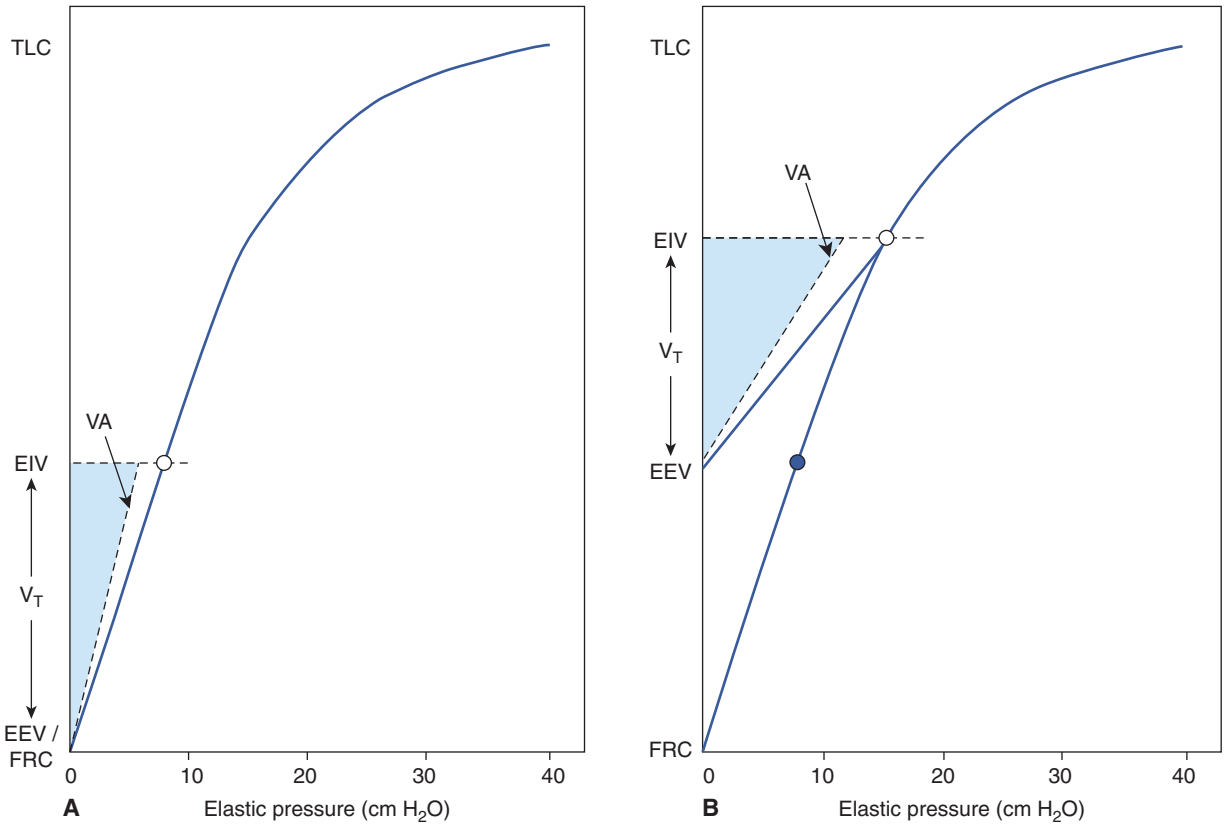

FIGURE 12-20 Impact of dynamic hyperinflation (DH) on PAV delivery. **A.** No DH (FRC and end-expiratory volume are the same). If 80% assist is dialed, the elastic work done by the ventilator (*shaded triangle*) is 80% of the total elastic work (*sum of shaded and open triangles*). **B.** DH: elastic recoil pressure at end-expiratory volume is 8 cm H_2O (*solid circle*). Measured elastance (E = plateau pressure/V_T) overestimates actual elastance because V_T, the denominator, underestimates the difference between end-inspiratory volume and FRC (compare the solid diagonal line with the slope of the main pressure-volume curve in the V_T range). At 80% of this inflated elastance (*VA line*), the ventilator is providing only 50% of elastic work (compare the shaded triangle with the pressure-volume area in the V_T range). There is little room to increase the assist. Forcing VA to exceed measured elastance will result in runaway. In such cases, therefore, the maximum assist that can be delivered is limited. *EEV*, end-expiratory volume; *FRC*, functional residual capacity; *TLC*, total lung capacity; *VA*, volume assist; V_T, tidal volume.

the VA line will cross to the right of the pressure-volume line (i.e., overassist).

The preceding account should not suggest that patients with severe COPD or other causes of DH are difficult to support. As judged by numerous reports[19–21,24–26,36,39,40] and my own experience, the vast majority can be supported very comfortably. Even in patients with severe COPD, elastic recoil at end expiration is usually approximately 3 to 5 cm H_2O,[114–116] a level that is accommodated easily by most patients. Nonetheless, a very high expiratory resistance combined with a high ventilatory demand and weak muscles may make it difficult to achieve adequate support.

The adverse impact of severe DH on PAV's performance can be mitigated in some patients by increasing PEEP. This is effective, however, only when the high expiratory resistance is related to expiratory flow limitation in the lung. Where the high resistance is in the tubing, raising PEEP simply increases lung volume without relieving DH. The impact of DH can be eliminated completely if the ventilator is made to trigger at the onset of inspiratory effort instead of being triggered by inspiratory flow or airway pressure. Because it is possible to measure passive E and R during PAV, it is also possible to generate a continuous estimate of Pmus in real time. Such a signal can be used to begin the assist at the time of onset of inspiratory effort, instead of the onset of inspiratory flow. Another method for noninvasive identification of the onset of effort in real time has also been developed recently (see "effort channel" in Fig. 12-7).[100] With either system, PAV assist continues to be a function of flow and volume, but the reference flow is the expiratory flow at onset of effort (as opposed to zero flow, as is currently practiced). In this fashion, assist would apply throughout inspiratory effort.

Nonlinearity in the Pressure–Volume Relationship within the Tidal Volume Range

The relation between volume and elastic recoil is sigmoid.[112] Most patients breathe in the linear midrange, and E is nearly constant within the V_T range. In others, the pressure–volume relationship is not linear within V_T. This creates some difficulties because there is no fixed E to use for the sake of setting the volume assist. The difficulties depend on whether V_T falls within the stiff upper range (high-end nonlinearity) or the stiff lower range (low-end nonlinearity).

1. *High-end nonlinearity* (Fig. 12-21A). This occurs when end-inspiratory volume approaches TLC, such as when external PEEP is excessive or in very severe restrictive disease (e.g., severe acute respiratory distress syndrome). Here, the maximum elastic assist that can be provided without runaway is limited, and the highest V_T, with or without runaway, is constrained by physiologic TLC (Fig. 12-21A). Should this V_T be inadequate for the patient's ventilatory demand, distress will develop and cannot be relieved by increasing percent assist. Unless heavily sedated, such patients (high demand plus very stiff respiratory system) require supraphysiologic distending pressures for adequate ventilation, and PAV is not suitable.
2. *Low-end nonlinearity* (see Fig. 12-21B). Here, the system is stiffest in the low range of tidal volume, for example, when end-expiratory volume is close to residual volume (abdominal distension and obesity[118–120]) or when derecruitment of airways or alveoli occurs within the tidal volume range. The impact of this abnormality on PAV delivery is similar to that of dynamic hyperinflation (see "Dynamic Hyperinflation" above); the assist received by patient is less than intended (see Fig. 12-21B). When assist requirement is low, this behavior presents no difficulty. When assist level must be high (e.g., 80%), however, the patient may be comfortable, but because of the usually large breath-by-breath variability in V_T, runaways may occur during large breaths, triggering alarms (see Fig. 12-21B). Therefore, in some patients it may be difficult to reach an assist level that is both adequate and free of frequent alarming. This problem can be eliminated by increasing PEEP, thereby placing V_T in the linear pressure–volume range.

Ventilator Response Time

Response delays are unavoidable in electromechanical systems. Excessive response delay would result in less assist than intended as well as delays in cycling off. In the original Winnipeg ventilator, the delay was approximately 40 milliseconds. I had assumed that the delay simply would result in a parallel shift relative to the target Paw waveform[93] and thought this would be acceptable. However, Du et al[76] demonstrated that ventilator response delay becomes compounded during the inspiratory phase, resulting in cycling-off delays that are longer than the nominal ventilator delay. In a recent study, cycling off delay while using the PAV+ option in ventilator-dependent patients averaged 0.25 second (range: 0.17 to 0.51 second).[117] This is acceptable, particularly when considering that transition from inspiration to expiration does not normally occur at peak Pmus but during the declining phase of inspiratory activity,[49,121–123] so that some delay is inevitable even without a ventilator. Nonetheless, that response delays become compounded during PAV delivery[76] emphasizes the need for fast-responding gas-delivery systems in this mode.

Excessive Alarming

Standard ventilator alarms that sound off every time a limit is reached proved to be a considerable nuisance in the PAV mode. Because of the spontaneous variability in breathing pattern, one or more limits may be reached frequently. Furthermore, without automatic mechanics, runaway breaths were frequent. With incorporation of automatic mechanics (see "Noninvasive Monitoring of Respiratory Mechanics, Pmus, and Work of Breathing" above), occurrence of

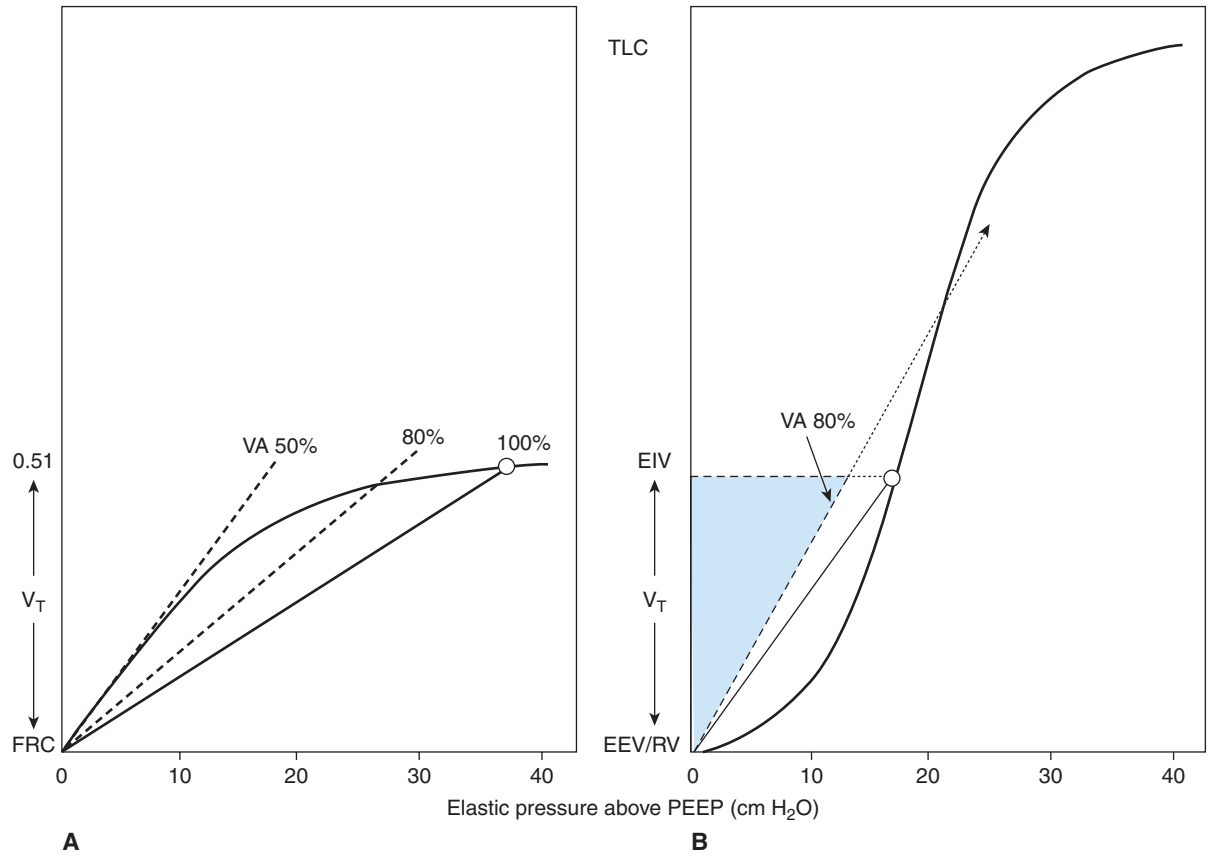

FIGURE 12-21 Impact of nonlinearity in the pressure–volume relationship within tidal volume. **A.** High-end nonlinearity. The pressure–volume relationship becomes quite flat within 0.5 L of FRC. Elastance at a volume of 0.5 L is 75 cm H_2O/L (pressure and volume values at the *open circle*). The maximum VA that can be given without runaway is 50%. At higher assist, runaway develops until the flat region is reached. In either case, the maximum V_T that can be obtained with PAV is limited by physiologic TLC. **B.** Low-end nonlinearity. Elastance is determined at an average V_T given by the open circle. At a VA of 80% E, the elastic assist received is only 55% (compare the *hatched area* with the total area inside the pressure–volume line). Furthermore, if the patient makes a larger effort and obtains a larger V_T, elastic assist may exceed elastic recoil, and runaway may occur (*arrow*). At 50% assist, runaways would not occur, but the patient receives only 35% assist (not shown). *EEV*, end-expiratory volume; *FRC*; functional residual capacity; *TLC*, total lung capacity; *VA*, volume assist; V_T; tidal volume.

runaway will be greatly reduced, but some may still occur (see "Dynamic Hyperinflation" and "Nonlinearity in the Pressure–Volume Relationship within the Tidal Volume Range" above), and spontaneous variability will remain as a possible source for activating alarms. Accordingly, alarms in the PAV mode should take into account the breath-by-breath variability in breathing pattern and mechanics. A reasonable approach (e.g., 840 PAV+ option) is to use special filters whereby ventilator limits still function as such for safety reasons, but alarms sound off only when the frequency of reaching a ventilator limit exceeds a threshold value.

INDICATIONS AND CONTRAINDICATIONS

PAV is appropriate to use in all but a few situations:

1. *Respiratory depression.* Safe use of PAV requires that the patient's respiratory muscle output be responsive to changes in Pa_{CO_2}, Pa_{O_2}, and pH. Absolute contraindications are patients with central apnea or very weak efforts and *no respiratory distress despite an abnormally low pH*. Patients who are intubated for respiratory depression (e.g., overdose or neuropathology) or who had to be heavily sedated for intubation should not be placed on PAV initially. The situation is different in patients already being ventilated with another mode. Here, weak efforts and even no efforts (e.g., on assist-control ventilation or having recurrent central apneas on PSV[58]) are almost invariably secondary to overventilation. The assist with the other mode should be reduced first to establish that efforts resume at a reasonably normal pH before switching to PAV.

Care should be exercised when initiating PAV in a patient with known or suspected chronic CO_2 retention whose Pa_{CO_2} and pH were normalized by another ventilation mode. Such patients often respond poorly to CO_2 until Pa_{CO_2} reaches a level commensurate with their preintubation value. This may result in acute hypercapnia and acidemia following a switch to PAV. Chronic CO_2 retention per se is clearly not a contraindication, and many

such patients were treated adequately with PAV. Patients who develop shallow, relatively slow breathing *with no distress* on PAV should have their blood gases checked, and if they are acidemic, they should be switched to another mode. These patients likely had undocumented prior chronic CO_2 retention.

2. *Need for heavy sedation*: The respiratory response to heavy sedation is unpredictable. When heavy sedation is required acutely for control of severe agitation or seizures, it is better to switch the patient to another mode until it is clear that the patient is making efforts at an acceptable pH.
3. *Severe neuromuscular weakness*: These patients may have difficulty triggering the ventilator and when triggering occurs it may be close to the end of inspiratory effort. Because with PAV, unlike other modes, the ventilator cycle terminates at the end of inspiratory effort, the inflation cycle may be very brief and ventilation may be inadequate.
4. *Bronchocutaneous fistulas.* Patients with bronchocutaneous fistulas should have their leak measured before switching to PAV. If the leak is high on another mode (e.g., exhaled volume less than 75% of inhaled volume), it is better not to use PAV unless the ventilator is equipped with automatic mechanics or leak-compensation algorithms.

Use of Sedatives in Patients on Proportional-Assist Ventilation

Sedatives are not contraindicated when PAV is used. When the response of a patient to sedatives is not known, the dose should be titrated initially until the amount required to attain the desired effect without severe depression is learned. Because backup systems always must be available on PAV delivery systems, the inadvertent use of an excessive amount of sedatives should not be hazardous.

ADJUSTMENT AT THE BEDSIDE

Noninvasive Application

General instructions regarding noninvasive ventilation are similar to those for other modes and are not discussed here (see Chapter 18). The following procedure pertains to BiPAP Vision (Respironics).

STARTUP

It is neither necessary nor recommended to attempt to measure respiratory mechanics. Patients are alert, and settings are best accomplished using patient feedback. Before attaching the ventilator to the mask, the limits should be set initially to a maximum pressure of 20 cm H_2O, a maximum volume of 1.5 L, and a maximum inspiratory duration of 3 seconds. Expiratory positive airway pressure should be set to the minimum value (4 cm H_2O). Many patients prefer a lower expiratory positive airway pressure, but 4 cm H_2O is the lowest setting on the BiPAP Vision. Set the ventilator in the "custom" mode to permit manual adjustment. Percent assist should be set to 99%. In this fashion, the E and R inserted in the ventilator are the actual VA and FA delivered to the patient. Set E and R initially to 2 and 1, respectively.

After attaching the ventilator to the patient and waiting a few breaths for the patient to adapt, inform the patient that the assist will be increased in steps and that he or she should signal approval/disapproval by some agreed-on system. Increase E in steps of one, waiting a few breaths between steps, until the patient signals that the assist is too high. Go back one or two steps. Repeat using the R input. Increase expiratory positive airway pressure by 1 cm H_2O. If the patient signals approval, keep increasing expiratory positive airway pressure. Most will not want more. Finally, perform final adjustment of E. Some patients will prefer a somewhat lower E setting once the other variables are optimized.

Observe the screen display for the range of airway pressure and V_T. Set the high limits a reasonable amount above the observed ranges. For example, if peak Paw ranges up to 15 cm H_2O and V_T ranges up to 0.7 L, set the pressure limit to 20 cm H_2O and the volume limit to 1 L.

SUBSEQUENT MANAGEMENT

This is guided by clinical course. If distress progresses or reappears, the values of E and R should be retitrated. Nasal congestion should be avoided. Ask the patient if his or her nose is congested. If so, use decongestant, or switch to full face mask. If distress persists, then other methods of therapy should be considered. With clinical improvement, percent assist is reduced in steps guided by patient feedback. Because improvement may occur rapidly, it is a good idea to ask the patient at intervals whether the assist is too much and to see whether a lower percent assist is tolerated.

TROUBLESHOOTING

Although the ventilator corrects for leaks, it takes it three to five breaths to adjust to a leak change. A sudden change (e.g., mouth opening or loosening of mask) may result in a transient increase in applied pressure (up to the set limit). Patients should be instructed to keep their mouth closed. For talking or feeding, percent assist can be reduced to zero (or the ventilator disconnected) temporarily. When the problem occurs without mouth opening, the straps need to be tightened.

Frequent activation of alarms may be secondary to the alarm levels being set too low relative to the prevailing ventilatory demand ($\dot{V}_E$ and V_T demands may have increased) or to improvement of mechanics since the last titration, with the assist now becoming excessive. Note the range of V_T on the display, in particular the highest volumes. Reduce percent assist by 20% or so. If the large V_Ts are eliminated and alarming stops, the problem was an improvement in mechanics, and the large breaths were runaways. Retitrate

E and R. Conversely, if the large volumes continue to occur, then the problem is large ventilatory demand or marked breath-by-breath variability. In such cases, the limits should be adjusted upward.

Intubated Patients

The following pertains to the PAV + option on the 840 ventilator because it is currently the only ventilator available with automatic mechanics and "smart" alarms. The procedure for setting basic PAV systems has been described elsewhere.[124] As indicated earlier, such systems are difficult to manage for extended periods. If other systems are used, *full* (i.e., 100%) automatic tube compensation should be avoided. With complete compensation for the nonlinear component of resistance, very small errors in estimated R may cause aggressive flow runaway with rapid loss of the assist secondary to ventilator limits (see "Runaway Phenomenon" above).

The following algorithm for start up and subsequent management (Fig. 12-22) was developed jointly by the author and Dr. D. Georgopoulos, based on experience with hundreds of patients with various pathologies. It was originally published in the *International Journal of Intensive Care*[125] and partly reproduced in *Essential Practices in Respiratory Care*.[126] The reader is alerted to errors in the flowcharts printed in these two publications which, accordingly, should not be followed.

A. INITIAL VENTILATOR SETTINGS:

1. Enter ideal body weight (IBW). *This is an important step.* IBW does not have to be precise but should be a reasonable approximation of reality. It takes the ventilator four breaths to determine actual E and R. In the interim, it uses default values based on normal E and R values for a patient of the specified size. Should the specified IBW value be for a much smaller patient, the first few breaths may be overassisted.
2. Enter endotracheal or tracheostomy tube size. This input is also quite important because part of the delivered assist is based on stated tube size.
3. Set expiratory sensitivity (Esense) to 3 (default value).
4. Set triggering to flow modality at 3 L/min.
5. Enter humidifier volume if applicable.
6. Set high tidal volume limit (V_{TI} limit) to a value corresponding to 15 mL/kg IBW.
7. Set high peak pressure (HIP) limit to 40 cm H_2O (default). The ventilator caps the assist at the HIP limit less 5 cm H_2O or 35 cm H_2O, whichever is less (i.e., breath is not terminated, but pressure cannot increase beyond this level). Setting HIP to a higher value has

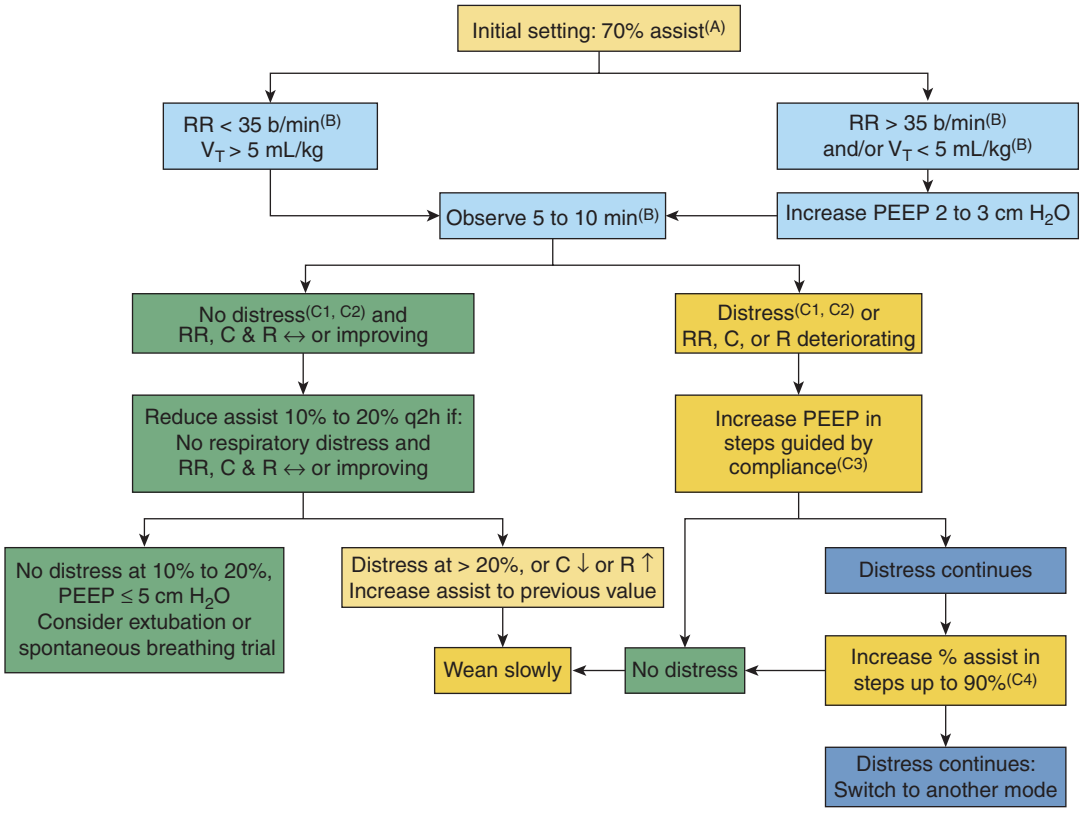

FIGURE 12-22 Proposed algorithm for PAV management. *C*, compliance; *R*, resistance; *RR*, respiratory rate; V_T, tidal volume. Superscripts refer to paragraphs in the text (under "adjustments at the bedside": Intubated Patients) with important clarifications.

no effect in this option. Setting it to a lower value may restrict the assist given unnecessarily.

8. Set percent assist to 70%. It is better to start on the low side and increase if necessary. Most patients do very well at 70%. The use of higher values at the outset, before enough mechanics values have accumulated, may result in overassist.
9. Set PEEP to 5 cm H_2O unless a higher value is deemed necessary for oxygenation.
10. Activate the PAV mode.

B. IMMEDIATE RESPONSES FOLLOWING TRANSITION TO PROPORTIONAL-ASSIST VENTILATION

The immediate response following a switch to PAV varies considerably depending on what the ventilator settings were before the switch and, in particular, on whether the patient was overassisted or there was significant nonsynchrony.

In patients who are not overassisted (i.e., have good triggering efforts) and have no ineffective efforts before the switch, ventilator rate will remain the same (Fig. 12-23) or increase slightly immediately (i.e., first one to two breaths) following the switch. An immediate increase in respiratory rate in this case (i.e., no ineffective efforts before) is the result improved expiratory asynchrony, with the ventilator cycle terminating soon after the end of effort, as opposed to continuing well into the expiratory phase before the switch (see, e.g., Fig. 12-13). Tidal volume typically decreases immediately, because the ventilator uses normal resistance and compliance values in the first breath. Tidal volume gradually increases as the actual respiratory mechanics are obtained from data during the brief inspiratory plateaus (see Figs. 12-14 and 12-23). Tidal volume often continues to increase for a minute or so before stabilizing. The final tidal volume and respiratory rate are generally not different from PSV unless the patient was overassisted on PSV. In the latter case, V_T and V_E may be slightly lower.

In patients with ineffective efforts before the switch there is an immediate increase in ventilator rate as a result of immediate disappearance of the ineffective efforts. This can be dramatic (Fig. 12-24). Concurrently, V_T decreases, often markedly so, in part because resistance and elastance are underestimated initially, but mostly because the inspiratory phase of the ventilator is much shorter than before as a result of disappearance of the preexisting expiratory asynchrony (see Fig. 12-13). V_T then gradually increases, in part because the estimated resistance and compliance become closer to actual values. Because, however, excessive ineffective efforts before the switch generally reflect weak efforts[77] and overassist, P_{CO_2} and efforts gradually increase. The final breathing pattern is invariably rapid and shallow relative to what it was before. This is so because V_E in assist modes cannot exceed the level dictated by the metabolic hyperbola and the apneic threshold. For example, in a patient whose metabolic hyperbola is similar to that in Figure 12-9 (VCO_2 = 0.2 L/min^{-1} and V_D/V_T = 0.4) and an apneic threshold of 40 mm Hg, V_E cannot exceed 7 L/min^{-1} or the patient becomes apneic. Assume that before the switch V_T was 0.6 L and ventilator rate was 10 min^{-1}, for a V_E of 6 L/min^{-1}.

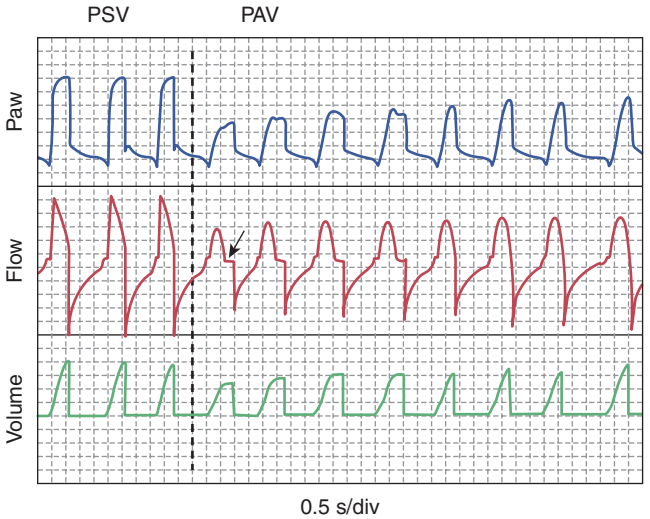

FIGURE 12-23 Example of transition to PAV from PSV in a patient with good efforts (note triggering artifact during PSV) and no important nonsynchrony (no ineffective efforts). Note the brief plateau (*arrow*) in the first four breaths, used to determine respiratory mechanics. Assist increases gradually as the values of resistance and compliance are updated. Breathing pattern is ultimately similar to the pattern on PSV but the patient is now in a mode that will automatically adjust the assist if there are changes in ventilatory demand or in respiratory mechanics.

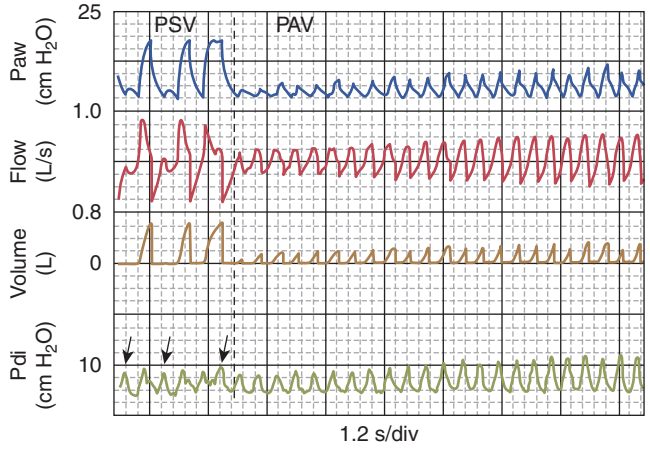

FIGURE 12-24 Example of transition to PAV from PSV in a patient with numerous ineffective efforts on PSV (*arrows*). Note the immediate increase in ventilator rate despite no change in patient's respiratory rate, reflecting the disappearance of ineffective efforts. Tidal volume decreases immediately and rises slowly as the values of resistance and compliance are updated and Pdi increases. Within 45 minutes, tidal volume had increased to approximately half of what it had been on PSV and now ventilator rate is 32 min^{-1}, twice the rate on PSV. Note, however, that despite a modest increase in Pdi, the patient's respiratory rate is actually lower that it was on PSV (36 min^{-1}). The relative rapid shallow breathing in this case reflects better synchrony and not distress. *Paw*, airway pressure; *Pdi*, transdiaphragmatic pressure.

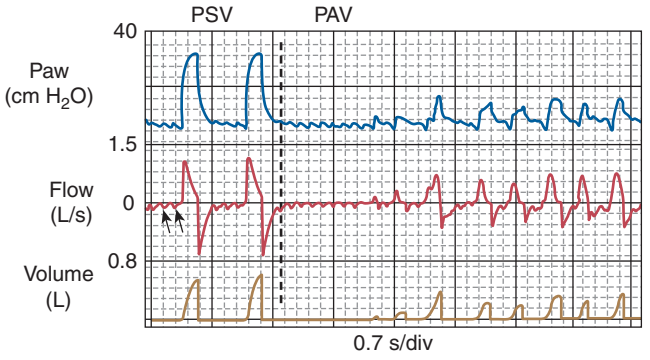

FIGURE 12-25 Example of transition to PAV from PSV in a passive patient in whom large PSV breaths were triggered by cardiac artifacts (*arrows*). Apnea develops upon transition to PAV and continues until Pa_{CO_2} rises above the apneic threshold.

The underlying respiratory rate, however, was 30 min^{-1}, with 20 ineffective efforts per minute. Upon switching to PAV ventilator rate increases to 30 min^{-1}. The highest that V_T can be without apnea is 7/30 or 0.23 L.

Finally, some patients are so over-assisted on conventional assist modes that they are apneic (e.g., Fig. 12-25). The ventilator continues to be triggered either by cardiac flow artifacts (Fig. 12-25) or by a high backup rate. In such cases, the switch to PAV is immediately followed by apnea (Fig. 12-25). The apnea lasts until P_{CO_2} rises above the apneic threshold. This may take a minute or more, depending on how much the patient was overventilated before the switch. Flow artifacts do not trigger significant assist in PAV because the inspiratory phase of the artifact is very brief. When breathing resumes, the breathing pattern will obviously be very different from that observed during apneic ventilation.

For a physician or therapist who is not familiar with the theory of PAV and the fact that patient-selected breathing pattern can be quite different from what is conventionally viewed as desirable, the above two scenarios (rapid shallow breathing or apnea upon transition to PAV) can be disconcerting, if not alarming. Many would, at this point, give up on PAV and return to the previous conventional mode. This is particularly so when respiratory rate is high (e.g., >30 min^{-1}) because these rates are conventionally believed to reflect distress. As indicated earlier (see "Respiratory Rate and Breathing Pattern"), the undistressed respiratory rate, defined as the rate observed with high assist that does not increase further at lower levels of assist (see, e.g., Fig. 12-8), can be up to 46 min^{-1}, or even higher (albeit extremely rarely). An extreme example is shown in Figure 12-26. This patient had a respiratory rate of 59 min^{-1} despite high level PSV and weak efforts. His rate did not change upon switching to PAV despite the increase in effort. Clearly, the high rate observed during PSV was not related to distress. If it had been, it would have increased more as respiratory output increased. This patient remained on PAV for several hours and his rate in fact gradually decreased to 50 min^{-1}.

A particularly useful approach to distinguish between pathologic apnea and overventilation, and between distress-induced tachypnea and undistressed tachypnea in such cases, is to return the patient to his or her previous settings. If the immediate response upon switching to PAV is apnea, the clinician should decrease the backup rate or increase trigger threshold, as the case may be. Apnea will almost always be observed. Reduce the assist until clear triggering efforts appear. A repeat switch to PAV will now not be followed by apnea, thereby establishing that the apnea was related to overventilation at the previous settings. If the immediate response to PAV is tachypnea, return to the previous settings, slow down the monitor speed to be able to observe eight to ten breaths on the same screen. Then, as the tracing is halfway into the screen, suddenly switch to continuous positive airway pressure. The rate observed in the first two to three breaths on continuous positive airway pressure is the patient's real undistressed rate. It is not possible to develop real distress within a few seconds of removing the assist. If this rate is the same rate observed upon switching to PAV, then one should not be concerned unless, of course, respiratory rate increases further later on. Because patient and ventilator rates are the same with PAV, a further increase in ventilator rate clearly reflects an increase in patient rate. In such cases distress must be suspected and dealt with (see "C. Subsequent Management and Troubleshooting" below.

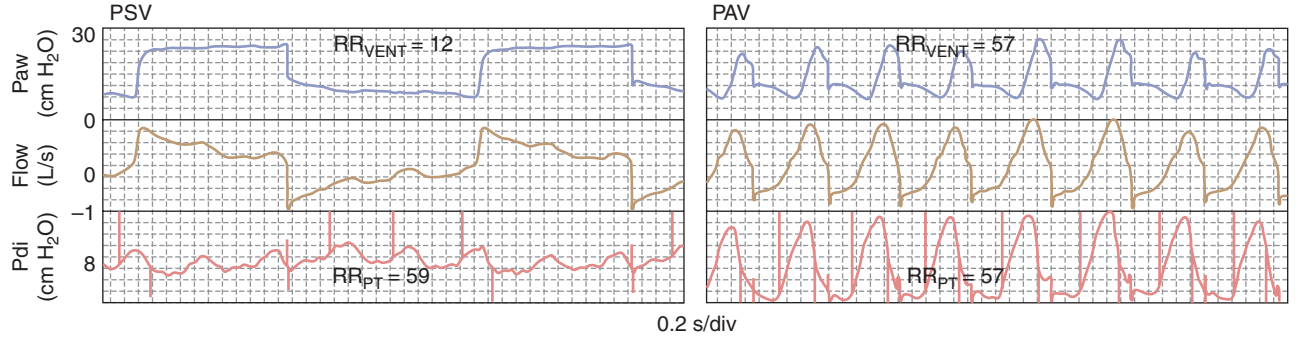

FIGURE 12-26 *Left panel:* Example of extreme tachypnea despite high level of PSV support. Note the efforts are quite small (approximately equal to 4 cm H_2O) and the extreme nonsynchrony (5:1 rhythm). *Right panel:* Upon switching to PAV patient's respiratory rate does not change despite the fact that efforts are now much higher.

In summary, because of the highly variable immediate responses upon switching to PAV, it is reasonable to wait a few minutes, or perform the above check, before concluding that PAV is not appropriate for the patient. Within a few minutes the body's homeostatic mechanisms will have adjusted respiratory output to the level and pattern preferred by the control system. In patients in whom breathing is rapid and shallow during this waiting period, it is advisable to increase PEEP by 2 to 3 cm H_2O to mitigate atelectasis. In addition, in such patients, particularly in those with a prior history of CO_2 retention, it is advisable to obtain an arterial sample for blood gases several minutes after the switch to ensure that the pH is acceptable. Respiratory acidosis (Pa_{CO_2} > 50 mm Hg and pH < 7.35) with no associated clinical distress suggests respiratory depression. Until the cause of respiratory depression is corrected, the patient should not be treated with PAV.

It is highly advisable to record respiratory rate in the first minute after a switch to PAV, as well as the values of estimated compliance and resistance 3 to 4 minutes later, when an adequate number of measurements have been collected. These values will provide important references for subsequent management.

C. SUBSEQUENT MANAGEMENT AND TROUBLESHOOTING

1. Subsequent management depends on whether respiratory distress develops within several minutes after the switch and whether there is a trend for respiratory rate or resistance to go up or for compliance to go down.

   Given the wide range of documented undistressed respiratory rate in ventilated patients (up to 46 min^{-1}),[33,34,96,117] it is my opinion that tachypnea with no other supporting manifestations should not be considered as evidence of distress. In their large study comparing PAV with PSV over a 48-hour interval, Xirouchaki et al[96] defined distress as the presence of at least two of the following: (a) heart rate greater than 120% of the usual rate for longer than 5 minutes and/or systolic arterial blood pressure greater than 180 or less than 90 mm Hg and/or systolic arterial blood pressure changes greater than 20% of the previous value for longer than 5 minutes; (b) respiratory rate greater than 40 breaths/min for longer than 5 minutes; (c) marked use of accessory muscles; (d) diaphoresis; (e) abdominal paradox; and (f) marked complaint of dyspnea. Thus, patients with a respiratory rate greater than 40 breaths/min were maintained on PAV for up to 2 days if there were no other manifestation of distress.

   While a high respiratory rate at a given point is not, per se, indicative of distress, an increase in ventilator rate (or in the respiratory frequency to tidal volume [f/V_T] ratio[127,128]) while the patient is on PAV, provided it is not short-lived, strongly suggests impending failure even in the absence of clinical distress, and even if the absolute rate is modest. Ideally, ventilators should be able to display trends in various physiologic variables (e.g., respiratory rate, compliance, resistance, and so on). In the absence of such a feature one can utilize the respiratory rate obtained immediately after transition to PAV as the reference.

   One advantage of PAV is that it makes it possible to monitor resistance and compliance in real time. At least in COPD patients, a trend of increasing resistance and decreasing compliance heralds frank failure.[1,129] In other patients, the compliance value can be used to derive the Integrative Weaning Index (compliance × arterial oxygen saturation × f/V_T), which shows promise in predicting failure.[130]
2. With the above guidelines, in most patients there will be no clinical distress, and respiratory rate and compliance and resistance will be stable or improving relative to the early measurements (*left blocks* in Fig. 12-22). For these patients, subsequent management is similar to that for other modes and consists of gradual reduction in assist as warranted by clinical condition. So long as there is no clinical distress and respiratory rate and mechanics remain stable or improve, percent assist can be reduced in 10% to 20% decrements every 2 hours until (a) there is no distress or deterioration in respiratory rate and mechanics at 10% to 20% assist. Here, the patient should be considered for extubation as 20% assist represents minimal assist. (b) The patient develops clinical distress or the patient's respiratory rate (or f/V_T) increases or the mechanics deteriorate. In such patients, the assist is increased to the previous level. Such patients are clearly not ready for extubation. Assist should be decreased in smaller steps over longer intervals.
3. A minority of patients will develop distress, or their mechanics will deteriorate, within a few minutes after switching to PAV at 70% assist (*right blocks*, Fig. 12-22). The most common reason for distress at such a high assist (70%) is delayed triggering secondary to severe dynamic hyperinflation or severe respiratory muscle weakness (see "Dynamic Hyperinflation" above). For this reason, the first step is to titrate PEEP up in small increments guided by the results of compliance. Allow 3 minutes between PEEP increases to allow the ventilator to obtain an adequate number of measurements on the new level. If dynamic hyperinflation is in part, or in total, related to expiratory flow limitation, compliance should increase as PEEP is increased. There is no value to increasing PEEP once compliance stabilizes. If distress disappears, the patient is managed with these settings and weaning can then be continued in small steps over long intervals, as tolerated (Fig. 12-22).
4. Distress continues despite PEEP optimization: This scenario is quite uncommon. The caregiver may decide at this point to switch to another mode or to engage in a process of upward titration of percent assist, in 5% steps, with close monitoring of the graphics. In the latter case:

   Ensure that the high inspiratory pressure limit is 40 cm H_2O. Inspect the Paw waveform display for several breaths.

a. If Paw is less than 35 cm H_2O in all breaths, you may continue increasing percent assist. If distress disappears, continue as in the previous groups.

b. If Paw reaches 35 cm H_2O in the latter part of inspiration only in the occasional breath (see Fig. 12-17), there is volume runaway. Here the problem is almost certainly severe dynamic hyperinflation not responsive to PEEP (i.e., high resistance is in the tubing [including the endotracheal tube]) or severe muscle weakness. If distress is still present, such patients cannot be supported adequately with PAV unless triggering is linked to onset of effort (see "Dynamic Hyperinflation" above and Fig. 12-7). This is the maximum that the patient can be supported in the PAV mode. Switch to another mode.

c. If Paw reaches 35 cm H_2O in the latter part of inspiration in most breaths, the patient needs more assist than can be provided by the PAV+ option. This scenario indicates high-end nonlinearity (see "Nonlinearity in the Pressure–Volume Relationship within the Tidal Volume Range" above) in a patient with high ventilatory demand. The patient needs to be sedated. If heavy sedation must be used, consider switching to another mode (e.g., assist control).

d. If Paw reaches 35 cm H_2O *immediately* after triggering and stays there until the cycle ends (i.e., square wave pattern), flow runaway exists. If ATC is concurrently used, it should be discontinued (Fig. 12-19 and related text). If the problem continues and the patient is still in distress, switch to another mode. This problem is occasionally seen in patients with gasping breathing and cannot be corrected by ventilator adjustments.

IMPORTANT UNKNOWNS

Whereas the physiologic advantages of PAV have been proven, it is not clear whether these necessarily translate into clinical benefits. There are reasons to believe that clinical outcome will improve (see "Clinical Outcome" above). This needs to be confirmed, however. Questions may be of a general nature (e.g., Are mortality, length of intubation, and length of ICU stay less with PAV?) or may be directed at specific aspects that we know affect outcome (e.g., by comparison with optimal protocols with other modes):

- If sedation is used on an "as-needed" basis, will patients need less sedation on PAV?
- Will tidal volume over the course of illness be smaller on average?
- Is weaning faster?

I believe that two other questions need to be addressed. These relate to management of tachypnea that is unrelated to distress, a phenomenon that is evident only when PAV is used:

- If a patient decides to breathe in a rapid, shallow manner while on high PAV support (see, e.g., Fig. 12-5B), should the patient be left on PAV or switched to another mode?
- If tachypnea (e.g., >35 breaths/min) with no other signs of distress is present during a weaning trial and does not decrease on high PAV, does the patient need to stay on a ventilator?

THE FUTURE

With the inclusion of automatic mechanics and "smart" alarms, PAV should become the easiest mode to set and use. There is only one variable to adjust: percent assist. The mode adapts automatically to changes in ventilatory demand and respiratory mechanics. A problem will remain, however, in the management of patients with severe DH secondary to very high expiratory resistance and high ventilatory demand. Future PAV delivery systems should include algorithms to begin the assist at the onset of inspiratory effort.

It is also possible that adjustment of percent assist can be automated. PAV offers two features that would facilitate the complete automation of ventilator adjustment. First, ventilator rate, something ventilators can keep track of easily, is an accurate reflection of the patient's respiratory rate. Thus, ventilator rate may be used as one feedback element for automatic adjustment of percent assist. Second, because PAV makes it possible to obtain passive mechanics on an ongoing basis, it is also possible to monitor respiratory muscle output and the work of breathing continuously. These can be used as additional feedback signals to automatically adjust percent assist.

SUMMARY AND CONCLUSION

PAV represents a paradigm shift in mechanical ventilation in that control of ventilator output is shifted from the caregiver to the patient. This shift has several advantages in that the ventilator output is more synchronous with patient efforts, and the support adjusts automatically to changes in ventilatory demand and respiratory mechanics. This mode is also the only mode that makes it possible to monitor respiratory mechanics in real time during assisted ventilation. These features have been all been documented in numerous physiologic studies. Until recently, application of PAV in the clinical setting has been hampered by lack of suitable commercial systems and several technical limitations that made it difficult for any but the sophisticated physiologist to use it, and then only for short periods. A commercial ventilator was introduced a few years ago that, in addition to providing the mode, has addressed several of the technical limitations. Now, it is possible to engage in clinical trials that address the important issue of whether better physiology leads to better clinical outcome? PAV is slowly gaining acceptance among clinicians and the main obstacle remains unfamiliarity with the responses to this mode and long-standing dogmas about

how breathing should be during mechanical ventilation. It is hoped that this latest description will help in this respect.

NEURALLY ADJUSTED VENTILATORY ASSIST

Christer Sinderby
Jennifer C. Beck

RATIONALE

Mechanical ventilation can be delivered with two extreme approaches: (a) by dictating a flow, volume, pressure, or respiratory timing (or some combination), or (b) by delivering assistance synchronized to and regulated by the patient's neural breathing efforts. Whereas the former approach is advantageous in patients who do not breathe, the latter approach is advantageous in spontaneously breathing patients.

Almost 50 years ago, Gunaratna[1] demonstrated that the problem of patients fighting the ventilator during controlled ventilation could be overcome by the use of patient-triggered ventilation. The patient-triggered ventilation was associated with immediate relief of the respiratory distress, apprehension, and agitation.

Since the 1970s, numerous modes of mechanical ventilation that aim to synchronize the ventilator and the patient have been introduced. Patient-triggered or cycled modes of ventilation are controlled by airway pressure,

flow, and/or volume measured in the respiratory circuit. Significant limitations of these signals to trigger and cycle-off the assist have been documented for decades.[2–12] Despite the term *patient-triggered* ventilation, severe patient–ventilator asynchrony occurs in at least 25% of ventilated patients[13–15] and is associated with prolonged duration of ventilation. Patients with frequent ineffective triggering also tend to receive excessive levels of ventilator support[13] and/or sedation.[16] In newborns, compared to controlled ventilation, patient-triggered ventilation is associated with shorter duration of ventilation.[17–20] Excessive assistance can cause muscle fiber injury and atrophy of the diaphragm.[21,22] Conventional ventilation can induce loss of inspiratory muscle force, as much as 75%.[22,23–27] Promoting spontaneous breathing[28–33] and reducing sedation,[34–39] alone or together,[40] shortens the duration of mechanical ventilation.

Last, but not least, regulation of spontaneous breathing constitutes a very complex interaction between motor-nerve output and sensory feedback.

In summary, conventional modes of ventilation have limitations with regards to (a) synchronizing assist delivery to the patient's neural breathing efforts; (b) bedside monitoring of patient respiratory drive and/or interaction with the ventilator; (c) adjusting the level of assist in response to patient demand; and (d) taking advantage of intrinsic lung protective reflexes.

An ideal approach, therefore, is to connect the patient's respiratory centers to the ventilator, as naturally as the respiratory muscles are connected to the brainstem via the phrenic nerves. This notion is what set the spirit for developing the mode known as neurally adjusted ventilatory assist (NAVA).[41]

BASIC PRINCIPLES AND PHYSIOLOGY OF ELECTRICAL ACTIVITY OF THE DIAPHRAGM

From Brain to Breath

Figure 13-1 (*left*) describes schematically the hierarchy of the steps involved in generating a spontaneous breath. Respiratory neurons originating in the brainstem of the central nervous system send their signals to the diaphragm via the phrenic nerves. After neuromuscular transmission, diaphragmatic excitation occurs, where action potentials propagate along the diaphragm muscle fibers. This is the source of the diaphragmatic electrical activity (Edi) (see "Electrical Activity of the Diaphragm" below). The Edi is generated by the neural respiratory output signal and is modulated by input from multiple respiratory reflexes feeding back to the respiratory centers. The Edi signal is the primary signal used to control NAVA (Figure 13-1, *right side*).

The latency time from stimulation of the phrenic nerve in the neck to the onset of the diaphragmatic compound muscle action potential in healthy subjects is approximately 6 to 8 milliseconds.[42–45] Diaphragmatic excitation stimulates contraction of muscle fibers and causes shortening. The result of diaphragmatic contraction is expansion of the thorax, which causes lung distension and lowers pleural and alveolar pressures, thereby lowering airway pressure creating inspiratory flow. These "pneumatic" signals (pressure, flow, and volume) are used today to control conventional patient-triggered ventilation.

The time between central respiratory output to the generation of inspiratory flow in a healthy subject is approximately 26 to 28 milliseconds.[42–44] Factors such as intrinsic positive end-expiratory pressure (PEEP), increased respiratory load, impaired respiratory muscle function, and reduced respiratory drive (secondary to sedation), alone or in combination, will weaken the flow signal. A weakened flow signal is more problematic to detect by the ventilator, increases the time delay to trigger the assist, and, in the worst case, fails to trigger the ventilator.

In summary, an impairment occurring at any of the steps in the hierarchy described in Figure 13-1 may result in delays, dampening, or even full blockage of the signals used to control the ventilator.

Respiratory Reflexes

Figure 13-2 demonstrates a schematic diagram of the major neural feedback systems to the respiratory centers. Neural feedback to the respiratory centers controls respiratory motor output, and hence the Edi.

FEEDBACK FROM THE LUNGS

For a detailed description of the lung reflexes, the reader is referred to Widdicombe[46,47] and Undem and Kollarik.[48]

Important for NAVA is that the lungs host receptors sensitive to stretch and respond to both lung distension and deflation. Based on the response to sustained lung distension these receptors are divided into slowly adapting receptors and rapidly adapting receptors. The classic experiments by Josef Breuer and Ewald Hering in the mid-nineteenth century[49] showed that lung distension shortens inspiration, or prolongs expiration, the so-called Hering-Breuer inspiratory sensitive reflex.[49] They also noted that deflation of the lungs at end-expiration shortens exhalation and stimulates inspiration, the Hering-Breuer deflation-sensitive reflex.[49] These reflexes are caused by slowly adapting receptors, and rapidly adapting receptors, respectively.

The rapidly adapting receptors are also stimulated by chemical stimuli and changes in lung compliance. When stimulated, the rapidly adapting receptors cause tachypnea, cough, and augmented breaths. Pulmonary edema, mediators of inflammation and immune responses, inhaled irritants, and direct tissue damage stimulate the bronchial C-fiber receptors, causing apnea, rapid shallow

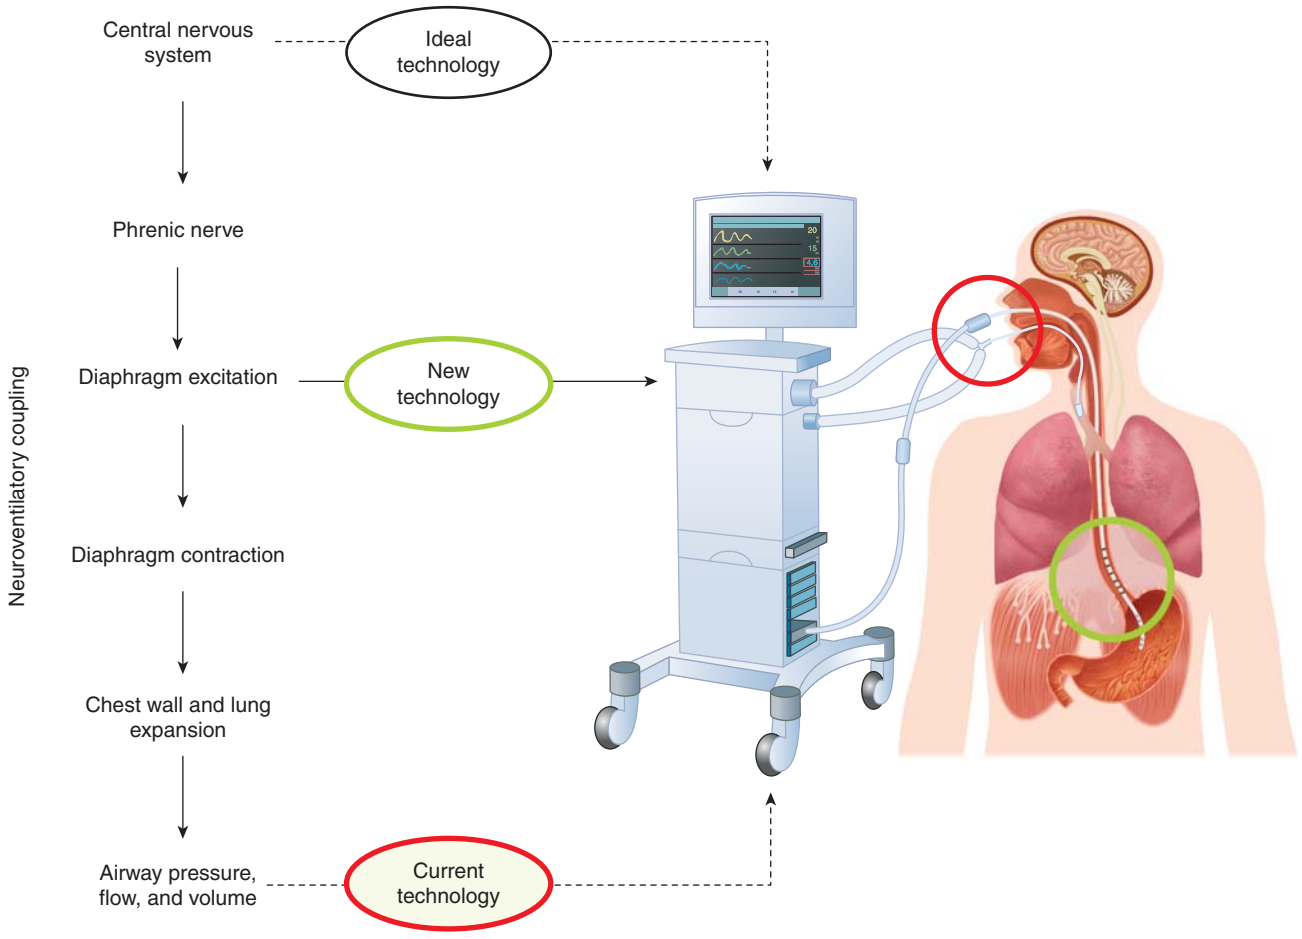

FIGURE 13-1 Overview of neurally adjusted ventilatory assist (NAVA). *Left:* Chain of events involved in spontaneous breathing, beginning with the respiratory centers in the central nervous system, then phrenic-nerve transmission, diaphragmatic electrical activity, diaphragmatic contraction, and ending with airway pressure, flow, and volume (the neuroventilatory coupling). Also indicated are the different levels of signals for ventilator control. During NAVA, electrical activity of the diaphragm is used to control the ventilator. *Right side:* Schematic of setup for NAVA. A feeding catheter equipped with an array of miniaturized electrodes is passed down the esophagus, where the electrical activity of the diaphragm is recorded (*green circle*). Diaphragmatic electrical activity is processed into a waveform, and is used for monitoring neural respiratory drive (in all modes) and for controlling the timing and magnitude of ventilator-delivered pressure during NAVA.

breathing or both, and cough. The above-described reflexes disappear with vagotomy.

FEEDBACK FROM THE RESPIRATORY MUSCLES

Afferent feedback from the respiratory muscles exists and affects neural drive to the different individual muscles.[50–52] Electrical stimulation of the phrenic nerve afferents elicits changes in phrenic efferent activity, breathing pattern, and ventilation, the so-called phrenic-to-phrenic reflex.[53,54] Stimulation of the phrenic afferents can also change neural drive to the intercostal muscles, the so-called phrenic-to-intercostal reflex.[55,56] Golgi tendons and muscle spindles are present in the diaphragm, albeit sparse, and provide feedback related to muscle tension and length, respectively.[57] Respiratory muscle feedback partially controls respiratory drive during unloading[58] and likely influences the sensation of breathing.[59]

JOINT RECEPTORS

Receptors in the costovertebral joints have been suggested as a primary determinant of a load-compensating reflex.[60]

CHEMORECEPTORS

Receptors sensitive to the concentration of oxygen, carbon dioxide, and the pH in the arterial blood are constantly modulating the breathing pattern. Activation of either the hypoxic or hypercapnic chemoreflex elicits hyperpnea (increased respiratory drive and, hence, increased Edi).[61,62]

FEEDBACK FROM THE UPPER AIRWAYS

The larynx contains receptors sensitive to pressure, temperature, and irritants; the laryngeal mucosa also contains C-fiber receptors or J receptors,[46,47] which, when stimulated,

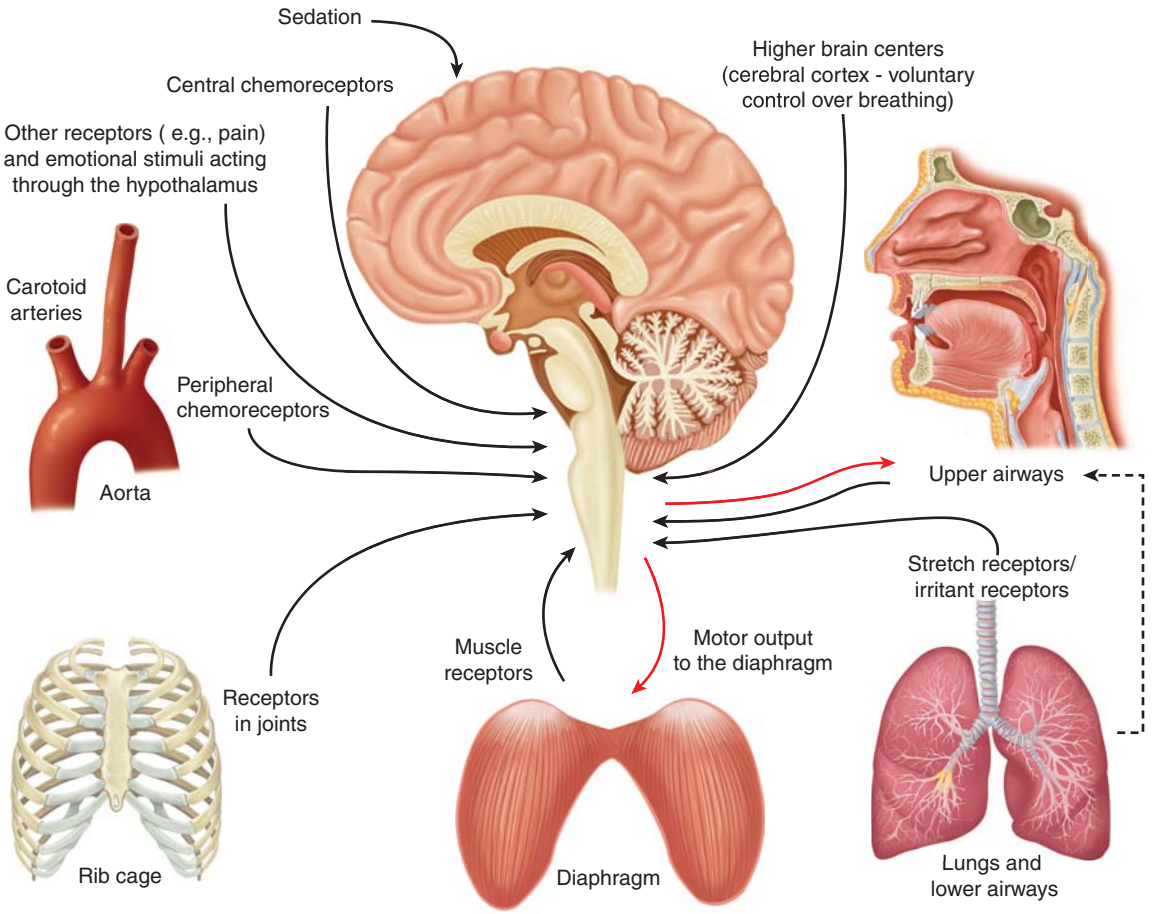

FIGURE 13-2 Respiratory inputs and reflexes important for NAVA. Schematic of the respiratory inputs and reflexes that can affect neural respiratory drive, and hence the motor output to the diaphragm (electrical activity of the diaphragm). The respiratory centers in the brainstem continuously receive information from the peripheral and central chemoreceptors (*upper left side*), receptors in the rib cage and diaphragm (*lower left* and *lower center*), stretch and irritant receptors in the lungs and lower airways (*lower right*), and receptors in the upper airways (*top right*).

cause cough, apnea, bronchoconstriction, and mucus secretion. Recent work by Praud et al[63] suggests that feedback exists from the lungs to the laryngeal muscles.

SEDATION AND ANALGESIA

Increases in sedation and/or analgesia depresses respiratory motor output.[64]

Electrical Activity of the Diaphragm

Petit et al were the first to present, in 1959, a "new technic for the study of functions of the diaphragmatic muscle by means of electromyography in man."[65] Taking advantage of the anatomy of the crural diaphragm, which forms a scarf-like structure around the lower esophageal sphincter, these investigators cleverly obtained the Edi with electrodes on a catheter that was passed down the esophagus.

Considering that nearly all ventilated infants and most intubated adult patients in the intensive care unit are equipped with nasogastric feeding tubes, it was logical to follow up on refining esophageal measurements of Edi for today's clinical use. Some of the obstacles that needed to be overcome included the development of standardized and automated methods to reduce artifacts and filtering effects related to electrode configuration and electrode positioning. Even though Lourenco et al[66] had demonstrated in dogs that the crural electromyogram (EMG) and costal EMG were related to phrenic nerve activity, it was necessary to validate that measurement of Edi with an esophageal electrode relates to global inspiratory effort in ventilated patients.[5]

The Edi signal used for monitoring respiratory drive and for controlling the ventilator during NAVA is an "interference-pattern EMG signal," and constitutes a temporospatial summation of motor-unit action potentials, which, in turn, represent a summation of single-fiber action potentials.

A single-fiber action potential is the extracellular potential generated by movement of ions across the sarcolemma during depolarization of a single muscle-fiber membrane. This current flow can be measured as a voltage difference over time, and when displayed as a waveform, is known as the

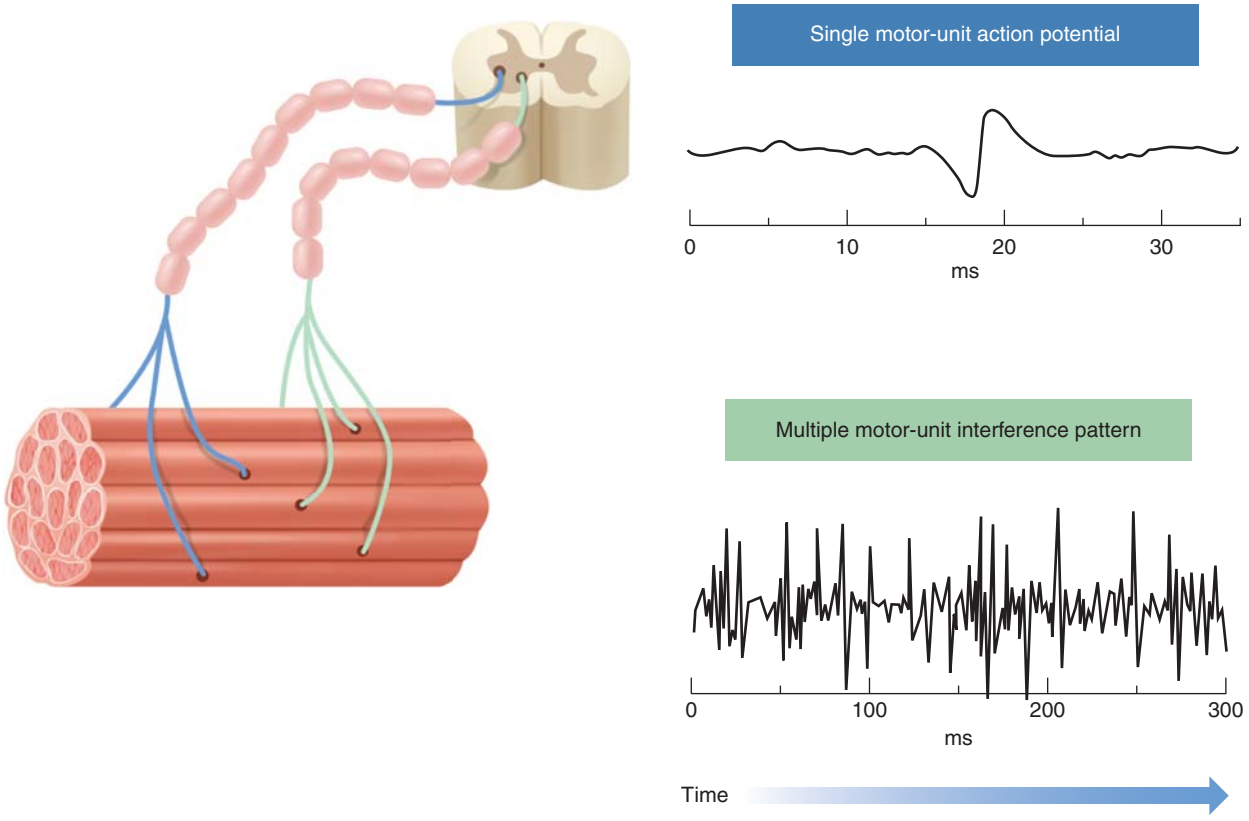

FIGURE 13-3 Skeletal muscle structure and the origin of the interference-pattern EMG. *Left side:* Representation of the structure of skeletal muscle and motor units. Two motor units are demonstrated for simplicity. A motor unit is a single motor neuron and all of the muscle fibers it innervates. Electrical activation of a single motor unit produces a motor unit action potential (*top right*). A spatial and/or temporal summation of the motor-unit action potentials, resulting in an interference-pattern EMG signal (*bottom right*), occurs when several motor units are recruited and/or their firing rate increases. The Edi signal measured during NAVA is an interference-pattern measurement of asynchronously firing diaphragmatic motor units.

action potential. Action potentials are "all or none" in terms of the voltage transient they generate, and they propagate along the muscle-fiber membrane to initiate contraction.

Action potentials occur because of voltage-dependent sodium-potassium channels in the muscle-fiber membrane. In humans, the propagation velocity of an action potential ranges between 2 and 6 meters per second,[67] and depends on the capacitance per unit length (dependent on circumference) and the internal resistance, all passive properties of the muscle fiber. The active properties (e.g., membrane excitability) depend on ion-concentration differences and ion-channel properties, the latter affected by temperature, pH, and electrical field strength. The action potential propagation velocity is dependent on temperature, fiber diameter, pH, fatigue, and ion concentration.[67–71]

Given the muscle innervation scheme, single-fiber action potentials are activated in groups because a single nerve fiber innervates multiple muscle fibers (Fig. 13-3). Thus, a motor-unit action potential represents many single fiber action potentials, which secondary to synchronized initiation, results in mainly a spatial summation of their amplitudes. Motor-unit action potentials are affected by the same factors as single-fiber action potentials, but also the number of muscle fibers within the motor unit, length of the motor unit terminal, fiber-to-fiber differences in action-potential conduction velocity, and dispersion of the motor-unit fibers.[72,73]

Neural breathing effort modulates motor-unit firing rate and recruitment. Hence, when resulting action potentials are summed up in time (temporally) and in space (spatially), the cumulated motor-unit action potential activity (i.e., the interference-pattern EMG) yields a signal where individual motor-unit action potentials can no longer be distinguished (see Fig. 13-3). All factors affecting the individual motor-unit action potentials will influence the interference-pattern EMG, as well as the number of individual motor-unit action potentials, their synchronization, and eventual cancellation of opposite phase potentials.[72,74]

Measurement of Electrical Activity of the Diaphragm

RECORDING ELECTRODES

Optimal Edi signals depend on the use of electrodes with appropriate configuration, maintenance of electrode position and orientation relative to the muscle, and avoidance of signal disturbances.

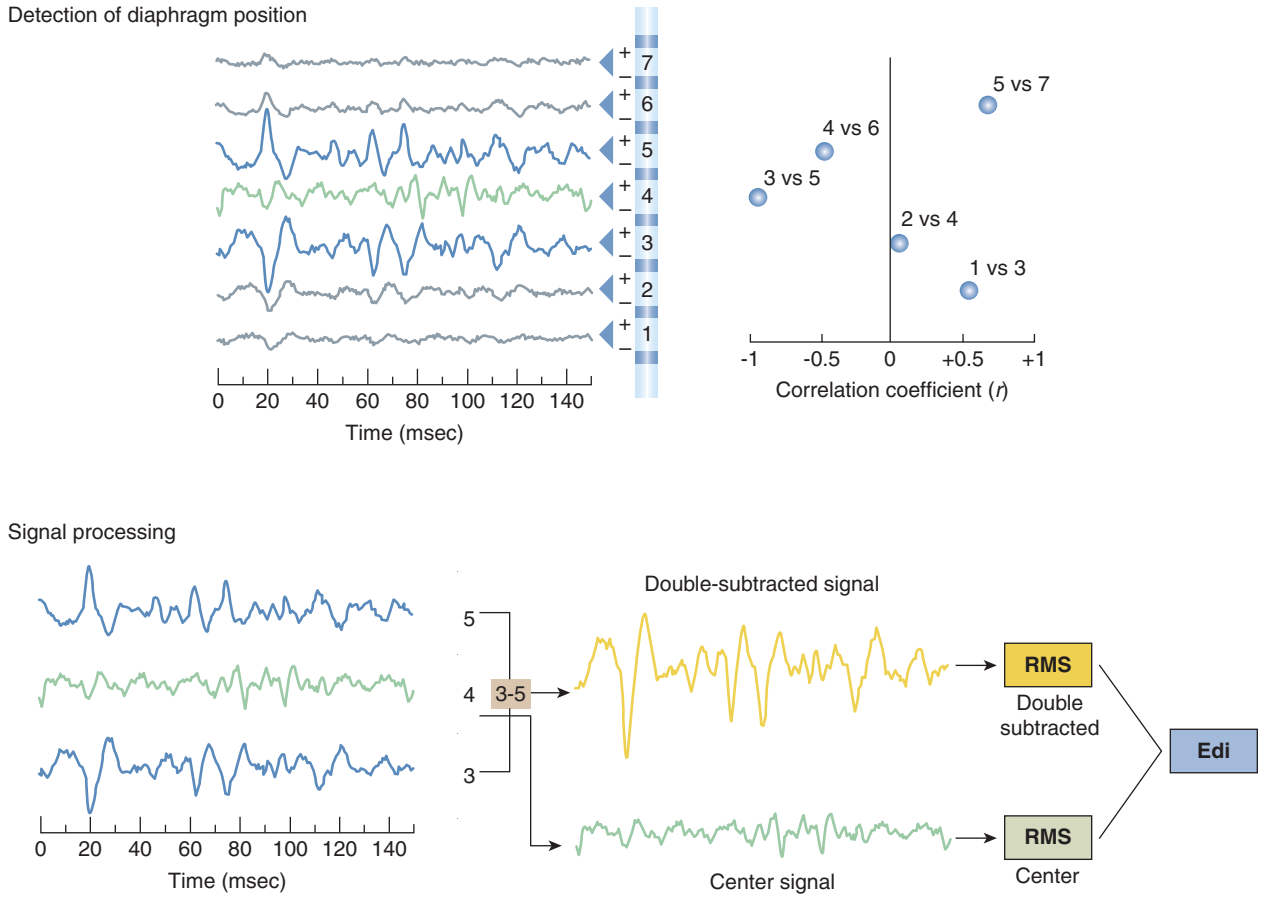

FIGURE 13-4 The double subtraction method. *Top*: Detection of diaphragm position along the array of electrode pairs. *Left:* Raw signals from each electrode pair (electrode array is illustrated in center). *Right*: The electrode pairs closest to the diaphragm are determined by cross-correlating signals from every second pair of electrodes (1 vs. 3, 2 vs. 4, 3 vs. 5, 4 vs. 6, 5 vs. 7, and 6 vs. 8, if eight electrodes are present), and the correlation (*r*) values are plotted (x axis) for each combination (y axis). Today, the cross-correlation algorithm is applied every 16 ms and eight electrode pairs are used. The two most negatively correlated electrode pairs are tagged (in *blue, left side*) for use in the double subtraction (in this example, electrode pairs 3 and 5). The "center signal" is also tagged (in *green*). *Bottom*: Signal processing. *Left:* The same signals that were tagged in the cross-correlation method as being above and below the diaphragm are displayed (*blue*) as well as the center signal (*green*). *Right*: Signal obtained after subtraction of signal from the most negatively correlated signals (electrode pair 5 and 3 in this example) yields the "double-subtracted signal" (*orange tracing*). The root-mean-square is calculated every 16 ms for this signal (*orange*), as well as the waveform at the center (*green*), and the two root-mean-square (RMS) values are summed (double subtracted + center values) to yield the Edi used during NAVA (*grey*). (Adapted, with permission, from Sinderby et al.[77])

In the context of NAVA, the Edi is measured with an array of electrode pairs placed on a nasogastric or orogastric catheter. The catheter is placed in the esophagus at the level of the gastroesophageal junction such that the direction of the electrode array is perpendicular to the crural diaphragmatic muscle fibers.[75]

The Edi is filtered depending on the electrode's position with respect to the diaphragm[75] (Fig. 13-4). If the electrode pair is centered at the level of the diaphragm (both electrodes receive a similar signal), the frequency increases and the power of the Edi decreases because of a cancellation effect (bipolar electrode filtering). If one of the electrodes of the pair is located at the level of the diaphragm and the second is away from the diaphragm (electrode pairs 3 and 5 in Fig. 13-4), the differential recording will be least influenced by bipolar electrode filtering and muscle-to-electrode distance filtering effects.[75] For the electrode pairs even further away in either direction (channels >6 and <2 in Fig. 13-4), there will be lower signal amplitude, because of muscle-to-electrode distance filtering. Given the sequential configuration of electrodes pairs with respect to the differential amplifiers (indicated by + and – signs in Fig. 13-4, top right panel) and the fact that the diaphragm constitutes an electrical sheet with a direction perpendicular to that of the electrode array, signal waveforms obtained above the diaphragm become inversed to those below the diaphragm (Fig. 13-4 top left panel).

Electrical Activity of the Diaphragm Signal Processing

The specific design of the electrode configuration and the signal processing techniques used with NAVA have been developed and tested since the late 1980s so as to overcome

the inherent difficulties associated with EMG measurements in general, as well as anatomical considerations.[76]

The most significant advance in the development of esophageal measurements of Edi was the use of bipolar electrodes in a sequential order and an automated processing technique to track the displacement of the diaphragm.[77] Implementation of a cross-correlation technique (for every second pair of electrodes) every 16 milliseconds determines the position of the diaphragm along the array (Fig. 13-4), and subtraction of opposite phase signals above and below the diaphragm results in a new signal, the "double-subtracted" signal, free from distance filtering, and enhanced signal-to-noise ratio (Fig. 13-4).[77] The root-mean-square (RMS) of this signal is calculated every 16 milliseconds, and added to the RMS of the center signal (i.e., from the electrode pair closest to the muscle[78,79]), as demonstrated in Figure 13-4. The resultant RMS values for every 16 milliseconds sample can be graphically connected, resulting in the Edi waveform (Fig. 13-5).

The RMS is linearly related to how much the muscle is activated, that is, the number of motor units recruited and their firing rate,[80] and under isometric, nonfatiguing conditions, reflects diaphragmatic force (up to 75% of its maximum).

Several artifacts can potentially influence the Edi waveform and need to be controlled for to avoid misinterpretation of the signal, or in the case of NAVA, miscontrolling the ventilator. Today, this is achieved automatically by the processing of the signal, and the user only needs be made aware of the artifacts' potential impact.

As the diaphragm can move as much as 13 centimeters during spontaneous breathing at large tidal volumes,[81] muscle-to-electrode distance filtering could play a role in amplitude measurements of Edi.[82] Signal processing techniques and design of catheter configuration have enabled automatic control over this factor.

Motion artifacts, induced by physical movement of the electrode, are low in frequency but large in amplitude. Signals that are common to both electrodes in the differential recording (e.g., electrical noise) will be suppressed because of the bipolar electrode configuration and the double-subtraction technique.[77] Esophageal recordings of Edi are particularly affected by the electrocardiogram (ECG) and the artifact should be removed from the Edi waveform, especially for the purpose of controlling the ventilator. The ECG is detected with an adaptive threshold level, and replaced by a value predicted from the previous Edi value. To further reduce electrical noise disturbances (e.g., 50 or 60 Hz) and motion artifacts and to minimize ECG and electrical activity from the esophagus, the signal is filtered with a cascade of filters.

The interelectrode distance affects the Edi signal, and hence catheters of different sizes and interelectrode distances are designed to suit different patient ages and sizes.[75]

A long-lived delusion was that changes in diaphragmatic configuration and length affect the Edi waveform.[83] Studies now confirm that diaphragmatic length[71] and chest wall configuration[80,82] do not affect the Edi waveform, or its frequency content, as long as control is achieved over the above-mentioned influences.

ELECTRICAL ACTIVITY OF THE DIAPHRAGM AS A MONITORING TOOL

Interpretation of the Electrical Activity of the Diaphragm Waveform

The Edi waveform, as any other waveform on the ventilator, such as airway pressure or tidal volume, can be characterized by its amplitude and timing, for both the inspiratory phase and the expiratory phase. The Edi waveform has the units of microvolts (μV), generally ranging between a few μV during resting breathing to above 100 μV during maximal inspiratory efforts. Figure 13-6 provides examples of the Edi waveform in a premature infant and in an adult patient.

Increased Edi amplitude on inspiration ("phasic Edi") indicates greater activation of the diaphragm. The amplitude of the Edi waveform has been shown to be related to global diaphragmatic activation[80] and diaphragmatic power output[84] in healthy subjects, outpatients with chronic obstructive pulmonary disease,[78] and ventilated patients.[5] Edi amplitude increases with worsening of respiratory status,[78] reduced ventilator assist,[5] reduced sedation,[85] increased demand for ventilation such as exercise,[79] and increased dead space.[86] The opposite holds true: Edi decreases within a given subject with respiratory improvement, increased sedation, increasing levels of assist, and reducing the partial pressure of arterial carbon dioxide (Pa_{CO_2}).

In a given subject, the amplitude measures of the Edi waveform can be reliably monitored and quantified, for example, during treatment and interventions. Because of anatomical differences (affecting the muscle-to-electrode distance filtering in particular), absolute Edi values can vary between subjects.[78] When trending Edi values over time, it should also be kept in mind that changes in ventilator settings and sedation level influence the magnitude of Edi. The published literature on Edi monitoring and NAVA using the commercially available $Servo_i$ ventilator demonstrates peak Edi values in the range of 8 to 18 μV in adults under a variety of conditions. In one study, values as low as 2 μV and as high as 50 μV were reported when Pa_{CO_2} was manipulated by extracorporeal membrane oxygenation.[87] Only one study to date has reported Edi values in children (mean values of 7 μV during NAVA).[88]

Edi values can be expressed relative to a maximum inspiratory effort (e.g., maximal inspiration without assist) in patients capable of performing the maneuver.[78,89] Sinderby et al[78] demonstrated that patients with impaired respiratory mechanics require a larger fraction of the maximum Edi to achieve the same mechanical output as healthy subjects

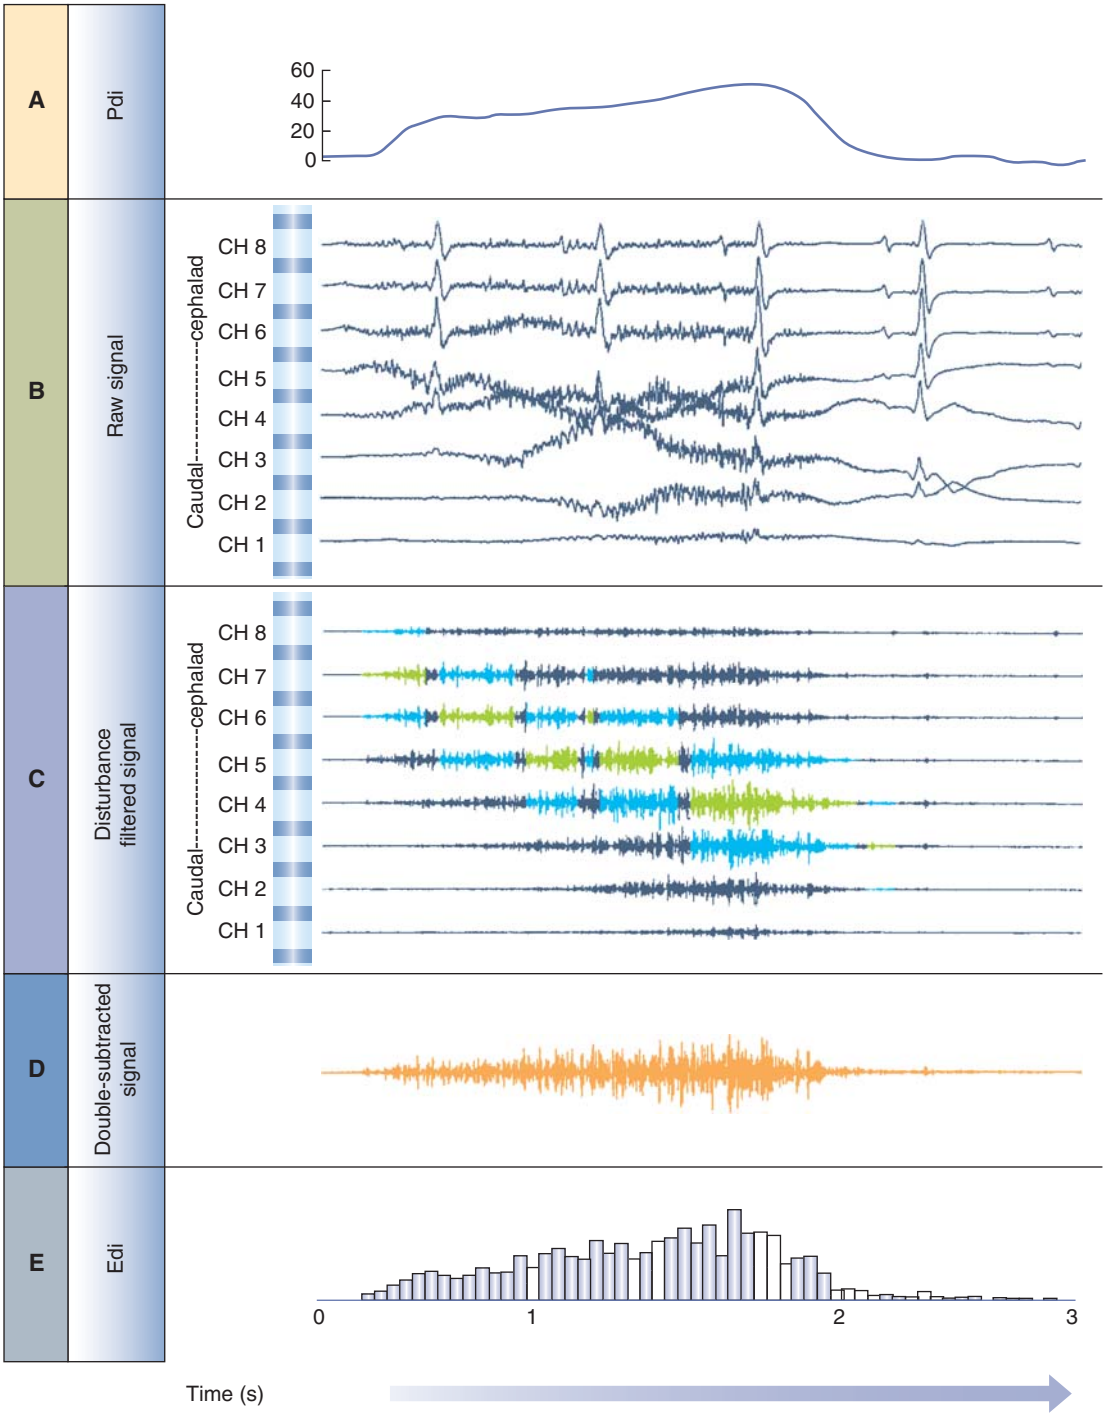

FIGURE 13-5 Edi signal processing during NAVA. **A.** Transdiaphragmatic pressure (Pdi) waveform obtained in a healthy subject performing an inspiration to total lung capacity. **B.** Raw signals obtained from the eight electrode pairs on the esophageal catheter during the same inspiration to total lung capacity. The electrode pair at the top is the most cephalad, whereas the one at the bottom is the most caudal (in the stomach). Note the presence of the electrocardiograms (ECGs) and slow-wave motion artifacts. **C.** Filtered raw signals after processing and removal of ECG and motion artifacts. *Blue* signals show electrode pairs above and below the diaphragm as detected by the cross-correlation algorithm described in Figure 13-4. Signals highlighted in *green* are the center signal as described in Figure 13-4. Note that the intensity of the signals increases throughout inspiration and moves downward with respect to the electrode pairs. **D.** Double-subtracted signal (*orange*) for the same inspiration to total lung capacity. **E.** Root-mean-square (RMS) values from the double-subtracted signal are plotted for every 16-millisecond segment. Note that the RMS values are plotted for the double-subtracted signal in this example from an earlier publication. Presently, the center signal RMS values are also included (as described in Fig. 13-4). (Adapted, with permission, from Sinderby et al.[78])

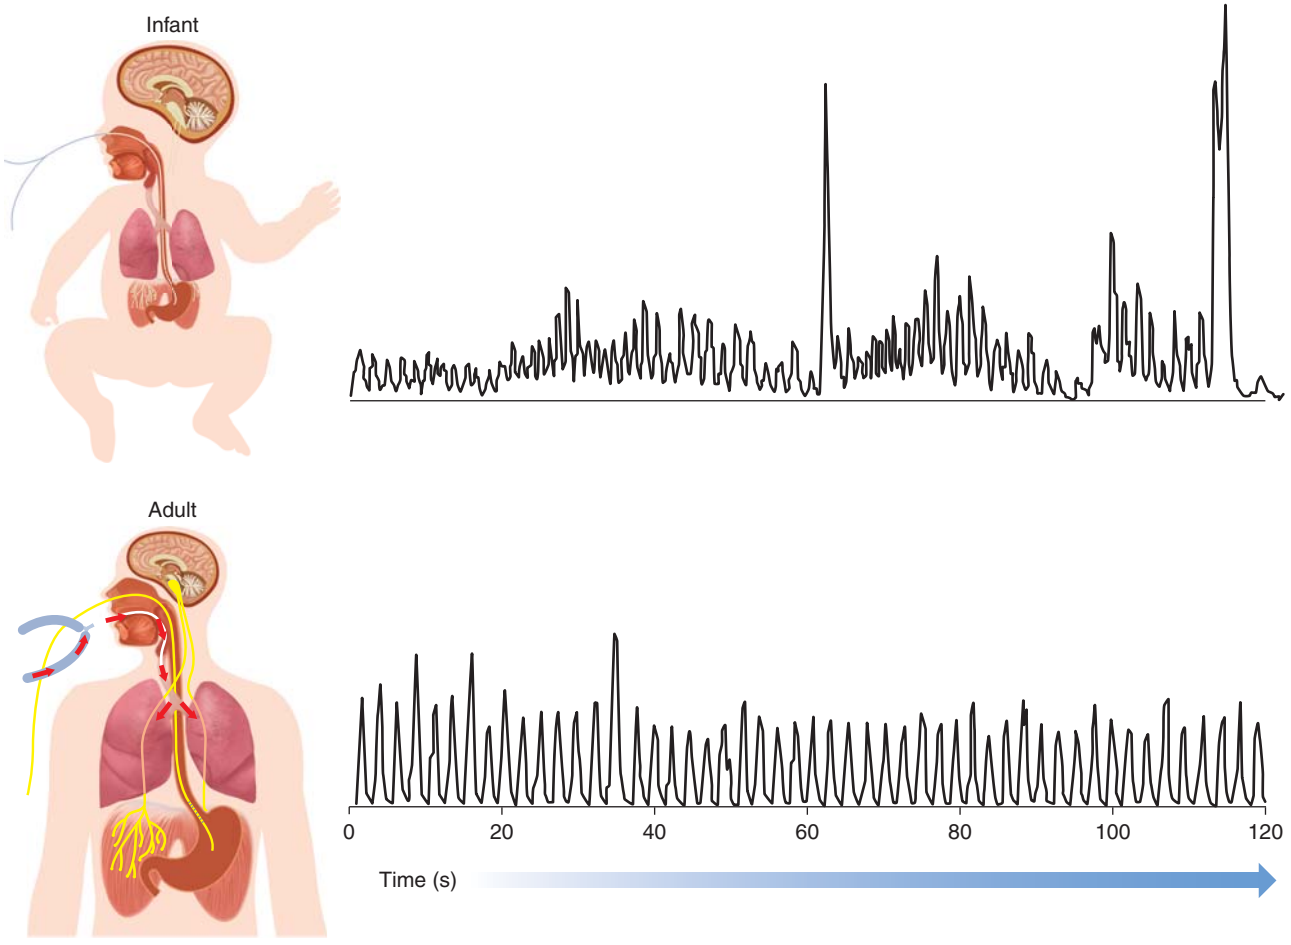

FIGURE 13-6 Examples of the diaphragmatic electrical activity (Edi) waveform in an adult patient and in a premature neonate. *Top panel*: Processed Edi waveform obtained in a nonintubated premature infant. *Bottom panel*: Processed Edi waveform obtained in an intubated adult. The Edi waveform in infants is characterized by larger variability in timing and amplitude, with a distinct amount of changes in the baseline, so-called tonic activity of the diaphragm. The Edi waveform in adults is generally less variable with minimal tonic Edi.

(Fig. 13-7). Statistically, the increase in Edi with respiratory impairment also holds true for absolute values in the same type of patients.[90] In patients with neuromuscular disorders, the Edi during spontaneous breathing, normalized to a maximal effort, can reveal the patient's neural activation reserve, where a ratio at or above 0.5 would indicate extremely little reserve.[78,91] In the same patient group, the absolute Edi observed during a maximal effort can provide information about changes in the total motor-unit pool, that is, a reduced maximal Edi (in μV) as the disorder progresses or vice versa. In patients with late-stage Duchenne muscular dystrophy, the absolute Edi values are low because of a reduced number of available motor units, but in relative terms, they represent approximately 50% of their maximum Edi.[91]

If the Edi persists after the end of an inspiration, the amplitude of the Edi waveform can be quantified (the so-called tonic Edi).[92] The presence of tonic Edi indicates continuous and elevated activation of the diaphragm between respiratory cycles (see Figs. 13-6 and 13-8). Studies in infants and animals suggest that elevated tonic Edi is a reflex response induced by lung derecruitment or removal of PEEP.[92–94] Experimental vagotomy abolishes this reflex.[93,94] Healthy subjects and *adult* mechanically ventilated patients show little, if any, tonic Edi.[78,95,96]

Besides amplitude parameters, the Edi waveform can be used to quantify the timing of the neural breathing pattern, such as neural inspiratory time, neural expiratory time, and neural respiratory rate.

If the catheter position has been deemed appropriate and functioning, a flat Edi waveform at zero μV indicates no diaphragmatic activation. This could be caused by numerous pathologies, including central apnea (no respiratory motor output, or suppressed respiratory drive secondary to mechanical ventilation-induced hyperventilation or sedatives), phrenic nerve damage, or neuromuscular transmission failure.

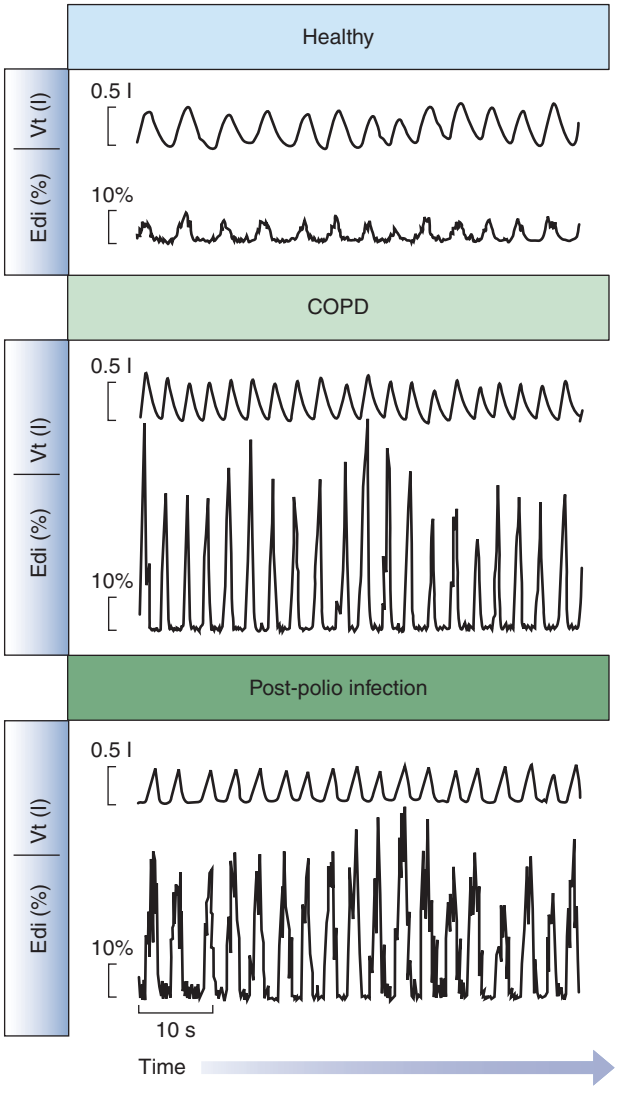

FIGURE 13-7 Examples of the Edi waveform and tidal volume in a healthy subject and in patients. Tidal volume and the Edi waveform are presented for a healthy subject (*top*), a patient with chronic obstructive pulmonary disease (*middle*), and a patient with prior polio infection (*bottom*), all breathing at rest with a mouthpiece (not on a ventilator). Note that all three subjects are breathing with a tidal volume of approximately 500 mL, although diaphragmatic activity required to achieve this tidal volume is eight times higher in the patients than the healthy subject. A higher Edi per milliliter indicates a worsened neuroventilatory efficiency. (Adapted, with permission, from Sinderby et al.[78])

Monitoring Patient–Ventilator Interaction in Conventional Modes of Ventilation Using the Electrical Activity of the Diaphragm

The Edi waveform is considered the reference standard for monitoring patient–ventilator interaction.[4,5,9,15,97,98] During conventional ventilation, when the Edi waveform is simultaneously displayed and superimposed with the airway pressure waveform, it provides immediate bedside information about the interaction between the patient and the ventilator.

An extreme case of poor patient–ventilator interaction is when a patient makes a neural inspiratory effort (Edi waveform starts to increase) and the ventilator does not deliver a breath (Fig. 13-9, *top left*)—often termed "wasted inspiratory efforts." In the example provided, wasted efforts occurred frequently (*red arrows*) during pressure control (PC) ventilation.

At the other extreme of poor interaction is delivery of a ventilator breath when the diaphragm is not active. In Figure 13-9 (*bottom left*), the diaphragm is not activated during the delivery of pressure-support ventilation (PSV). This situation can be a result of too-sensitive trigger settings and too-high levels of assist.

The differences in timing between Edi and ventilator pressure can be quantified for the start (triggering delay) and end (cycling-off delays) of the assisted breaths. Trigger delays are defined as the time interval between the onset of neural inspiratory effort and the onset of the ventilator breath. In Figure 13-9 (*top left*), the assist (*shaded*) can be seen to begin long after the start of neural inspiratory effort. Trigger delays can result from patient characteristics (such as hyperinflation) or ventilator characteristics (trigger sensitivity, trigger algorithms, valve performance).

Cycling-off of a ventilator breath, in healthy subjects, should coincide with the end of neural inspiration. Cycling-off is asynchronous when the ventilator breath terminates while the subject is neurally inspiring (premature cycling-off) or if it cycles-off long after the onset of neural exhalation (delayed cycling-off) (Fig. 13-9, *top left*). In PSV, pneumatic cycling-off algorithms are designed to sense a decrease in flow relative to the peak inspiratory flow. This makes the ventilator cycling-off dependent on the ratio of the time constant of the respiratory system to neural inspiratory time, and the ratio of the pressure support to maximal inspiratory pressure.[99]

Double-triggering can also be detected with the Edi,[98] and can be defined as the delivery of two ventilator breaths for one neural effort. During volume control ventilation or PSV, double-triggering results in the delivery of two full breaths, and could result in "breath stacking" and delivery of higher-than-targeted volumes or pressures.[100]

Monitoring Electrical Activity of the Diaphragm during Weaning from Conventional Ventilation

Monitoring the Edi alone, or in conjunction with other variables, can also be used for decisions about weaning and extubation. The use of daily Edi monitoring during spontaneous breathing trials or during the same fixed level of assist can provide information about changes in

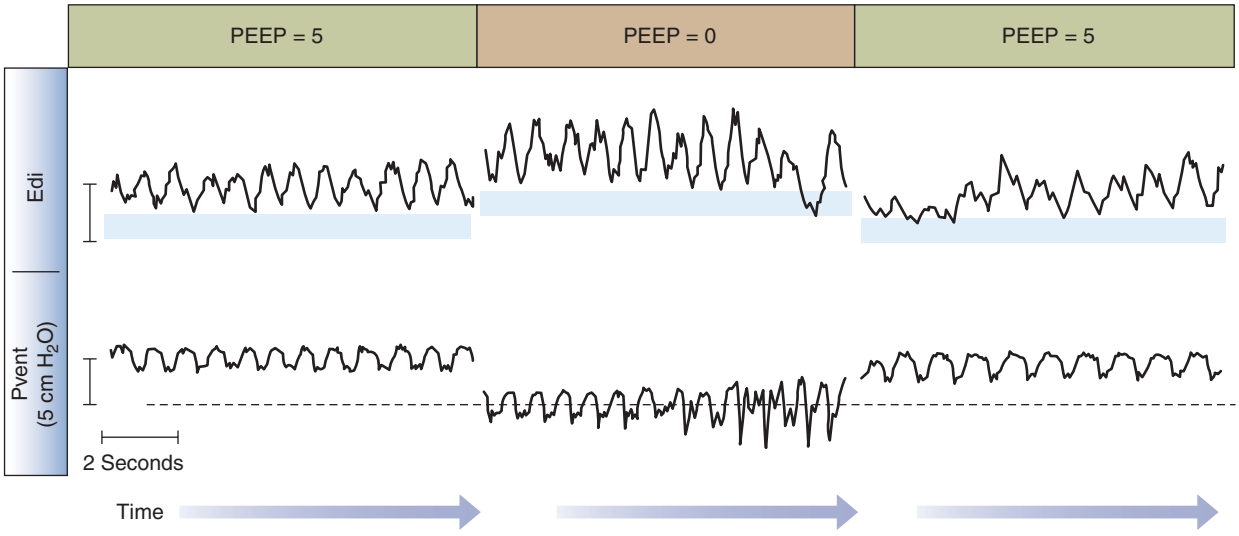

FIGURE 13-8 Impact of removal of positive end-expiratory pressure (PEEP) on tonic Edi. Example of tracings of ventilator-delivered pressure (Pvent) and diaphragmatic electrical activity (Edi) obtained in one intubated and mechanically ventilated infant on synchronized intermittent mandatory ventilation (only the spontaneous breaths in between mandatory breaths are displayed). The amount of tonic Edi (*blue horizontal bars*) increases with brief removal of PEEP (*center*). (Reproduced, with permission, from Emeriaud et al.[92])

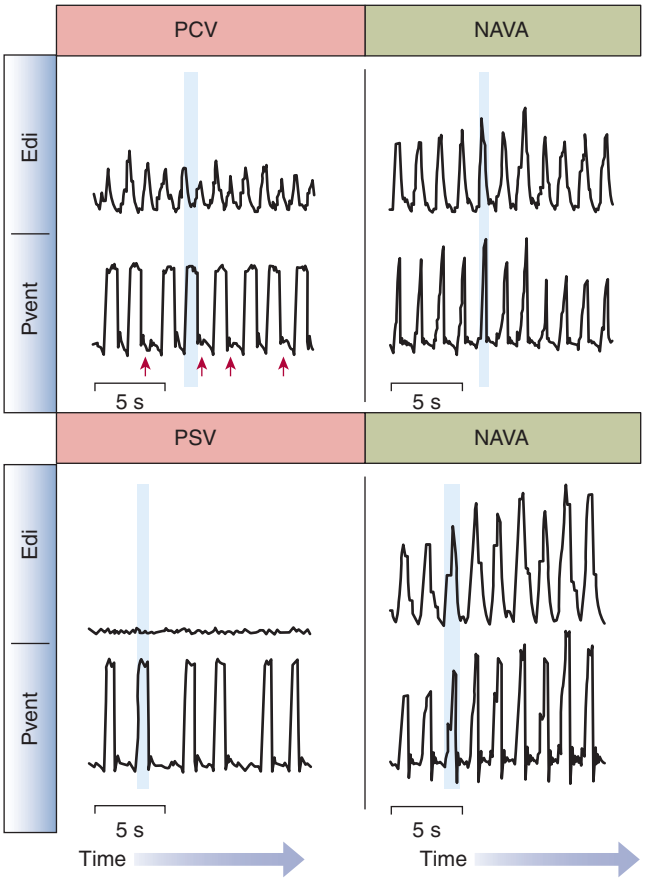

FIGURE 13-9 Patient–ventilator interaction during conventional ventilation and during NAVA. *Top*: Waveforms for Edi and ventilator-delivered pressure (Pvent) for an intubated adult patient breathing on pressure-control ventilation (PCV, *left*) and neurally adjusted ventilatory assist (NAVA, *right*). During PCV, there was a significant amount of wasted efforts (indicated by *red arrows*). During PCV, the delivery of assist (*shaded vertical blue bar*) occurred during neural exhalation, indicating poor patient–ventilator interaction. During NAVA (*right panel*), there were no wasted efforts and the assist was delivered during neural inspiration (*vertical blue shaded bar*). *Bottom*: Waveforms for Edi and ventilator-delivered pressure (Pvent) for an intubated adult patient breathing on pressure-support ventilation (PSV, *left*) and neurally adjusted ventilatory assist (NAVA, *right*). During PSV, too sensitive trigger settings, and too high levels of assist resulted in ventilator-induced hyperventilation and elimination of the Edi. The assist continued to be triggered and delivered (*blue shaded vertical bar*), despite no activation of the diaphragm. During NAVA (*right panel*), Edi controls the ventilator, and cannot be suppressed by ventilator-induced hyperventilation. (Adapted from Sinderby et al,[85] with the kind permission of Springer Science+Business Media.)

respiratory function. If the Edi is referenced to tidal volume during an unassisted breath, the tidal-volume-to-Edi ratio provides an index of the patient's efficiency to generate volume. If an inspiratory occlusion is performed at end-expiration, the ratio of the airway pressure to the Edi expresses the efficiency to generate force. In a recent study, these indices were shown to add important information about extubation failure and success.[101]

BASIC PRINCIPLES AND PHYSIOLOGY OF NEURALLY ADJUSTED VENTILATORY ASSIST

The Edi waveform is today used to control mechanical ventilation in NAVA.[41] NAVA can be delivered by invasive or noninvasive interfaces in all patient ages. Because NAVA uses the Edi waveform to control the assist, the assist is delivered in synchrony and in proportion to the patient's neural respiratory efforts, the latter governed by respiratory demand and reflexes (see Fig. 13-2).

Concept of Neurally Adjusted Ventilatory Assist

NAVA principally works as an artificial respiratory muscle under the same neural control as the patient's respiratory muscles. Figure 13-10 describes how, during NAVA, the patient's respiratory centers serve as the controller for both the patient's diaphragm and the ventilator at the same time. The diaphragm's pressure-generating efficiency depends on its neuromechanical coupling,[80] and is affected by such factors as dynamic hyperinflation and muscle weakness. For the ventilator, the efficiency of pressure generation depends on the NAVA level, a gain factor that controls the amount of pressure for a given Edi. The sum of the patient and ventilator pressures is the transpulmonary pressure, that is, the pressure that distends the lungs.

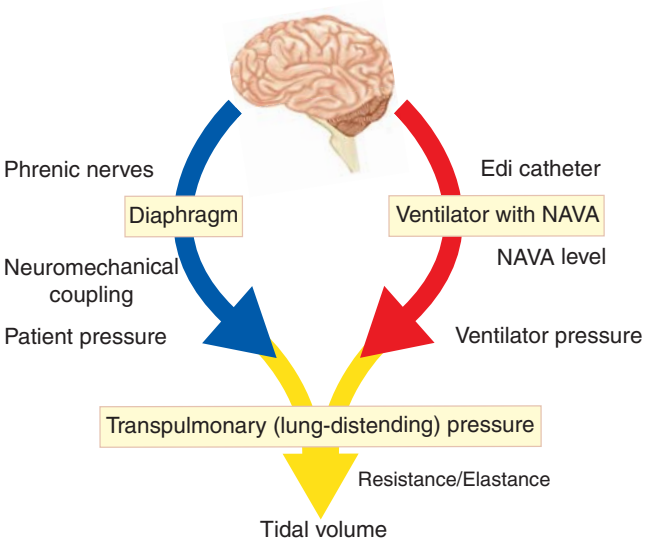

FIGURE 13-10 Concept of NAVA. During NAVA, the respiratory centers control both the patient's own diaphragm (*left*), resulting in a patient pressure, and the ventilator (*right*), creating a ventilator pressure (*right*). Their sum is the transpulmonary (or lung-distending) pressure. Depending on the patient's neuromechanical efficiency (*left*) and on the NAVA level (*right*), the relative contribution of the patient or ventilator to the lung-distending pressure will vary. For a given lung-distending pressure, the tidal volume generated will depend on the elastance and resistance of the patient.

At a fixed NAVA level, the Edi is solely responsible for changes in transpulmonary pressure. If respiratory drive (and hence Edi) is doubled, this doubles the patient pressure *and* doubles the ventilator pressure, therefore doubling transpulmonary pressure. Conversely, reducing the Edi by half reduces the patient pressure by half, *and* the ventilator pressure by half. Therefore, at a constant NAVA level, the patient is in full control of lung-distending pressure.

When the Edi remains constant, an increase in the NAVA level only increases the ventilator's relative contribution to the transpulmonary pressure. Therefore, in relative terms, the patient's contribution to volume is reduced compared to the ventilator.

Triggering

In its current platform, the assist is triggered by the initial increase in Edi (Fig. 13-11). Note that NAVA is triggered by a *deflection* in Edi and not at an absolute level of Edi; the latter would not function when tonic Edi is present. In principle, the Edi signal should precede the airway pressure signal and inspiratory flow signal and trigger on Edi (see Fig. 13-1). There are instances, however, when the filtering of the ECG or artifacts may coincide with the beginning of the Edi, or other inspiratory muscle groups could generate flow first. In this case, the ventilator is triggered by either changes in Edi *or* flow, on a "first-come, first-served" basis. This is to avoid inspiratory occlusions during triggering. If pneumatic triggering occurs (before Edi triggering), a pressure of 2 cm H_2O is delivered until the Edi appears.

Assist Delivery

Throughout neural inspiration, the ventilator delivers pressure in proportion to Edi. The pressure waveform follows the inspiratory portion of the Edi waveform (see Fig. 13-11). This matching of the pressure to the Edi is updated every 16 milliseconds. The Edi is multiplied by a proportionality constant known as the NAVA level, to increase or decrease the assist. The NAVA level has units of cm $H_2O/\mu V$.

The NAVA level is set manually. The range available today is between 0 and 15 cm $H_2O/\mu V$, and can be adjusted in steps of 0.1 cm $H_2O/\mu V$. The response of the ventilator to changes

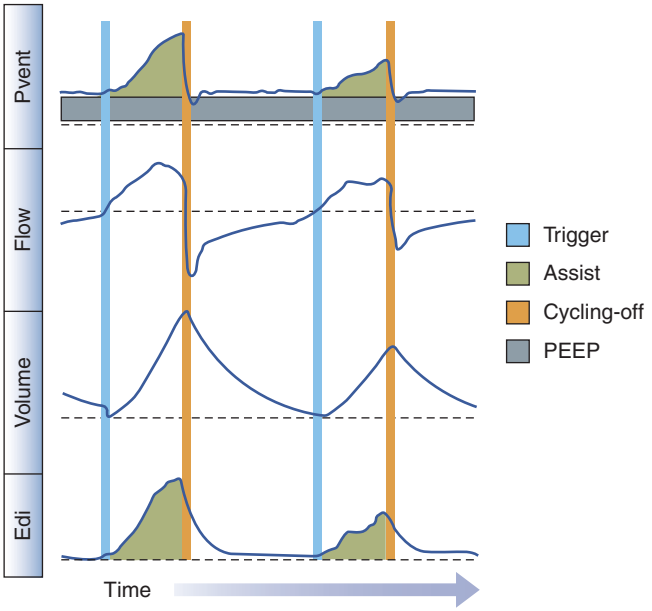

FIGURE 13-11 Features of NAVA. *From top to bottom:* Tracings for ventilator pressure (Pvent), flow, volume, and Edi are displayed for a patient breathing on NAVA. During NAVA, triggering of the ventilator occurs when the Edi exceeds a threshold deflection in Edi, as indicated by the *blue vertical line*. Throughout the inspiration, the ventilator pressure follows the Edi waveform (*green-shaded area*), and the NAVA level determines the proportionality between the ventilator pressure and the Edi. When the Edi waveform has decreased to 70% of the peak, the ventilator cycles off (*orange vertical line*) to a user-defined PEEP (*gray horizontal bar*). During NAVA (and a fixed NAVA level), a larger Edi waveform produces a larger pressure delivery (first breath) and a smaller Edi waveform produces a smaller pressure (second breath).

in the NAVA level is dependent on the absolute level of Edi, which varies between patients. If the Edi is large, it takes only a small change in the NAVA level to produce a large change in ventilator-delivered pressure. For example, an increase in the NAVA level by 1 cm $H_2O/\mu V$ when Edi peak is 10 μV results in an increase in ventilator pressure of 10 cm H_2O, whereas if the Edi is 1 μV, the increase in ventilator pressure is only 1 cm H_2O.

Upper pressure limits are applied during NAVA and can be adjusted. During NAVA the pressure is limited to 5 cm H_2O below the dialed-in limit.

Cycling-Off

During NAVA, the ventilator cycles-off the breath once the Edi drops to 70% of the highest value (see Fig. 13-11). When Edi peak values are low, cycling-off occurs at lower percentages. The breath is cycled off with pressure criteria any time the peak pressure exceeds the predicted NAVA pressure by 3 cm H_2O. In the case of a long neural inspiration, there are time criteria for cycling off: 1.5 seconds in infants and 2.5 seconds in adults.

Physiologic Response to Increasing Neurally Adjusted Ventilatory Assist Levels

If a patient is in respiratory failure, the typical physiologic response to increasing the NAVA level (from zero) is the following (Fig. 13-12).

- "Phase 1": At lowest NAVA levels (see Fig. 13-12, *left*), Edi is highest, indicating a large patient effort with insufficient ventilation. As the NAVA level is progressively increased, ventilator pressure increases, until at some NAVA level, a "patient-desired" transpulmonary pressure (and tidal volume) is reached. This first phase indicates that NAVA supplements the respiratory muscles to restore adequate ventilation.
- "Phase 2": Further increases in the NAVA level result in a constant transpulmonary pressure secondary to a reduction in Edi (see Fig. 13-12).[58,94,96,102,103] This second phase indicates a "comfort zone" where assist levels are adequate to sufficiently unload the respiratory muscles. In this second phase of unloading with NAVA, ventilator pressure, respiratory rate, and tidal volume change minimally.[58,94,96]
- "Phase 3": If the increase in NAVA level continues, the Edi will decrease further until it reaches a plateau (a minimum level). At highest NAVA levels, the Edi is not abolished (see Figs. 13-12 and 13-13),[58,102] but results in an irregular breathing pattern secondary to a too-high loop gain.[96] Even with maximum unloading of the diaphragm, Edi is still present and able to control the ventilator[102] (see Fig. 13-13), without inducing reflex reductions in respiratory rate.[4,15,104–106]

The downregulation of Edi and the avoidance of excessive assist delivery during NAVA have been verified experimentally as preventing ventilator-induced lung injury.[107]

Weaning

Improvement of respiratory function or reduced respiratory demand reduces the Edi waveform. Considering that the pressure delivered during NAVA follows the Edi, as the patient's respiratory status improves and Edi decreases, the pressure delivered will also decrease as long as NAVA levels and sedation management remain constant. Thus, with respiratory improvement, NAVA can—secondary to its close neural integration—be thought of as a "self-weaning" mode.

Noninvasive Neurally Adjusted Ventilatory Assist

The principal difference between invasive and noninvasive NAVA is that the bias flow during PEEP is automatically adjusted (during noninvasive NAVA) and can reach much higher flow levels, ensuring maintained PEEP during the

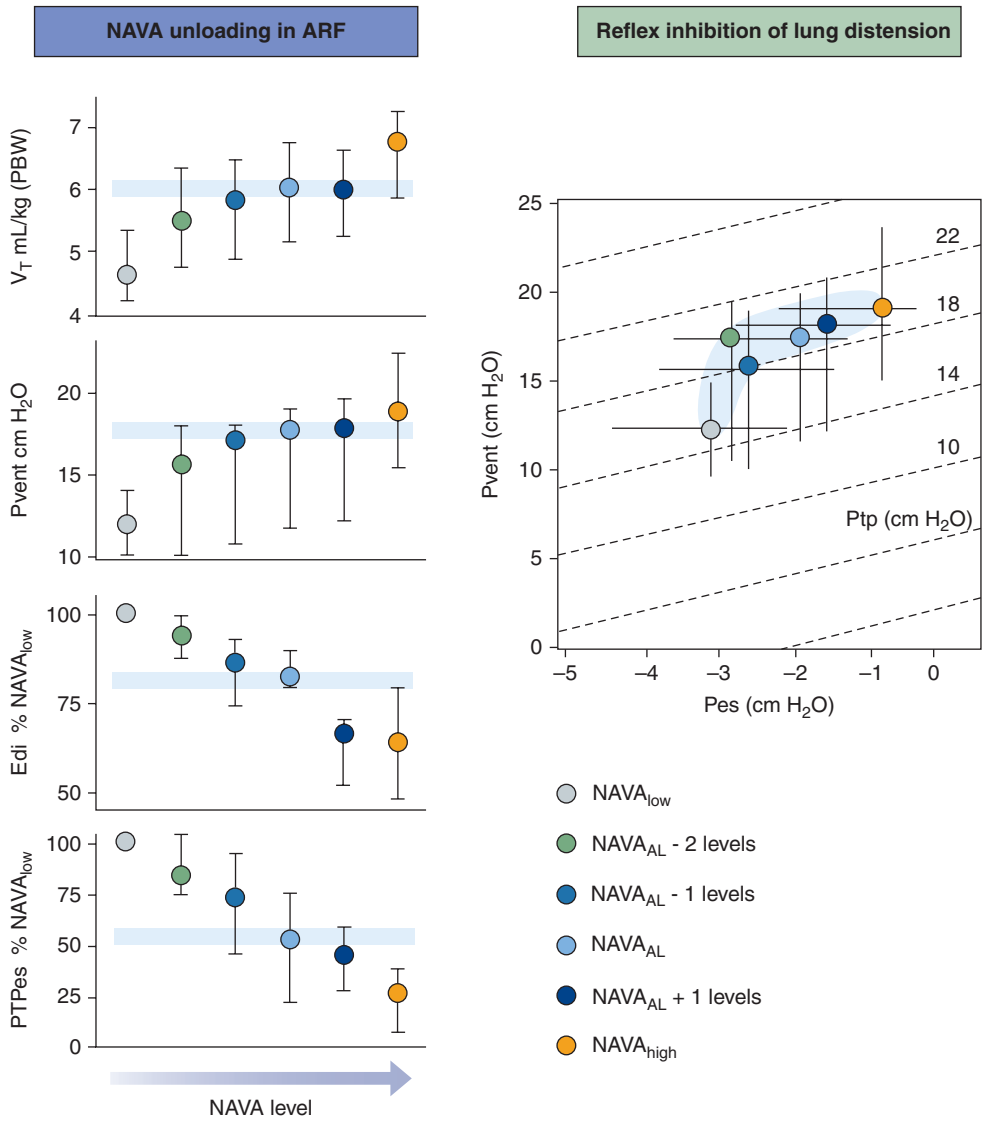

FIGURE 13-12 Physiologic response to increasing NAVA levels. *Left panel:* Changes in tidal volume (V_T) per predicted body weight (PBW), mean inspiratory ventilator pressure (Pvent) including positive end-expiratory pressure (PEEP), electrical activity of the diaphragm (Edi), and esophageal pressure time product (PTPes) for a group of patients during titration of the NAVA level. The initial increase in Pvent and V_T between the lowest NAVA level (*gray dot*, $NAVA_{low}$) and the adequate NAVA level (*royal blue dot*, $NAVA_{AL}$) was associated with a reduction in Edi and PTPes. Thereafter, further increases in the NAVA level did not significantly change either Pvent, V_T, nor minute ventilation (not shown) while the reduction of PTPes and Edi continued from $NAVA_{AL}$ to $NAVA_{high}$ (*orange dot*). *Right:* Interaction between mean inspiratory ventilator pressure (Pvent, *y axis*), esophageal pressure (Pes, *x axis*), and transpulmonary pressure (Ptp, *dashed diagonal lines*) during a NAVA level titration. In this example, from $NAVA_{low}$ (*gray dot*) to one level below $NAVA_{AL}$ ($NAVA_{AL}$–1 level), Pvent increased by 5.0 cm H_2O and reduced the Pes deflection by 0.5 cm H_2O such that transpulmonary pressure increased by 4.5 cm H_2O. Further increasing the NAVA level from $NAVA_{AL}$ to $NAVA_{high}$ resulted in changes of Pvent and Pes that were similar in magnitude and, hence, in an essentially unaltered transpulmonary pressure. PEEP remained unchanged during the NAVA level titration. *ARF*, acute respiratory failure. (Adapted, with permission, from Brander L et al.[96])

neural expiration even in the presence of large leaks. There are also some differences in alarms, which are beyond the scope of this chapter.

In reference to Figure 13-1, Edi precedes inspiratory flow in the chain of events of spontaneous breathing. When a leak is present, Edi is a true indicator of when the breath starts, whereas the flow measurement in itself is affected by the leak. Studies have confirmed that patient–ventilator interaction during NAVA is not affected by severe leaks.[108,109]

Regarding noninvasive ventilation, an important consideration is the anatomical and physiologic consequences of avoiding intubation. Endotracheal intubation conveniently divides the air and food passages such that ventilator assist can be delivered with no interference from upper airway regulation and swallowing. Delivery of assist through the upper respiratory tract using a noninvasive interface, however, introduces a demand to synchronize assist delivery with inspiration for several reasons.

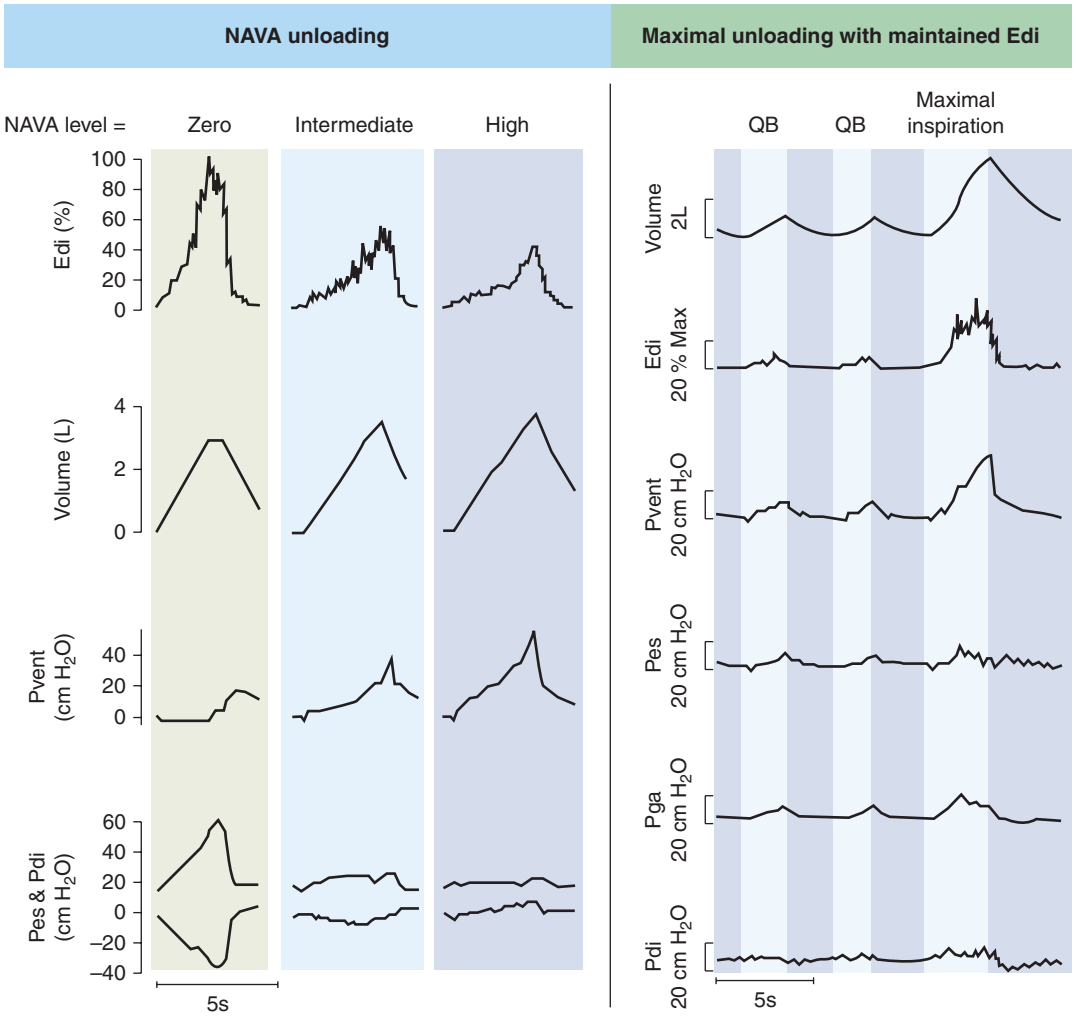

FIGURE 13-13 Respiratory muscle unloading with NAVA. *Left:* Tracings (*from top to bottom*) of electrical activity of the diaphragm (Edi), volume, ventilator pressure (Pvent), and esophageal (Pes) and transdiaphragmatic pressure (Pdi) obtained in one healthy subject performing maximal inspirations with three NAVA levels (zero, intermediate, and high). Increasing the NAVA level resulted in increased ventilator-delivered pressure and deactivation of the diaphragm (by 60%). Note that this was occurring while the Pdi and Pes deflections disappeared, indicating 100% unloading. *Right:* Tracings (*from top to bottom*) of volume, Edi, ventilator pressure (Pvent), esophageal pressure (Pes), gastric pressure (Pga), and transdiaphragmatic pressure (Pdi) obtained in a healthy subject breathing on NAVA at high NAVA levels. The first two breaths were obtained during quiet breathing and the third breath during a maximal inspiration. Note the 100% unloading of the diaphragm (flat Pdi) in all breaths regardless of the level of diaphragm activation, and the remaining Edi, which is still able to control the ventilator at both volumes. (Adapted, with permission, from Sinderby et al.[102])

In humans, the upper airways constitute a common tract allowing ventilation, ingestion, and speech, requiring neural control systems to coordinate respiration with swallowing, speech, cough, and vomiting.[110–113] In 1949, Negus[114] provided the first notation that the glottis opens before inspiration starts. In 1969, Suzuki and Kirchner[115] demonstrated that phasic activity of vocal cord dilators occurs in synchrony with phrenic nerve activity. Kosch et al[116] demonstrated that laryngeal abductors are activated before the diaphragm. The genioglossus is activated and dilates the airway before diaphragmatic activation[117] and airway flow.[118,119] During expiration, activation of, for example, the pharyngeal constrictors also has been suggested to modulate the resistance to airflow.[120,121] Recently, active glottal closure was described during high levels of noninvasive conventional ventilation in nonsedated newborn lambs[122]; active glottal closure is likely mediated by bronchopulmonary receptors.[63]

Another factor complicating the implementation of noninvasive ventilation is swallowing. Swallowing must interact with the inspiratory muscles in a fashion that minimizes disturbances to breathing. In awake human subjects, swallowing is associated with apposed vocal cords and an apneic period,[123] normally followed by expiration.[124] It is suggested that this sequence (swallow followed by expiration) may be protective against aspiration.

The role of the upper-esophageal sphincter is to prevent reflux of food into the airways as well as avoid entry of

air into the digestive tract. During swallowing, the upper-esophageal sphincter is open to accommodate passage of a bolus into the esophagus, and hence delivery of pressure during swallowing increases the risk of gastric distension. During noninvasive NAVA, no gastric distension was observed even at extremely high levels of assist.[108]

Vocal control is achieved by the coordinated efforts of respiratory, laryngeal, and articulatory muscles. Given that speech is an expiratory maneuver, diaphragmatic involvement only occurs on inspirations between phonation, thus assist delivery will be synchronized with NAVA. Abnormal rhythm of the breathing pattern and Edi waveform are anticipated during speech.

In 1937, Coryllos[125] described cough as being composed of three distinct phases: (a) inspiratory, (b) compressive (expiratory pressure generation against a closed glottis), and (c) expulsive (opening of the glottis). The diaphragm is only electrically active during the first two phases and not during the expulsive phase.[121,126] Figure 13-14 illustrates coughing during NAVA.

During the expulsive phase of vomiting, the crural and costal diaphragm dissociate their activities, with the crural diaphragm relaxing (i.e., not triggering NAVA) to allow the ejection of the gastric contents, and the costal diaphragm contracting, to increase the abdominal pressure and thus force the gastric contents outwards.[127–130]

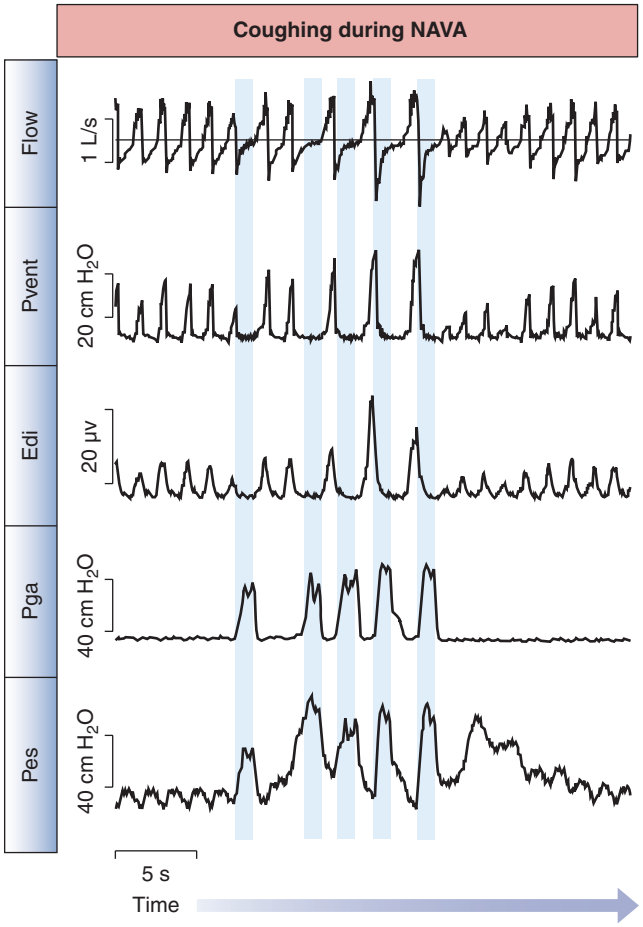

FIGURE 13-14 Coughing during NAVA. Tracings (*from top to bottom*) of flow, ventilator pressure (Pvent), diaphragmatic electrical activity (Edi), gastric pressure (Pga), and esophageal pressure (Pes) in an adult intubated patient ventilated with NAVA who is coughing. The *blue-shaded* vertical areas highlight the coughs (upswing in Pga). The Edi waveform shows termination of Edi during coughs. The functionality of NAVA was not affected by the coughs. (Note that the second compressive phase described in the text is lacking in the intubated patient.)

INDICATIONS AND CONTRAINDICATIONS

Indications

NAVA is indicated for use in patients of all ages who require and qualify for partial ventilator assist, and in whom spontaneous respiratory activity is present. NAVA may prove especially useful in patients at risk for prolonged mechanical ventilation and who fail spontaneous breathing trials.

Monitoring the Edi is indicated in all patients of all ages in any mode of ventilation, invasive or noninvasive, when the goal is to perform bedside evaluation of patient–ventilator interaction and neural breathing pattern, and to ensure that spontaneous breathing is present.

Contraindications

NAVA cannot be applied if (a) Edi is absent, (b) nasogastric and/or orogastric catheters are contraindicated, or (c) ventilatory parameters are unacceptable.

ADJUSTMENTS AT THE BEDSIDE

Implementation of NAVA requires a ventilator with the NAVA option, module, and software, and an Edi catheter.

Electrical Activity of the Diaphragm Catheter Positioning

Catheter positioning is achieved by inserting the tip of the catheter nasally or orally to a predicted distance, and then adjusting the position with feedback from a display showing an Edi curve and four raw signals not filtered for ECG (Fig. 13-15). With the catheter in appropriate position, both P and QRS waveforms should be present at the top and P waves should disappear toward the bottom as illustrated in middle panel of Figure 13-15. The top and bottom panels of Figure 13-15 demonstrate examples of ECG waveforms when the catheter is too far out or too far in, respectively.

A secondary verification method on the same window involves the highlighting of the leads closest to the diaphragm (in blue on the commercially available system), as determined

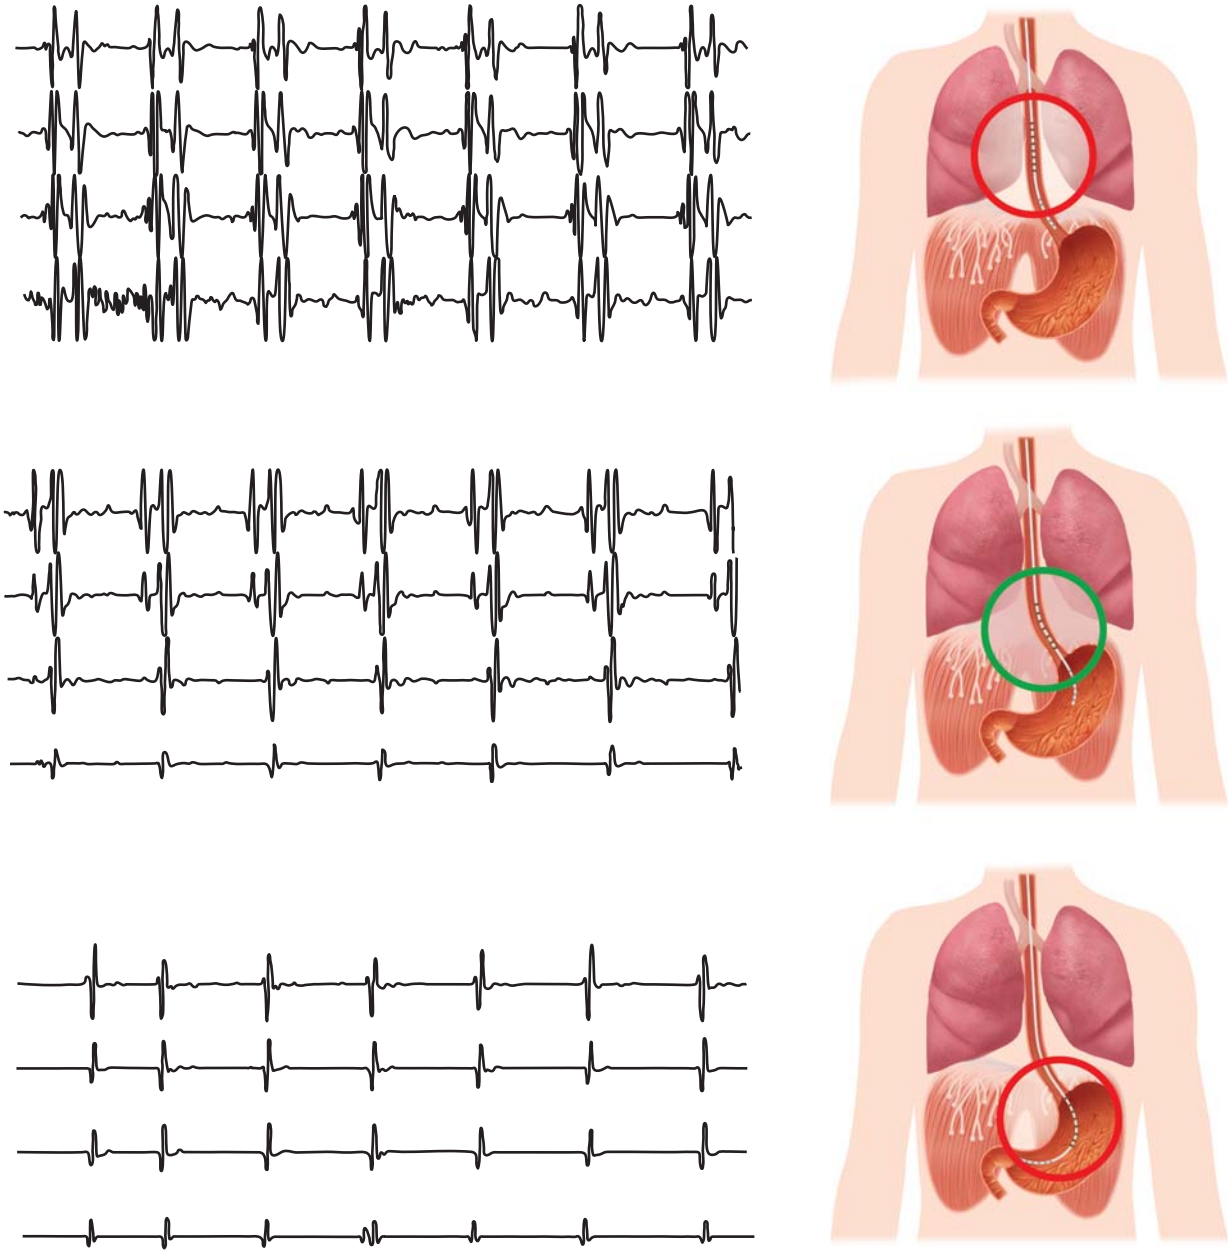

FIGURE 13-15 Electrode positioning during NAVA. Unfiltered tracings obtained from four electrode pairs (top is most cephalad, bottom most caudal) on the Edi catheter when the catheter is too far out (*top*), in good position (*middle*), and too far in (*bottom*). The *middle panels* indicate the correct pattern for the ECG waveforms when the Edi catheter is positioned appropriately (diaphragm located approximately in the middle of the electrode array). This pattern is characterized by distinct P waves and QRS waves whose amplitude is largest at the top, and diminishes more distally. See text for details.

by the cross-correlation method (see Fig. 13-4).[75] Ideally, the two middle leads should be highlighted during inspiration.

The catheter should be fixed after appropriate positioning and the final insertion distance noted. This method has been validated in adult[131] and pediatric[132] patients.

Setting the Neural Trigger

The trigger during NAVA detects a threshold increase in the Edi waveform. The sensitivity of the neural trigger is adjustable, with a default setting of 0.5 μV.

Initial Setting of the Neurally Adjusted Ventilatory Assist Level

To deliver a target pressure, the following formula can be used: Ventilator pressure (above PEEP) in cm H_2O = (peak Edi – min Edi) in μV × NAVA level (cm H_2O/μV). It is possible, that once the NAVA level has been set, and the patient is switched over to the NAVA mode, the Edi waveform might change, and may therefore be different from the targeted pressure.

As an alternative, the NAVA level can be set so that the peak pressure attained during conventional ventilation can be matched. A designated "NAVA preview window" allows feedback for this. It is possible that once the patient is switched over to the NAVA mode, the Edi waveform might change, and may be therefore different from the predicted pressure.

The NAVA level can be titrated by performing stepwise increases in the NAVA level from a minimal level.[58,95,96] It has been suggested that the adequate NAVA level is the one where the increase in ventilator-delivered pressure is slowing—or even plateaus.[96]

Setting Backup Parameters

As in other modes of mechanical ventilation, upper pressure limits and backup parameters should be set for the appropriate patient age and condition.

Setting Positive End-Expiratory Pressure

PEEP should be set as with other modes of mechanical ventilation. In infants, monitoring the tonic Edi may aid with adjustment of PEEP. Emeriaud et al[92] and Allo et al[94] have demonstrated that applying PEEP can reduce tonic Edi (see Fig. 13-8). Monitoring the ratio between tidal volume and Edi (neuroventilatory efficiency) allows identification of an efficient PEEP level.[95] During NAVA, PEEP does not have to be applied to overcome intrinsic PEEP.

Adjustment of the Neurally Adjusted Ventilatory Assist Level during Weaning

NAVA can be combined with any weaning method, for example, daily spontaneous breathing trials, with the advantage that it provides numerical and bedside information about respiratory drive. Any improvement in patient respiratory function (as indicated by a decrease in Edi for the same NAVA level) should be corrected by reducing the NAVA level. The easiest method is to note the Edi value obtained when the patient was comfortable (Edi baseline) and if Edi decreases, reduce the NAVA level until the Edi returns to baseline value. If the patient has undergone a spontaneous breathing trial, another approach is to target an Edi amplitude relative to that observed during a spontaneous breathing trial.[133] Yet another approach is to perform daily titrations of the NAVA level to determine an adequate NAVA level.[96]

TROUBLESHOOTING

The reader is referred to the manufacturer's user manual (Maquet Critical Care AB, Solna, Sweden).

ADVANTAGES AND LIMITATIONS

Table 13-1 lists the advantages and limitations of NAVA.

TABLE 13-1: ADVANTAGES AND LIMITATIONS OF NAVA

Advantages of NAVA
Edi monitoring
Standardized Edi catheter position procedure allows reliable feeding tube placement
Monitoring presence or not of spontaneous breathing during conventional ventilation
Monitoring patient–ventilator interaction during conventional ventilation
NAVA Mode
Improved timing between patient effort and assist delivery independent of
a. Leaks
b. Properties of interface
c. Liquid in respiratory circuit
d. Cardiogenic oscillations in the airway flow
e. Intrinsic PEEP
Neurally integrated with timing of upper airway activity and function
Matching of magnitude assist delivery to patient effort
a. Preservation of respiratory drive
b. No runaway
c. Prevention of excessive assist delivery
d. Responds to changes in respiratory demand
Limitations of NAVA
Cannot use in absence of respiratory drive
Cautious use with uncontrollable respiratory drive
Too-high NAVA levels cause irregular breathing pattern
Cannot be used when feeding tube is contraindicated
Signal disturbances on Edi signal may affect NAVA performance, e.g., ECG leak through

COMPARISON WITH OTHER MODES

Fundamental Differences between Neurally Adjusted Ventilatory Assist and Other Modes

The difference between conventional ventilation (such as PSV, pressure control ventilation, assist-control ventilation, and synchronized intermittent mandatory ventilation) and NAVA lies in the signal used to control the ventilator (see Fig. 13-1). Conventional modes of ventilation control the timing of assist delivery by pneumatic signals (pressure or flow at the airway) or time criteria, and the level of assist is pressure or volume targeted. NAVA, on the other hand, is controlled by the patient's own Edi, occurring at a level proximal to muscle function and respiratory mechanics, and which also responds to respiratory feedback loops.

Neurally Adjusted Ventilatory Assist versus Conventional Ventilation, Impact on Patient–Ventilator Interaction

Compared to conventional modes of ventilation, NAVA improves patient–ventilator synchrony in terms of triggering and cycling-off delays.[4,15,98,103,109] The amount of improved synchrony depends on the disease etiology and the settings in the conventional ventilation arm.

The improvement in trigger delays with NAVA is in the 100 millisecond range.[4,98,103] When expressed as a percentage of the neural inspiratory time, NAVA also shows less relative trigger delay (13% to 14% of neural inspiratory time) than PSV (up to 35% of neural inspiratory time at high levels of PSV).[4] One study recently showed that of their twenty-five patients with mixed etiologies, none had trigger delays greater than 150 milliseconds during NAVA.[98] The trigger delay increases with increasing PSV, but is not affected by increasing NAVA levels.[4,15,103,134] In premature infants, 13% of the breaths during conventional ventilation began *before* the onset of Edi.[109]

Wasted efforts are worsened when the PSV level is increased.[3,4,103,134] In contrast, with NAVA, no wasted efforts have been reported in the literature, even when the NAVA level is increased.[4,15,103,134]

Several investigators have reported shorter cycling-off delays during NAVA compared to PSV in adults[4,98] and in rabbits with lung injury.[103] The cycling-off delays are prolonged with increasing PSV, whereas with increasing NAVA, there is no effect.[4,103,134] In premature infants, cycling-off during PSV or PSV with volume guarantee actually occurs *before* the cycling-off during NAVA.[109]

Some investigators have combined the observed asynchronies (trigger delays, wasted efforts, cycling-off delays) to quantify an "asynchrony index," which was found to be significantly lower during NAVA compared to PSV in adults[4,15,98,137] and neonates,[138] and worsened with increasing levels of PSV.[4,15,137]

One challenge for achieving patient–ventilator synchrony is when leaks are present. Figure 13-16 demonstrates airway pressure tracings obtained during noninvasive PSV and noninvasive NAVA, with increasing leak. The worsening asynchrony with increasing leak was accompanied by an eightfold increase in breathing effort (esophageal pressure-time product, not shown). In premature infants and in rabbits with acute lung injury, trigger delays, and cycling-off delays were equal during invasive NAVA and during noninvasive NAVA.[108,109]

Patient-ventilator interaction is difficult to achieve with pneumatically controlled non-invasive ventilation applied with the helmet interface because of its large volume, high compliance, and sensitivity to leaks.[139] Moerer et al[135] examined patient–ventilator synchrony during neurally and pneumatically triggered and cycled-off PSV with the helmet in healthy subjects. Trigger delays, wasted efforts, and cycling-off delays all increased with increasing PSV when pneumatic control was used. During neural triggering and cycling-off, increasing PSV and breathing frequency did not affect trigger and cycling off delays. The comfort of breathing was significantly better during neurally triggered and cycled-off PSV.

By design, NAVA delivers assist in proportion to the Edi, and a few studies have demonstrated a high correlation between Edi and peak airway pressure delivered,[15,103,109] which was superior to the correlation between Edi and pressure during PSV (Fig. 13-17). The high correlation between Edi and peak ventilator pressure was not affected by the presence of a large leak during noninvasive NAVA in premature babies.[109] During PSV plus volume guarantee, Beck and Sinderby demonstrated a negative correlation between Edi and pressure, indicating a reversed proportionality.[140]

As a result of the improved synchrony with NAVA, the pressure-time product of the diaphragm and the Edi-time product are both less during NAVA than during PSV.[4,103] The diaphragmatic work of breathing during the trigger phase was also found to be less for NAVA compared to PSV, which also showed increased diaphragm work when the PSV level was increased.[4]

Double triggering, delivery of two ventilator breaths back-to-back, occurs during NAVA and PSV; while the prevalence is low,[15,16,98,141] it can sometimes be frequent.[13]

Neurally Adjusted Ventilatory Assist versus Conventional Ventilation, Impact on Breathing Pattern and Gas Exchange

In studies where peak airway pressure was matched, tidal volume was lower during NAVA compared with

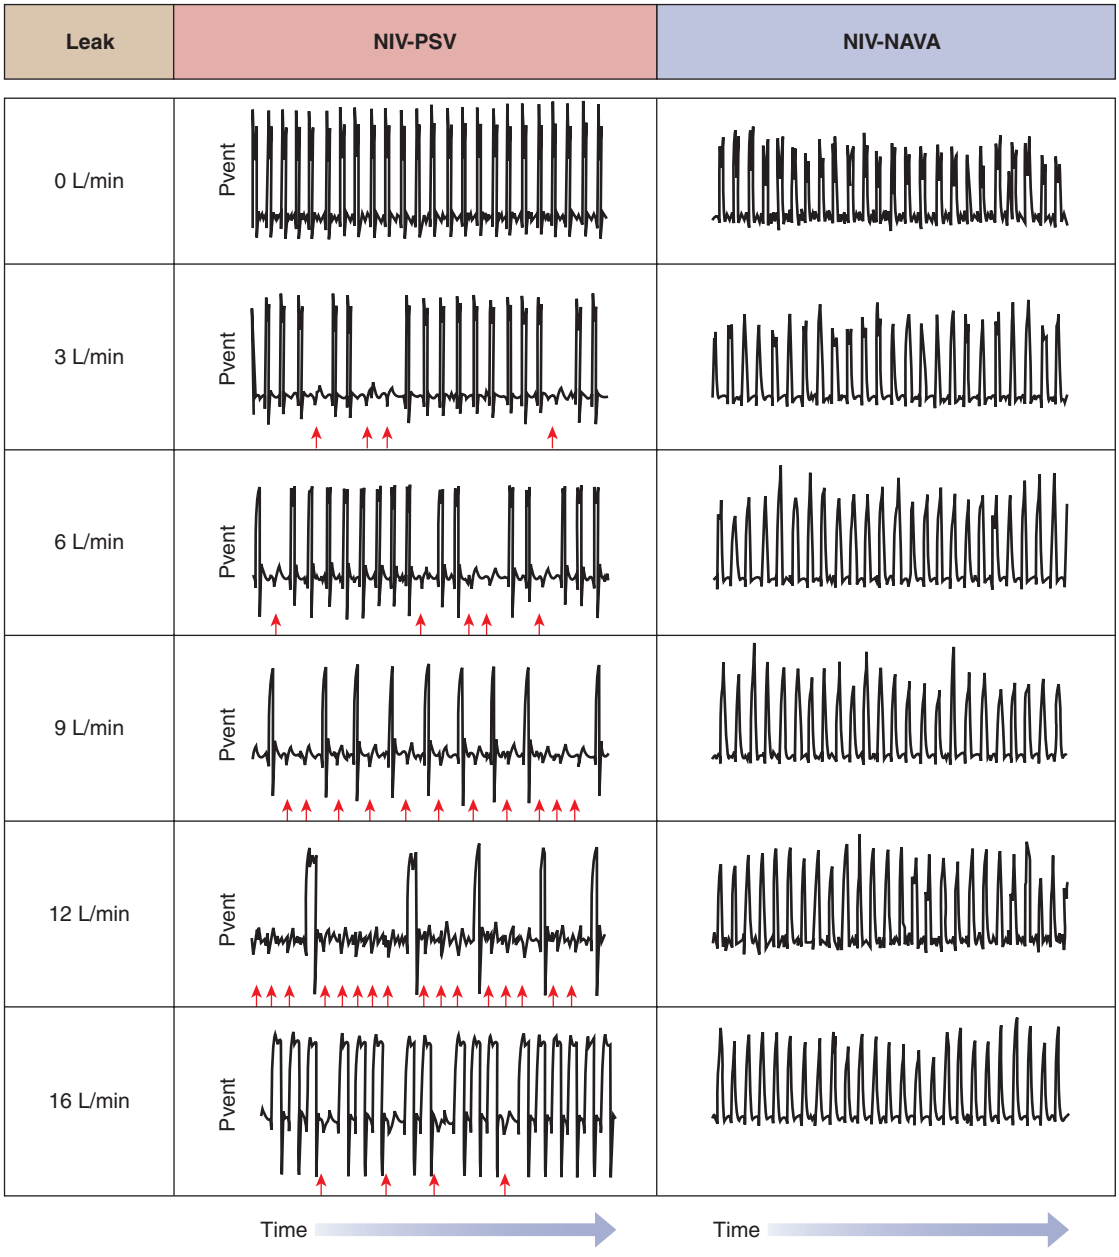

FIGURE 13-16 Patient–ventilator interaction during noninvasive PSV and noninvasive NAVA. Ventilator-delivered pressure (Pvent) is displayed for noninvasive pressure support (NIV-PSV, *left*) and noninvasive NAVA (NIV-NAVA, *right*), for periods of increasing leak (0 to 16 L/min, *top to bottom*). The wasted efforts (*red arrows*) increased with increasing leak during NIV-PSV, whereas wasted efforts were not observed during NIV-NAVA. At the highest leak tested (16 L/min), the ventilator also demonstrated autotriggering and hangup of the ventilator breaths (that were cycled-off by time criteria). During NAVA, synchrony was maintained in terms of timing and proportionality, despite the increasing leak. The increasing asynchrony during NIV-PSV with increasing leak was associated with an eightfold increase in effort (not shown).

PSV,[15,96,137,141] usually 6.5 to 8.5 mL/kg of predicted body weight in adult patients of all illnesses and severities. In animal studies, tidal volume during NAVA is lower than during PSV[103] or volume control set to a lung-protective strategy of 6 mL/kg.[104] When attempts are made to systematically increase PSV and NAVA levels, tidal volume increases during PSV but remains more or less unchanged during NAVA, secondary to downregulation of Edi.[4,103,137] In critically ill postoperative patients, Coisel et al[142] demonstrated no significant differences in tidal volume between NAVA and PSV at baseline, although after 24 hours of each, tidal volume was lower during NAVA.

Some studies report a higher respiratory rate with NAVA compared to PSV.[4,98,137,141,143] The results, however, should be interpreted with caution because the distinction is not always made between neural respiratory rate and ventilator rate. Colombo et al[15] and Spahija et al[4] both reported a reduction in neural respiratory rate with increasing PSV

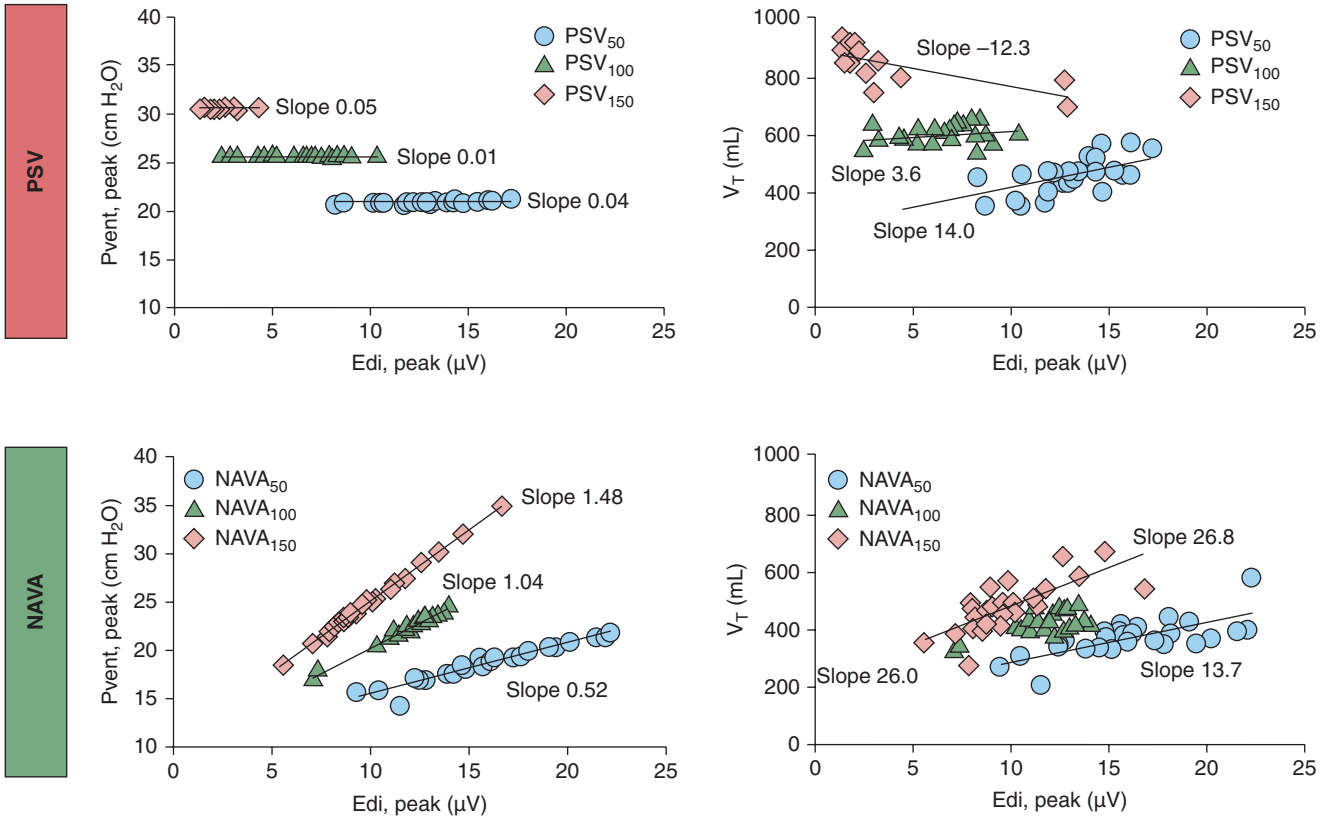

FIGURE 13-17 Proportionality between Edi and ventilator pressure during pressure-support ventilation (PSV) and during NAVA. Relationships between ventilator pressure (Pvent) and Edi (*left panels*), and tidal volume (V_T) and Edi (*right panels*) are depicted for three assist levels with PSV (*upper panels*) and NAVA (*lower panels*), in one patient. The three levels of assist are indicated by different colors. Pvent did not change with varying Edi in PSV. Oppositely, in NAVA, Pvent varied in proportion to Edi. During PSV, V_T slightly rose when increasing Edi only at the lowest level of support. During NAVA, V_T augmented as Edi increased at all levels of assistance. (Adapted, with permission, from Colombo et al.[97])

levels, whereas this was not observed during increasing NAVA levels.[15,96] Another confounding factor in the interpretation of respiratory rate is that, during conventional ventilation, wasted efforts mask the patient's neural respiratory rate. During PSV, the neural respiratory rate can be higher than the ventilator rate.[103] Hence the increased respiratory rate sometimes observed during NAVA may simply be the elimination of wasted efforts. Coisel et al[142] showed no significant differences in ventilator respiratory rate between PSV and NAVA in their group of postoperative patients at baseline or after 24 hours. Beck et al showed a reduced neural respiratory rate during NAVA compared to PSV in preterm infants.[109]

Breathing pattern variability was higher during NAVA compared to PSV[142,143] and was held responsible for improved oxygenation.

All studies comparing NAVA to PSV show maintained clinical stability in terms of heart rate,[109,138] oxygen saturation in both adult[142] and neonatal populations,[109,141,144] minute ventilation,[98,137] and equivalent values of Pa_{CO_2} and partial pressure of arterial oxygen (Pa_{O_2}).[4,15,137,141,143,144] Coisel et al[142] reported an improved Pa_{O_2}/FI_{O_2} (fractional inspired oxygen concentration) ratio after 24 hours of NAVA in postoperative patients. In one pediatric study that measured hemodynamics, NAVA and PSV were equivalent.[138]

Neurally Adjusted Ventilatory Assist versus Conventional Ventilation, Limitation of Excessive-Assist

In rabbits with lung injury, Beck et al[103] demonstrated that a fourfold increase in PSV generated four times as much airway pressure, whereas, a fourfold increase in NAVA level resulted only in an increase from 3.5 cm H_2O to 7 cm H_2O, secondary to downregulation of Edi at higher NAVA levels. In adult and critically ill patients, progressively increasing the NAVA level is associated with a deactivation of the diaphragm at higher levels, such that delivered pressure and tidal volume do not increase excessively.[4,15,96,134,137,143] This is in clear contrast to studies with increasing PSV where the targeted pressure (and volume) increases as directed.

In general, the shape of the waveform during PSV is squarer than the triangular shape observed with NAVA.[4] Thus, for matched peak airway pressures, NAVA resulted in lower mean airway pressure as compared with NAVA.[4,15,98,103,143]

Breatnach et al[144] used NAVA for several hours in infants, and found, similar to what Allo et al[94] found in rabbits, that mean airway pressures decreased over time. In premature infants weighing <1500 g, Stein et al[145] also demonstrated reduced mean airway pressures over time when ventilated on NAVA.

High levels of PSV in association with involuntary triggering can produce hyperventilation, and may even eliminate the Edi completely (see Fig. 13-9). In contrast, high levels of NAVA do not eliminate the Edi (see Fig. 13-13).[102]

Neurally Adjusted Ventilatory Assist and Proportional-Assist Ventilation

NAVA and proportional-assist ventilation have not been directly compared. Both modes strive to improve assist delivery in spontaneously breathing patients and both have been found to improve synchrony and physiological variables compared to conventional modes.[140]

SUMMARY AND CONCLUSION

Many patients receiving conventional modes of ventilation receive substandard treatment, which has been associated with prolonged ventilator time. This is secondary to the limitations of conventional ventilators to detect and correct inappropriate timing and delivery of pressure.

Diaphragmatic electrical activity represents the neural output from respiratory centers, a signal which responds to respiratory demand. Diaphragmatic electrical activity is modulated by chemo, muscle, lung and other receptors, which act to ensure adequate ventilation while protecting the lungs. Simply monitoring the diaphragmatic electrical activity waveform is suitable for clinical monitoring of respiratory drive, neural breathing pattern, as well as patient–ventilator synchrony.

NAVA is a mode of ventilator assistance for spontaneously breathing patients, and uses the diaphragmatic electrical activity to trigger, to deliver assist, and to cycle-off the ventilator. Neural triggering and cycling-off improve patient–ventilator synchrony and are unaffected by leaks in the respiratory circuit. Because NAVA is modulated by neural feedback, assist is adjusted instantaneously in response to changes in patient respiratory demand.

NAVA introduces a new avenue for mechanical ventilation, and, different from the conventional deterministic approach of delivering static quantities of assistance, encourages personalized care that takes into account patient's individual differences and needs for every breath.

ACKNOWLEDGMENTS

Drs. Beck and Sinderby have made inventions related to neural control of mechanical ventilation that are patented. The license for these patents belongs to Maquet Critical Care. Future commercial uses of this technology may provide financial benefit to Drs. Beck and Sinderby through royalties. Dr. Beck and Dr. Sinderby each own 50% of Neurovent Research Inc. (NVR). NVR is a research and development company that builds equipment and catheters for research studies. NVR has a consulting agreement with Maquet Critical Care.

PERMISSIVE HYPERCAPNIA

John G. Laffey
Brian P. Kavanagh

Carbon dioxide (CO_2) is the "waste product" of aerobic respiration. In health, arterial carbon dioxide tension (Pa_{CO_2}) is tightly regulated, with minute ventilation potently enhanced in response to small elevations in CO_2 tension. In critical illness its role is becoming better understood; indeed, in survivors of cardiac arrest, elevated CO_2 is associated with a higher incidence of reported near-death experiences.[1] Although usually well tolerated, hypercapnia traditionally has been considered to be an adverse event. In fact, the extent and severity of acidosis are predictive of adverse outcome in diverse clinical contexts, including cardiac arrest,[2,3] sepsis,[4–6] and in neonatal practice.[7] Traditional approaches to CO_2 management in the operating room and for patients with acute respiratory failure generally focused on the deleterious effects of hypercapnia, traditionally targeting therefore normocapnia or even hypocapnia.

This approach, however, has been increasingly questioned. The potential for high tidal volumes to injure the lung directly, a phenomenon termed *ventilator-induced lung injury,* is clear from experimental[8,9] and clinical[10–14]

studies. Current "protective" ventilator strategies mandate lower tidal volumes (V_T), and generally necessitate hypoventilation and tolerance of hypercapnia. This "permissive hypercapnia" has been accepted progressively in critical care for adult, pediatric, and neonatal patients requiring mechanical ventilation.

RATIONALE

The potential for mechanical ventilation to contribute to lung and systemic organ injury and to worsen outcome in patients with the acute respiratory distress syndrome (ARDS) is clear. The use of high V_T may cause injury via several mechanisms.[8,9] Increased mechanical stress may activate the cellular and humoral immune response directly in the lung.[8,15–17] Intrapulmonary mediators and pathogens, such as prostaglandins,[18] cytokines,[19] endotoxins,[20] and bacteria,[21] have been demonstrated to access the systemic circulation following high-stretch mechanical ventilation. The demonstration that mechanical ventilation may cause systemic organ dysfunction in animal models could explain in part the high rate of multiorgan failure in ARDS.[22] In current practice, hypercapnia is tolerated as the lesser of two evils so as to realize the benefits of lower tidal volumes.[23,24]

BASIC PRINCIPLES

Permissive Hypercapnia

Conventionally, the protective effect of ventilator strategies incorporating permissive hypercapnia is solely secondary to lower tidal volume, with hypercapnia being permitted so as to achieve this goal. Protective ventilator strategies that involve hypoventilation cause both limitation of lung stretch and elevation of arterial P_{CO_2}; thus, low tidal volume is distinct from elevated P_{CO_2} and, by manipulation of respiratory variables (frequency, V_T, dead space, and inspired CO_2), can to some extent be controlled separately.

Therapeutic Hypercapnia

If hypercapnia were proven to have independent benefit, then deliberately elevating Pa_{CO_2}, termed *therapeutic hypercapnia*, might provide an additional advantage over reducing V_T alone. Conversely, in patients managed with conventional permissive hypercapnia, adverse effects of elevated Pa_{CO_2} may be concealed by the benefits of lessened lung stretch. These issues are underscored by the fact that hypercapnia has adverse effects in some clinical settings, such as critically elevated intracranial pressure or pulmonary vascular resistance. Because patient outcome from critical illness may be related to systemic rather than lung injury, the clinician also must consider the effects on the brain and cardiovascular systems.

These issues have led several investigators to study the direct effects of induced hypercapnia per se in models of lung and systemic organ injury. These studies raise the potential that hypercapnia may exert active roles—beneficial or adverse—in the pathogenesis of inflammation and tissue injury. Thus, therapeutic hypercapnia may someday become a testable clinical approach to critically ill patients.[25]

Accidental Hypercapnia

This is reported most commonly in the context of errors in mechanical ventilation, such as circuit disconnects (or malconnections that permit rebreathing of exhaled gases).[26] A second cause is hypoventilation secondary to drug-induced respiratory depression,[27] severe respiratory failure (e.g., status asthmaticus),[28] or massive aspiration (e.g., grain inhalation).[29]

Determinants of Hypercapnia

The determinants of hypercapnia can be described as the balance of CO_2 production versus elimination.

$$Pa_{CO_2} \propto \frac{CO_2 \text{ production}}{CO_2 \text{ elimination}} + \text{inspired } [CO_2] \qquad (1)$$

Inspired CO_2 (FI_{O_2}) usually is negligible. Increased CO_2 production is a potential contributor to hypercapnia, particularly in hypermetabolic disease states such as hyperpyrexia. Therefore, for practical purposes, Pa_{CO_2} reflects the rate of elimination of CO_2; there are no common "physiologic" causes of hypercapnia. Hypercapnia is seen most commonly in the context of acute or chronic respiratory failure associated with reduced minute ventilation or increased dead space.

Effects on Alveolar Gas Exchange

The effects of hypercapnia on systemic oxygenation are discussed below. It is often forgotten that decreasing V_T can reduce oxygenation of pulmonary venous blood. This has two contributing elements: the composition of the alveolar gas and the increase in intrapulmonary shunt. Decreased V_T increases propensity to atelectasis, which increases intrapulmonary shunt.[30] In addition, when V_T is decreased, there is a proportionate decrease in alveolar ventilation ($\dot{V}_A$), resulting in an elevated alveolar CO_2 tension (Pa_{CO_2}). As pointed out by Bidani et al,[31] the alveolar gas equation

$$PA_{O_2} = FI_{O_2}(P_B - 47) - (Pa_{CO_2}/R) \qquad (2)$$

where PA_{O_2} is the alveolar oxygen tension, P_B is the barometric pressure, and R is the respiratory quotient, can be combined with the following relationship:

$$Pa_{CO_2} = (\dot{V}_{CO_2}/\dot{V}_A) \times P_B \qquad (3)$$

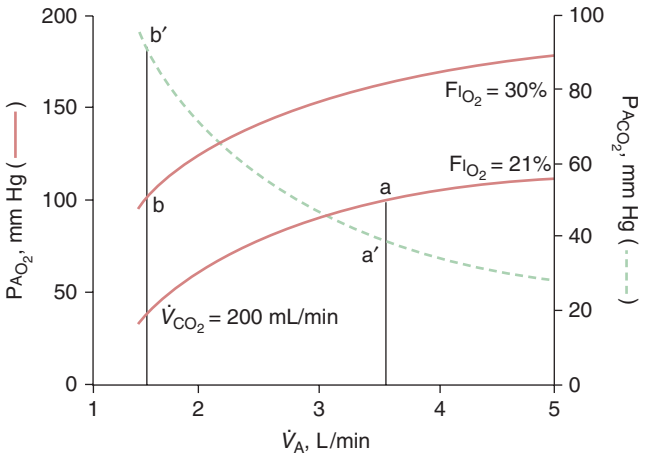

FIGURE 14-1 Relationship of alveolar oxygen tension ($P_{A_{O_2}}$) and alveolar ventilation ($\dot{V}_A$) at $F_{I_{O_2}}$ (0.21 and 0.30), calculated assuming a constant carbon dioxide production ($\dot{V}_{CO_2}$ of 200 mL/min). At either $F_{I_{O_2}}$, decreasing $\dot{V}_A$ to low values significantly reduces $P_{A_{O_2}}$, especially with very low levels of $\dot{V}_A$. A small increase in $F_{I_{O_2}}$ (21% to 30%) easily compensates for the fall in $P_{A_{O_2}}$ resulting from hypoventilation. *Solid line*, relationship between $P_{A_{O_2}}$ and $\dot{V}_A$; *dotted line*, relationship between Pa_{CO_2} and $\dot{V}_A$. (Modified, from Bidani A, Tzouanakis AE, Cardenas VJ Jr, Zwischenberger JB. Permissive hypercapnia in acute respiratory failure. *JAMA*. 1994;272: 957–962.)

where $\dot{V}_{CO_2}$ is CO_2 production, to express alveolar O_2 as a function of $F_{I_{O_2}}$ and $\dot{V}_A$:

$$P_{A_{O_2}} = F_{I_{O_2}}(P_B - 47) - (\dot{V}_{CO_2}/\dot{V}_A) \times (P_B/R) \qquad (4)$$

Thus, with the exception of very low levels of minute ventilation, increases in $\dot{V}_A$ have minor impact on alveolar—and consequently pulmonary venous—oxygenation. In contrast, modest increases in $F_{I_{O_2}}$ can have a far more significant impact on oxygenation and can compensate easily for reduced V_A (Fig. 14-1).[31]

PHYSIOLOGIC EFFECTS

The physiologic effects of hypercapnia are complex and incompletely understood, with direct effects often counterbalanced by indirect effects. To understand hypercaponia in critically ill patients, the effects of pH and Pa_{CO_2} need to be considered together.

Carbon Dioxide versus Hydrogen Ion

Hypercapnia generally results in acidosis (greater H^+ concentration) via its spontaneous and carbonic anhydrase–catalyzed combination with water to form carbonic acid. The protons thus generated can react with titratable groups in certain amino acids, resulting in structural changes in many proteins and enzymes in cell membranes and cellular aqueous environments.[32] Because acidosis suppresses most cellular functions, the body uses a number of strategies to defend its intracellular and extracellular pH within remarkably narrow limits.[25] The intracellular acidosis produced by hypercapnia may be corrected within a few hours, as opposed to 1 to 2 days for renal compensation.[33] This buffering occurs via active cell-membrane ion transporters that extrude protons and exchange them for extracellular sodium.

During hypercapnia, CO_2 per se may react directly with some free amine groups in proteins to form carbamate residues.[34–36] This binding of CO_2 also modifies protein structure and function and may explain some of the differences in the observed effects of CO_2 and H^+ when both lead to equal changes in pH. A good example is the Bohr effect, where increased Pa_{CO_2} results in a rightward shift of the hemoglobin (Hb)-O_2 dissociation curve, reflecting a lowered affinity of hemoglobin for O_2.

Effects of Hypercapnia on the Lung

PULMONARY VASCULAR EFFECTS

In contrast to the systemic circulation, hypercapnic acidosis produces vasoconstriction and increased resistance in the pulmonary circulation;[37] such effects are exacerbated in the setting of preexisting pulmonary hypertension.[37] Hypercapnic vasoconstriction generally is weaker than hypoxic pulmonary vasoconstriction; its more important effect may be in augmenting hypoxic vasoconstriction.[32] Little is understood about how CO_2 acts on pulmonary vascular smooth muscle.

PULMONARY GAS EXCHANGE

Acute respiratory acidosis can alter shunt via autonomic or direct effects on pulmonary vasculature and on the airways. Acidosis enhances hypoxic pulmonary vasoconstriction and therefore usually reduces shunt and increases partial pressure of arterial oxygen (Pa_{O_2}), whereas alkalosis has the opposite effect.[38] CO_2 administration improves matching of ventilation and perfusion and increases arterial oxygenation by this mechanism in both health[39–41] and disease.[42] A dose–response relationship exists wherein increased $F_{I_{CO_2}}$ results in progressive augmentation of Pa_{O_2}.[40,43] In fact, administration of CO_2 during late inspiration—limiting its exposure to the conducting airways—results in most of the beneficial pulmonary effects (i.e., $\dot{V}_A/\dot{Q}$ matching and oxygenation) and less systemic acidosis (Fig. 14-2).[44] Permissive hypercapnia in patients with ARDS appears to increase shunt secondary to a reduction in V_T and airway closure rather than from elevated CO_2 levels.[45]

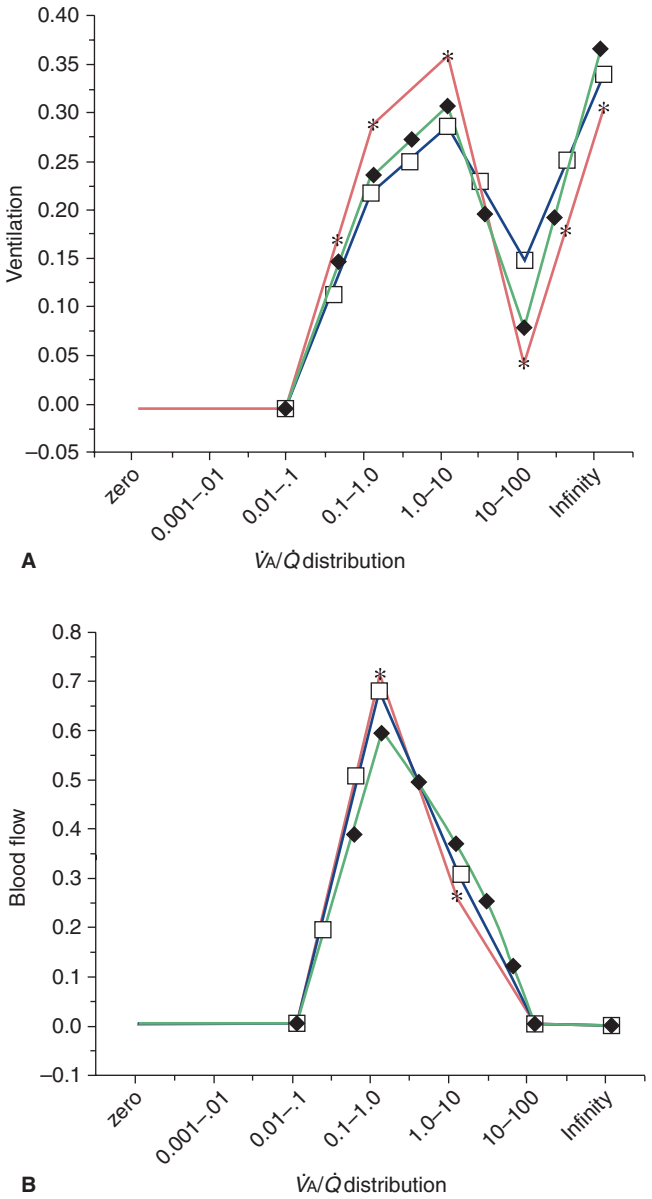

FIGURE 14-2 Effects of room air and inspired CO_2 on the distribution of ventilation (**A**) and of perfusion (**B**). The lowest values of $\dot{V}_A/\dot{Q}$ correspond to regions of intrapulmonary shunt and the highest to regions of alveolar dead space. Addition of CO_2 to inspired gas (throughout the respiratory cycle, *; restricted to late inspiration, □) resulted in more homogeneous ventilation and perfusion compared to no added CO_2 (room air ♦). $\dot{V}_A/\dot{Q}$, ratio of ventilation to perfusion. (Reproduced, with permission, from Brogan TV, Robertson HT, Lamm WJ, Souders JE, Swenson ER. Carbon dioxide added late in inspiration reduces ventilation–perfusion heterogeneity without causing respiratory acidosis. *J Appl Physiol.* 2004;96:1894–1898.)

AIRWAY TONE

Hypercapnia has been reported to either increase[46] or decrease[47] airway resistance. These effects may be explained the direct dilation of small airways and the indirect (i.e., vagally mediated) large airway constriction.[32] These opposing but balanced actions may produce little net alteration in airway resistance.[48]

LUNG COMPLIANCE

Parenchymal lung compliance increases in response to hypercapnic acidosis. This may be secondary to increased surfactant secretion or more effective surface tension–lowering properties under acidic conditions.[49]

PHYSIOLOGIC ROLE OF HYPERCAPNIA IN THE LUNG

In health, CO_2 alters lung compliance as well as pulmonary vascular and airway tone.[32] The combined effect of small airways constriction and decreased compliance explains the phenomenon of hypocapnic bronchoconstriction and pneumoconstriction that occurs following acute regional pulmonary artery occlusions.[50,51] These effects either may alter regional ventilation to keep pace with a primary change in perfusion or may alter regional perfusion to match a primary change in ventilation.[32]

Central Nervous System Effects of Hypercapnia

NEUROVASCULAR REGULATION

Hypercapnic acidosis causes cerebral vasodilation. The increase in cerebral blood flow and blood volume must be considered carefully in any patient at risk for raised intracranial pressure.[25] The mechanism of cerebral vasodilation depends on the arterial bed and type of artery. Nakahata et al[52] demonstrated that hypercapnic acidosis induced cerebral precapillary arteriolar vasodilation, which depended on acidosis rather than CO_2. They demonstrated that the adenosine triphosphate (ATP)-sensitive potassium channel plays a major role. Others have suggested roles for both ATP-sensitive and calcium-activated potassium channels[53] and the neuronal isoform of nitric oxide synthase.[54]

REGULATION OF VENTILATION

Hypercapnia is a potent regulator of ventilation. Mild hypercapnia (increase in end-tidal pressure of carbon dioxide [P_{CO_2}] of 8 mm Hg) in healthy volunteers resulted in a compensatory metabolic alkalosis over 24 to 48 hours that was maintained over the course of exposure.[55] Although there was a modest increase in ventilatory chemosensitivity to acute hypoxia, no change occurred in response to acute elevations in CO_2.

CEREBRAL TISSUE OXYGENATION

Hare et al[40] demonstrated that hypercapnic acidosis increases cerebral tissue partial pressure of oxygen (P_{O_2}) through augmentation of Pa_{O_2} and increased cerebral blood flow (Fig. 14-3), although, studies in patients suggest that in the presence of sepsis, hypercapnia may impair cerebral

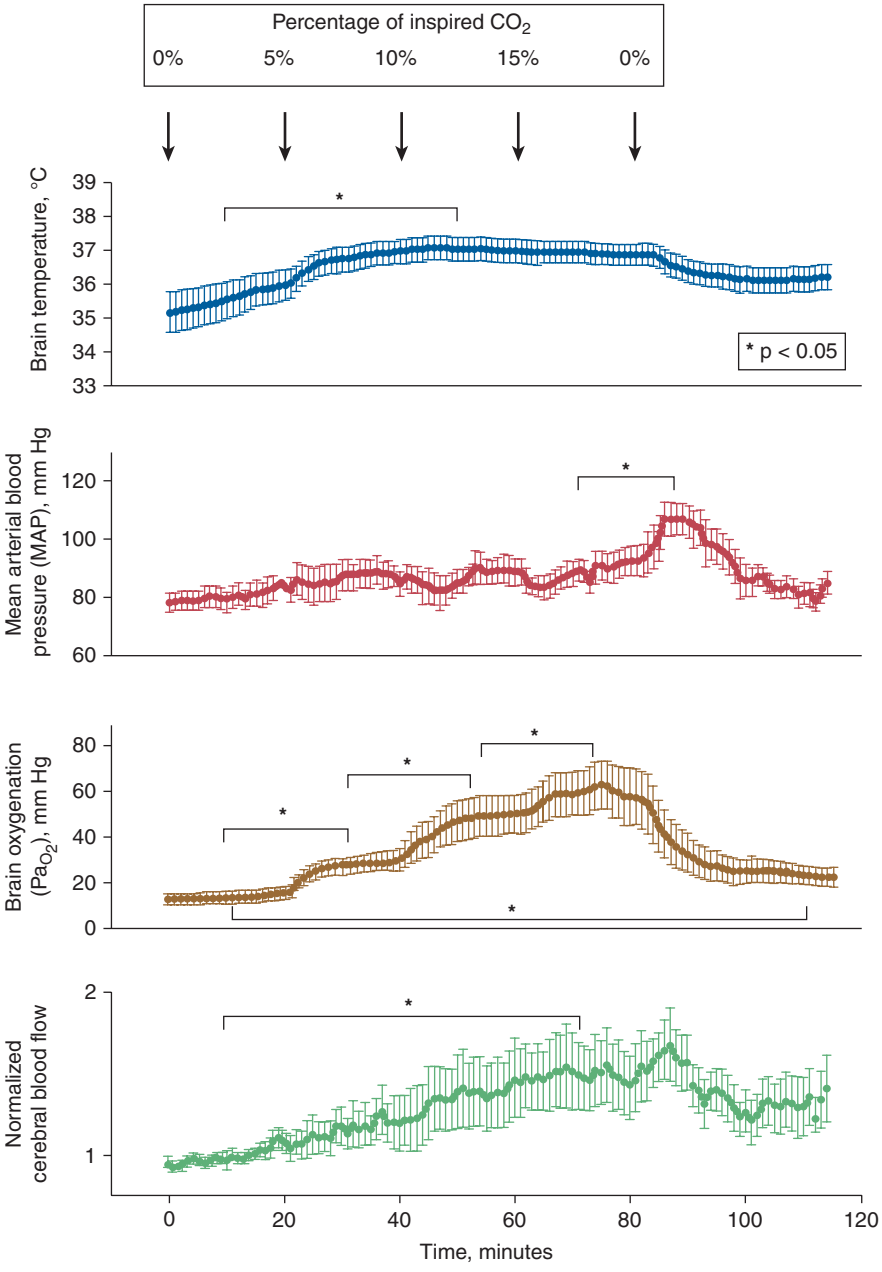

FIGURE 14-3 Increases in inspired CO_2 concentration produce progressive increases in brain tissue O_2 tension and cerebral perfusion. (Reproduced, with permission, from Hare GM, Kavanagh BP, Mazer CD, et al. Hypercapnia increases cerebral tissue oxygen tension in anesthetized rats. *Can J Anaesth.* 2003;50:1061–1068.)

autoregulation.[56] The faster recovery times associated with administered CO_2 in animals[57] and patients[58] following general anesthesia may reflect increased perfusion and anesthetic washout.

Neuromuscular Effects of Hypercapnia

DIAPHRAGMATIC FUNCTION

Recent studies highlight the potential for hypercapnia to exert deleterious neuromuscular effects. Rat diaphragms exposed to prolonged hypercapnia (7.5% CO_2 for 6 weeks) undergo significant changes,[59] including depressed diaphragmatic tension and time to contraction and relaxation, and altered diaphragmatic composition (i.e., increased slow-twitch and decreased fast-twitch fibers). In fact, even short-term exposure (7% inspired CO_2) may impair neuromuscular function transiently through effects on afferent transmission or synaptic integrity in healthy volunteers.[60] Relatively brief exposures to hypercapnia may also cause reversible impairment of diaphragmatic muscle contractility.[61]

Cardiovascular Effects of Hypercapnia

HEMODYNAMIC EFFECTS

Hypercapnic acidosis directly reduces the contractility of cardiac and vascular smooth muscle.[32] This is counterbalanced by the hypercapnic-mediated sympathoadrenal effects causing increased preload, increased heart rate, and decreased afterload, which lead to a net increase in cardiac output.[32] In intact animals and human subjects, myocardial contractility and cardiac output increase during hypercapnia because of increased sympathetic activity.[62]

EFFECTS ON TISSUE OXYGENATION

Hypercapnia results in a complex interaction of altered cardiac output, hypoxic pulmonary vasoconstriction, and intrapulmonary shunt, with a net increase in Pa_{O_2}. Because hypercapnia generally elevates cardiac output, global O_2 delivery is increased.[63] Regional (including mesenteric) blood flow also is increased,[64] thereby increasing organ oxygen delivery. Because hypercapnia and acidosis shift the Hb-O_2 dissociation curve rightward and may cause an elevation in hematocrit,[65] tissue oxygen delivery is further facilitated. Acidosis may reduce cellular respiration and oxygen consumption,[66] which further correct supply–demand imbalance, in addition to enhancing O_2 delivery. Acidosis may protect against ongoing tissue production of *further* organic acids by a negative-feedback loop, providing a mechanism of cellular metabolic shutdown at times of nutrient shortage (e.g., ischemia).[67] In addition, hypercapnic acidosis increases P_{O_2} in subcutaneous tissues and in the intestinal wall.[68]

Hypercapnia and Development

Hypercapnia may exert complex effects on development,[69] such as inhibition of embryonic morphogenesis, as well as egg laying and hatching in the *Drosophila*.[70] It induces aberrant motility and slows development, decreases fertility, and increases life span in *Caenorhabditis elegans*.[71] Tissue effects in neonates may differ from those in adults as exposure to hypercapnia for 2 weeks reduced expression of several matrix proteins in infant, but not in adult, lungs,[72] and sustained exposure in the neonate may cause microvascular injury and impair brain growth via induction of nitrative stress.[73] In the neonatal lung, hypercapnia may increase alveolar budding, but may also increase central nervous system apoptosis.[74]

CELLULAR AND MOLECULAR EFFECTS OF HYPERCAPNIA

A clear understanding of cellular and biochemical mechanisms underlying the effects of hypercapnia is essential for successful translation of laboratory findings to the bedside, as well as for prediction of potential side effects.

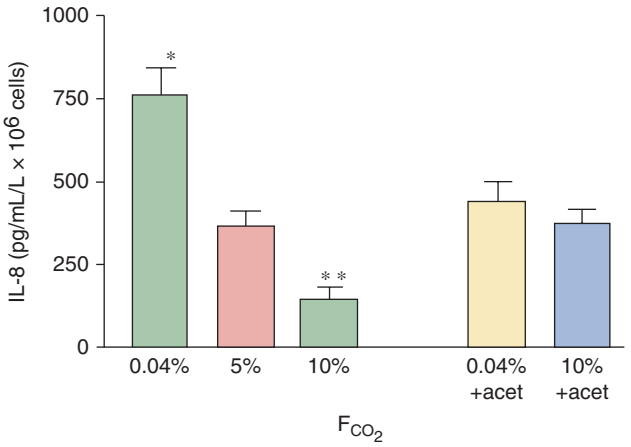

FIGURE 14-4 Hypercapnia (10% CO_2) inhibits, whereas hypocapnia (0.04% CO_2) potentiates, the release of interleukin (IL)-8 from endotoxin-stimulated neutrophils. Incubation with acetazolamide, which impairs the effect of extracellular CO_2 on intracellular pH, abolished the influence of extracellular CO_2. (Reproduced, with permission, from Coakley RJ, Taggart C, Greene C, McElvaney NG, O'Neill SJ. Ambient pCO_2 modulates intracellular pH, intracellular oxidant generation, and interleukin-8 secretion in human neutrophils. *J Leukoc Biol.* 2002;71:603–610.)

Effects on the Immune Response

Hypercapnia and acidosis modulate diverse components of the host immune response, particularly cytokine and chemokine signaling, as well as neutrophil and macrophage function.

CHEMOKINE AND CYTOKINE SIGNALING

Hypercapnia interferes with coordination of the immune response by modulating signaling among immune effector cells. Hypercapnic acidosis inhibits neutrophil release of interleukin (IL)-8 following endotoxin stimulation[75] (Fig. 14-4), reduces release of tumor necrosis factor-α (TNF-α) and IL-1 from stimulated macrophages in vitro,[76] and inhibits IL-6 and TNF-α in macrophages[77] as well as in whole (human) blood.[78] Hypercapnic acidosis reduces TNF-α concentrations in the bronchoalveolar fluid following in vivo pulmonary ischemia-reperfusion.[79] Such effects on cytokines and chemokines may be sustained; for example, intraperitoneal macrophages demonstrate impaired TNF-α production for up to 3 days following exposure to hypercapnia.[80,81] These actions appear to be mediated, at least in part by inhibition of the transcriptional regulator nuclear factor kappa B (NF-κB).[82]

THE CELLULAR IMMUNE RESPONSE

Hypercapnia may impact the cellular immune response via several mechanisms, including impaired coordination of cytokine signaling as well as inhibition of neutrophil expression of key inflammatory and adhesion molecules (e.g., chemokines, selectins, and intercellular adhesion molecules).[75] Neutrophil chemotaxis may be directly impaired.[83] These

effects also occur in vivo as lung neutrophil recruitment is inhibited during ventilator-induced[84] and endotoxin-induced[85] lung injury. Hypercapnic acidosis directly impairs neutrophil[86] and macrophage[70] phagocytosis, effects that appear to be a function of the acidosis rather than the CO_2 tension.[87]

The cellular and molecular mechanisms underlying the inhibitory effects of hypercapnic acidosis in the neutrophil and macrophage are increasingly understood. Both hypercapnia and acidosis impair neutrophil intracellular pH regulation. Intracellular pH decreases when neutrophils are activated by immune stimuli[75] and, where pH is normal, there tends to be a recovery in neutrophil intracellular pH (toward normal). Hypercapnia decreases extracellular and intracellular pH in the local milieu, resulting in a rapid fall in neutrophil cytosolic pH,[88] potentially overwhelming the capacity of phagocytes—especially when activated[89]—to regulate cytosolic pH.

Free Radical Generation and Activity

In common with many biologic systems, the enzymes that produce oxidizing free radicals function optimally at physiologic pH. Oxidant generation by both basal and stimulated neutrophils appears to be regulated by ambient CO_2 levels, with oxidant generation reduced by hypercapnia and increased by hypocapnia.[75] Production of superoxide by stimulated neutrophils in vitro is decreased at acidic pH.[90] Hypercapnic acidosis inhibits the generation of oxidants such as superoxide by neutrophils[75] and by macrophages.[91] Although free radicals such as superoxide have been implicated in the pathogenesis of injury in acute lung injury and/or ARDS, effective phagocyte generation of free radicals is necessary for killing of ingested bacteria. The finding that hypercapnia reduces endotoxin-induced pulmonary oxidant production[92] reinforces concerns that neutrophil-mediated bacterial killing might be critically inhibited.

In the brain, hypercapnic acidosis attenuates glutathione depletion and lipid peroxidation,[93] which reflect free-radical activity and tissue damage, respectively. In the lung, hypercapnic acidosis reduces free-radical tissue injury following ischemia–reperfusion[79] and attenuates the production of the higher oxides of nitric oxide, such as nitrate and nitrite, following both ventilator-induced[94] and endotoxin-induced[85] injury. Hypercapnic acidosis inhibits injury mediated by xanthine oxidase and directly inhibits the enzyme.[95] Interactions between CO_2 and free radicals may also have fundamental effects as recent work indicates that hypercapnia may cause signaling, in part, by cellular oxidation.[96]

PEROXYNITRITE-MEDIATED TISSUE NITRATION

Specific concerns exist regarding the potential for hypercapnia to potentiate tissue nitration by peroxynitrite, a potent free radical. Peroxynitrite is produced in vivo largely by the reaction of nitric oxide with superoxide radical and causes tissue damage by oxidizing a variety of biomolecules and by nitrating phenolic amino acid residues in proteins.[97] The potential for buffered hypercapnia to promote the formation of nitration products from peroxynitrite has been clearly demonstrated in vitro.[98,99] The potential, however, for hypercapnic acidosis to promote nitration of lung tissue in vivo depends on the injury. For example, hypercapnic acidosis decreased tissue nitration following pulmonary ischemia–reperfusion,[79] but increased nitration following endotoxin exposure[85,98,100] (Fig. 14-5).

Regulation of Gene Expression

Some effects of hypercapnia may be mediated by regulation of gene expression. Several unidentified proteins are upregulated by hypercapnia in the normal lung,[101] and hypercapnia may regulate this process at the level of gene transcription via altering the half-life of messenger RNA or by modulating protein synthesis. Molecular mechanisms underlying hypercapnic acidosis–mediated control of gene transcription include membrane acid-sensing ion channels and acid-responsive gene promoter regions.[102–104] Furthermore, the coding for certain proteins for messenger RNA has pH-sensitive regions.[103]

Hypercapnic acidosis has been demonstrated to regulate the expression of genes central to the inflammatory response in models of cell injury. NF-κB is a key regulator of the expression of multiple genes involved in inflammatory response, and its activation represents a pivotal early step in activation of the inflammatory response.[105] NF-κB is found in the cytoplasm in an inactive form bound to inhibitory proteins called *inhibitory protein* κB (IκB). The important isoforms are IκB-α and IκB-β. IκB proteins are phosphorylated by the IκB kinase complex and subsequently degraded, thus allowing NF-κB to translocate into the nucleus, bind to specific promoter sites, and activate target genes.[105] Hypercapnic acidosis inhibits endotoxin-induced NF-κB activation and DNA binding in pulmonary endothelial cells by decreasing IκB-α degradation[82] (Fig. 14-6). Hypercapnic acidosis also suppressed endothelial production of intercellular adhesion molecule-1 and IL-8, which are critically regulated by the NF-κB pathway.[82] Importantly, although inhibition of NF-κB may have important antiinflammatory effects, it may also reduce repair following injury.[106]

Effects on Recovery and Repair Mechanisms

EXTRACELLULAR FLUID CLEARANCE

Hypercapnia appears to inhibit epithelial fluid transport, a potentially important mechanism by which alveolar edema is cleared during lung injury.[107] The effect appears to be mediated via hypercapnia per se and seems to be independent of

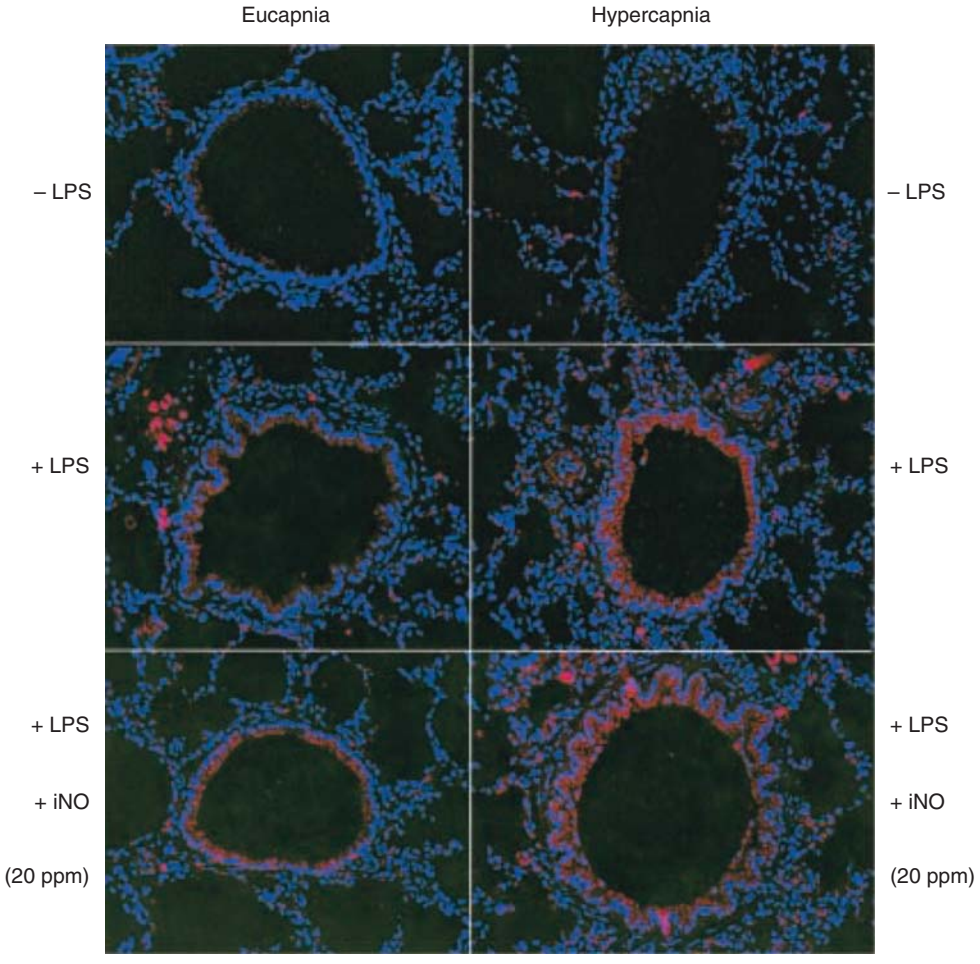

FIGURE 14-5 Hypercapnia and inhaled nitric oxide significantly increased the formation of 3-nitrotyrosine following lipopolysaccharide pretreatment. *HC*, Hypercapnia; *iNO*, inhaled nitric oxide; *LPS*, lipopolysaccharide. Hypercapnia via reduced rate and tidal volume contributes to lipopolysaccharide-induced lung injury. *Am J Respir Crit Care Med.* 2005;171:147–157.)

ambient pH.[107] The mechanism of action involves adenosine monophosphate (AMP)-activated protein kinase, which, when activated by hypercapnia, promotes Na, K-ATPase endocytosis.[108] The decrement in alveolar fluid clearance can be prevented by β-adrenergic agonists or cyclic adenosine monophosphate.[108] More recent studies have also implicated extracellular signal-regulated kinase in the activation of AMP-activated protein kinase by hypercapnia, leading to Na, K-ATPase endocytosis.[109]

EPITHELIAL WOUND REPAIR

Hyercapnia appears to inhibit pulmonary epithelial-cell resealing[110] following ventilator-induced lung injury via a pH-dependent mechanism,[111] and also inhibits the closure of pulmonary epithelial wounds via a mechanism that involves reduced activation of NF-κB, which, in turn, inhibits cellular migration.[106] These effects of hypercapnia on wound healing appear to be a function of CO_2 tension rather than acidosis.

EFFECTS IN THE SETTING OF ORGAN INJURY

Hypercapnia and the Injured Lung

INSIGHTS FROM LABORATORY DATA

Ischemia–Reperfusion Injury. Hypercapnic acidosis attenuates the increased lung permeability consequent to free-radical-mediated lung injury (Fig. 14-7).[95] Although hypercapnic acidosis reduces xanthine oxidase activity,[95] this does not account for all its protective effects.[112] Subsequent in vivo studies confirmed and further characterized the protective effects of hypercapnic acidosis in ischemia–reperfusion lung injury. Hypercapnic acidosis preserved lung mechanics, attenuated protein leakage and reduced pulmonary edema in addition to preserving oxygenation in comparison with control conditions following in vivo pulmonary ischemia–reperfusion,[79] as well as in lung injury secondary to splanchnic reperfusion.[43] Such protective

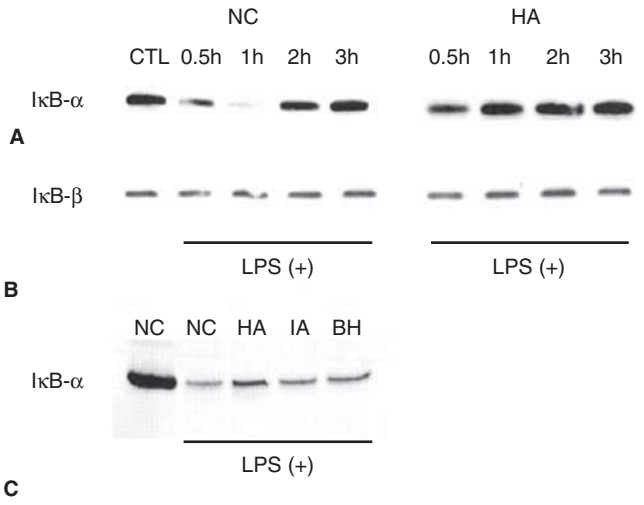

FIGURE 14-6 Hypercapnia suppresses the degradation of IκB-α (**A**) but not IκB-β (**B**) following exposure to lipopolysaccharide, thereby inhibiting the nuclear translocation of NF-κB and downstream cytokine production. The effects of isocapnic acidosis and buffered hypercapnia (**C**) on IκB-α degradation were intermediate between normocapnic control and hypercapnic acidosis conditions. *BH*, buffered hypercapnia; *HA*, hypercapnic acidosis; *IA*, isocapnic acidosis; *LPS*, lipopolysaccharide; *NC*, normocapnia; *NF-κB*, nuclear factor κB. effects of hypercapnic acidosis are not mediated via decreases in pulmonary artery resistance; on the contrary, protection occurred despite elevated pulmonary artery pressures.[43]

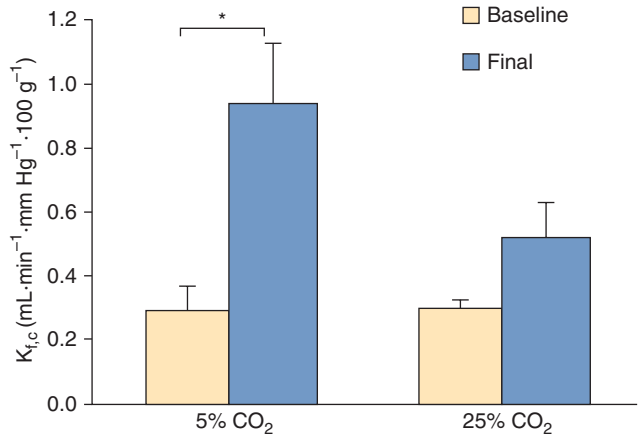

FIGURE 14-7 Effects of CO_2 on ischemia–reperfusion in the isolated perfused lung. Pulmonary microvascular permeability is significantly less following reperfusion in the presence of hypercapnia (25% CO_2) compared with normocapnia (5% CO_2). $K_{f,c}$, pulmonary microvascular filtration coefficient. Hypercapnic acidosis may attenuate acute lung injury by inhibition of endogenous xanthine oxidase. *Am J Respir Crit Care Med.* 1998;158(5 Pt 1):1578–1584.)

Ventilation-Induced Lung Injury. The direct effects of hypercapnic acidosis in ventilator-induced lung injury have been examined in both ex vivo and in vivo models. The addition of inspired CO_2 decreased ventilator-induced lung injury in the isolated rabbit lung,[94] the in vivo rabbit[84] (Fig. 14-8), and in the in vivo mouse.[113] Not all the data are positive. Supplemental CO_2 exhibits more modest protective effects in the setting of more clinically relevant tidal stretch. Strand et al[114] demonstrated that significant hypercapnic acidosis (mean Pa_{CO_2} of 95 mm Hg) was well tolerated in preterm lambs and also appeared to reduce lung injury. In the context of a clinically relevant high V_T adult model (V_T 12 mL/kg, positive end-expiratory pressure 0 cm H_2O), Laffey et al[43] reported that hypocapnia was deleterious and conversely that hypercapnic acidosis was protective. In contrast, inspired CO_2 did not attenuate lung injury in an atelectasis-prone model that mimics neonatal respiratory distress syndrome.[115] Taken together, these findings suggest that while hypercapnic acidosis substantially attenuates injury secondary to excessive stretch, its effects in the context

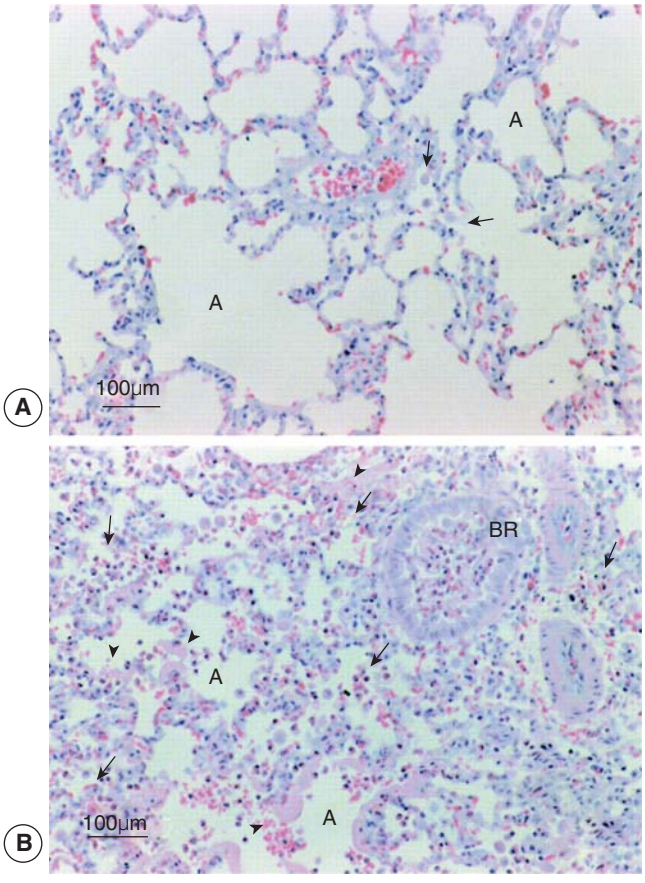

FIGURE 14-8 Lung histology following high tidal volume ventilation in the in vivo rabbit. The extent of histologic injury is far less with addition of inspired CO_2 (Pa_{CO_2} of 80 to 100 mm Hg) (**A**) than with a Pa_{CO_2} of 40 mm Hg (**B**). (Sinclair SE, Kregenow DA, Lamm WJ, Starr IR, Chi EY, & Hlastala MP. Hypercapnic acidosis is protective in an in vivo model of ventilator-induced lung injury. *Am J Respir Crit Care Med. 2002*;166:403–408.)

of more clinically relevant lung stretch or, with extensive atelectasis, may be more modest.

Pulmonary Hypertension. In neonatal models, chronic hypercapnia attenuates the development of hypoxia-induced pulmonary hypertension[116,117] in part via augmentation of L-arginase expression resulting in increased local nitric oxide[117] and in part via inhibition of endothelin expression.[118] Although no mechanism was established, comparable effects were described wherein chronic hypercapnia attenuated the development of long-term hypoxia-induced pulmonary hypertension in the rat.[119]

Pulmonary Sepsis. The mechanisms of lung injury in sepsis-induced ARDS are quite distinct from those in "sterile" experimental models. Lipopolysaccharide, a key endotoxin of gram-negative bacteria, initiates lung injury by activating a specific receptor, the Toll-like receptor-4.[120] Hypercapnic acidosis can reduce the severity of lung injury induced by local administration of endotoxin.[85] Mechanisms of sepsis-induced injury, however, include damage to host tissue from the inflammatory response, as well as damage caused by direct bacterial invasion.[24,85] In preclinical sepsis models, the effects of hypercapnia appear to depend also on the severity—and phase—of the injury. Although hypercapnic acidosis did not alter the severity of mild injury induced by instilled *Escherichia coli*,[121] it did reduce the severity of more severe lung injury induced by the same organism.[122] In the setting of established *E. coli* pneumonia, short-term hypercapnia reduced lung injury, particularly when effective antimicrobial therapy was used.[122] In contrast, in the setting of prolonged *E. coli*-induced pneumonia (i.e., 72 hours), ongoing environmental hypercapnia worsened the severity of the lung injury.[86] Here, prolonged hypercapnia reduced bacterial killing, in part by reduced neutrophil phagocytic activity (Fig. 14-9).[86] Subsequent studies confirmed that these effects in prolonged infection appear to be a function of the hypercapnia and not acidosis, as buffered hypercapnia also worsened infection-induced injury.[87] Nonetheless, deleterious effects of hypercapnia in the setting of prolonged pneumonia were completely ablated by antimicrobial therapy.[86]

Concerns regarding harm caused by hypercapnia in prolonged lung infection are reflected in an elegant series of studies in the *Drosophilia*[70] demonstrating an increased mortality in infections with multiple different bacterial pathogens, including *Staphylococcus aureus*, *Enterococcus faecalis*,

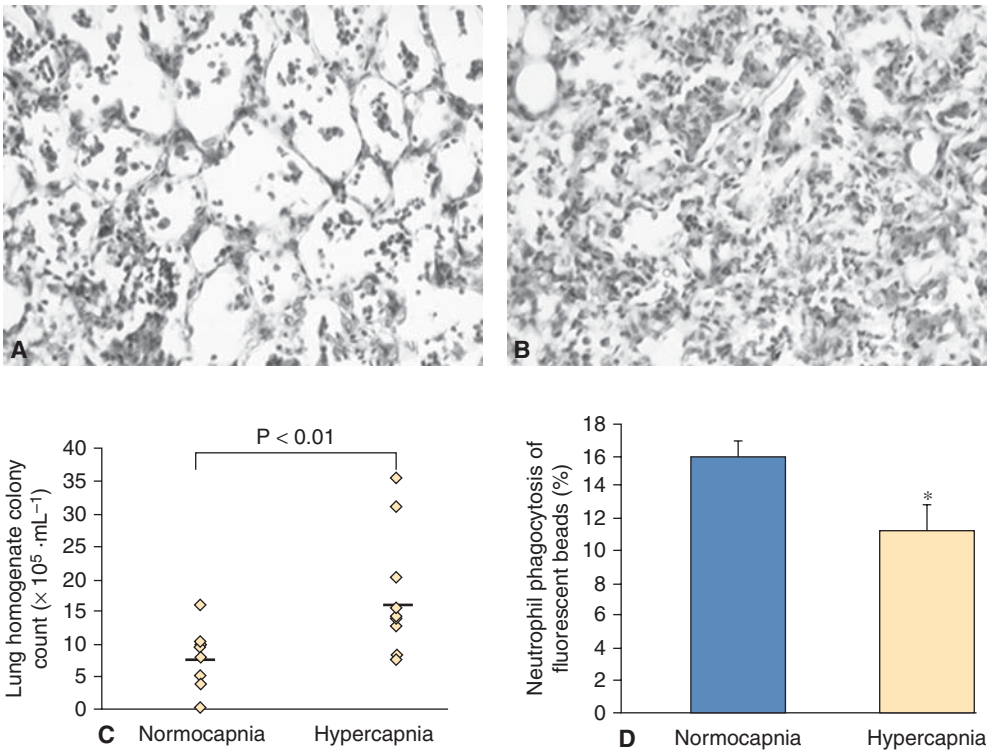

FIGURE 14-9 Sustained hypercapnic acidosis worsens pneumonia-induced lung injury and increases bacterial load. *Panels A* and *B* represent photomicrographs of section of lung tissue from a lung exposed to normocapnia and hypercapnia respectively, 2 days after intratracheal infection with *E. coli*. Animals exposed to environmental hypercapnia (inspired CO_2 5%) sustained a more severe lung injury. *Panel C* demonstrates greater bacterial load in lungs from *E. coli* infected groups exposed to hypercapnia compared to normocapnia. *Panel D* demonstrates that neutrophils from rats exposed to hypercapnia have a reduced ability to phagocytose fluorescent latex beads compared to neutrophils from normocapnic rats. (Modified, with permission, from O'Croinin DF, Nichol AD, Hopkins N, et al. Sustained hypercapnic acidosis during pulmonary infection increases bacterial load and worsens lung injury. *Crit Care Med*. 2008;36:2128–2135.)

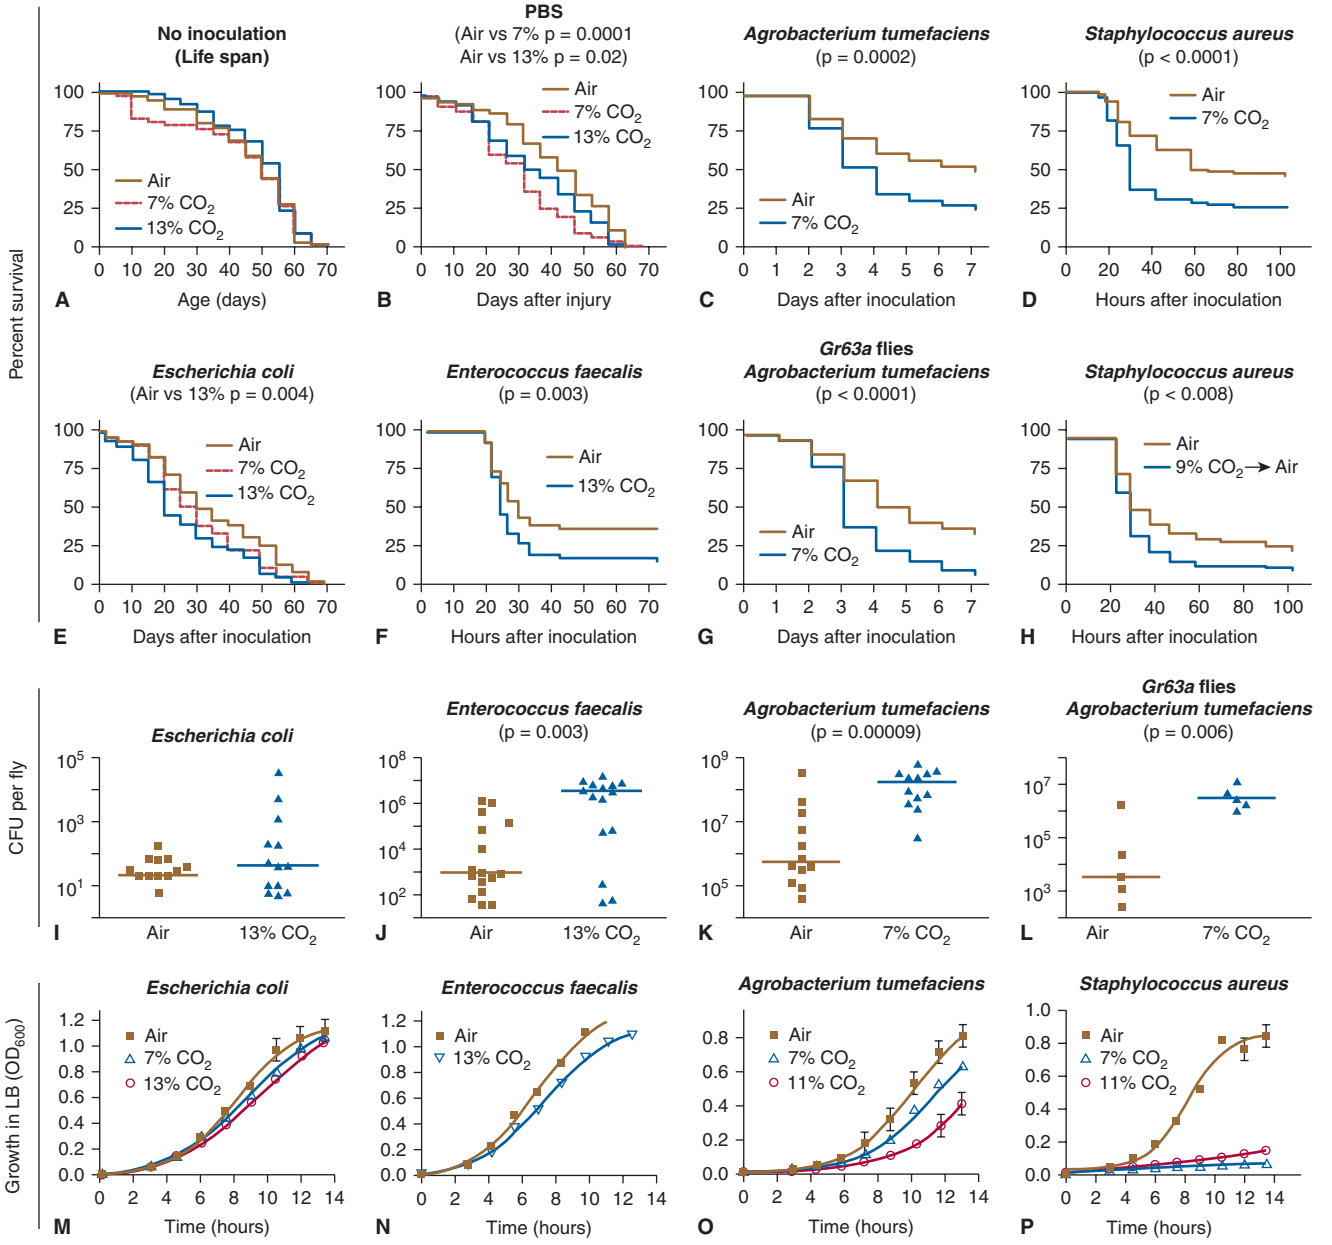

FIGURE 14-10 Prolonged hypercapnia decreases resistance of *Drosophila* to specific bacterial infections. *Panel A.* Hypercapnia does not affect *Drosophila* life span. *Panels B* to *H.* Hypercapnia slightly increases death of flies inoculated with sterile phosphate-buffered saline (*PBS*) (*Panel B*) or with *E. coli* (*Panel E*), but significantly increases mortality at CO_2 levels as low as 7% after inoculation with *A. tumefaciens* (*Panel C*), the human pathogen *S. aureus* (*Panel D*), and the *Drosophila* natural pathogen *E. faecalis* (*Panel F*). Immune suppression does not require the neuronal CO_2 receptor Gr63a (*Panel G*). *Panel H.* Pretreatment of flies with 9% CO_2 before *S. aureus* infection in air is sufficient to increase mortality, even when flies are cultured in air after inoculation. For *Panels A* to *H*, unless otherwise noted, flies were exposed to indicated CO_2 level for 24 hours before inoculation and returned to hypercapnia until end of assay. We show representative results for the lowest CO_2 levels at which significant effects on mortality were consistently observed. *Panels I* to *L.* Hypercapnia increases the bacterial load for strains causing increased mortality during hypercapnia. *Horizontal lines* show medians. *Panels M* to *P.* Effects of hypercapnia on bacterial growth. Note that *S. aureus* growth is dramatically reduced in 7% CO_2 even though hypercapnia increases mortality of flies infected with *S. aureus*. (Reproduced, with permission, from Helenius IT, Krupinski T, Turnbull DW, et al. Elevated CO_2 suppresses specific *Drosophila* innate immune responses and resistance to bacterial infection. *Proc Natl Acad Sci U S A*. 2009;106(44):18710–18715.)

and *E. coli*.[70] The effects appear to be a function of the elevated CO_2 (not lowered pH) and are mediated in part via suppression of Rel/NF-κB, an important conserved pathway (Fig. 14-10).[70]

Systemic Sepsis. In a sheep model of established sepsis, hypercapnia augmented hemodynamics (comparably to dopamine) and resulted in increased systemic oxygenation.[123] In a small animal model of established systemic sepsis

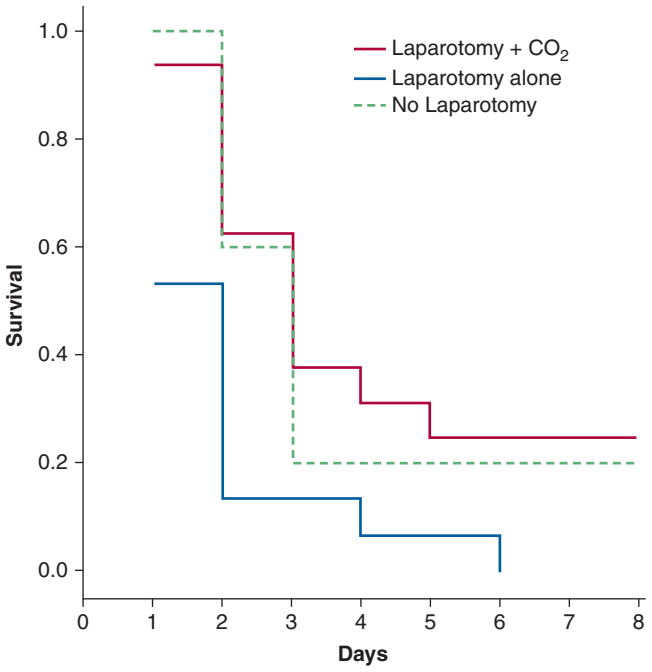

FIGURE 14-11 Insufflation of CO_2 into the peritoneal cavity improves survival following cecal ligation and puncture-induced systemic sepsis. Animals were first subjected to cecal ligation and puncture. Four hours later, animals underwent a laparotomy and induction of a CO_2 pneumoperitoneum (laparotomy + CO_2), laparotomy alone, or no laparotomy, and survival was determined over the following 8 days. (Modified, with permission, from Metzelder M, Kuebler JF, Shimotakahara A, et al. CO_2 pneumoperitoneum increases survival in mice with polymicrobial peritonitis. *Eur J Pediatr Surg.* 2008;18:171–175.)

induced by cecal ligation and perforation, hypercapnia had similar effects on hemodynamics.[124] In contrast to established pulmonary sepsis,[86] hypercapnia reduced the lung injury—in terms of histology and lung mechanics—associated with cecal ligation and perforation[124]; importantly, in this setting, hypercapnia did not increase bacterial load in the lung, bloodstream, or peritoneal cavity.[124] Buffering the hypercapnic acidosis maintained the hemodynamic benefits, but ablated the lung protection.[125] Direct intraabdominal administration of carbon dioxide—by introducing operative pneumoperitoneum—may reduce the severity of abdominal sepsis. In experimental endotoxin sepsis, CO_2 pneumoperitoneum reduced mortality following laparotomy,[126] and insufflation before laparotomy also increased survival.[127] These protective effects are seen also in polymicrobial sepsis (Fig. 14-11),[128,129] and may be secondary to the immunomodulatory effects of hypercapnia,[127,130] which appear to be mediated by the localized peritoneal acidosis.[131,132]

Insights from Other Models. Inhaled CO_2 protects against hyperoxic lung injury in the neonatal rat.[116] In lung injury induced by oleic acid, metabolic alkalosis increased intrapulmonary shunt.[133] Whereas metabolic acidosis decreased shunt and increased arterial oxygen saturation (SaO_2) and mixed venous oxygen tension (PvO_2), hypercapnic acidosis did not affect intrapulmonary shunt fraction ($\dot{Q}_S/\dot{Q}_T$), Sa_{O_2} or mixed venous oxygen saturation (SvO_2). Both Pa_{O_2} and PvO_2, however, increased with hypercapnic acidosis possibly in part because of a rightward shift of the Hb-O_2 dissociation curve and/or increased cardiac output. When the hypercapnia was buffered with bicarbonate, gas exchange deteriorated during hypercapnia, shunt increased, and Sa_{O_2} was reduced.[133] The direct vasodilator effect of hypercapnia in hypoxic lung regions may be opposed by acidosis with little overall net effect on shunt from respiratory acidosis. With buffering however, the vasodilator effect of CO_2 may be unopposed, hypoxic pulmonary vasoconstriction inhibited, and shunt increased.[133]

Therapeutic versus Permissive Hypercapnia. The effects of hypercapnia may also depend on the means of achieving it. The effects of hypercapnia in preclinical models described earlier were generally obtained by increasing CO_2 in the inspired gas. Hypercapnia, however, can be induced by reducing V_T and/or respiratory rate; achieved this way, hypercapnia appears to worsen lung damage induced by systemic endotoxin administration.[100] Inspired CO_2 is distributed uniformly through all ventilated regions, whereas hypercapnia caused by reducing alveolar ventilation may not be.[134] These issues underline the need to consider the means of achieving hypercapnia, as well as the diversity of experimental models.[135]

INSIGHTS FROM CLINICAL DATA

Reduction of V_T results in permissive hypercapnia. The lung alterations, however, involve the reduced V_T, the ensuing hypercapnic acidosis, and the potential influence of altered respiratory frequency. No clinical studies to date have dissected out these changes; it is difficult to conceive of how this would be done. Nonetheless, conventional application of permissive hypercapnia involves reduction of V_T, some increase in respiratory frequency, and tolerance of hypercapnic acidosis.

Pulmonary Vascular Effects. Pulmonary hypertension is almost invariable in ARDS. While protective ventilation may augment pulmonary vascular flow, the net effect of hypercapnic acidosis is usually to increase pulmonary vascular resistance. Inhaled nitric oxide usually can overcome such hypercapnia-induced pulmonary hypertension and may increase cardiac output.[136] Pulmonary hypertension may result in high capillary wall stress; therefore, worsening of such stress by hypercapnia theoretically could exacerbate stretch-induced lung injury.[33,137]

Pulmonary Gas Exchange in Acute Respiratory Distress Syndrome. In ARDS, hypercapnia usually results in a slight increase in Pa_{O_2} and a somewhat larger increase in venous and tissue P_{O_2}.[138] The increase in Pa_{O_2} occurs partly because of an increase in cardiac output and partly because of a rightward shift of the Hb-O_2 dissociation curve, which

facilitates oxygen unloading to the tissues.[25,139] The overall effect, therefore, is likely to enhance tissue oxygen uptake. In patients with ARDS, the reduction in mean airway pressure after initiation of pressure-limited ventilation (without high positive end-expiratory pressure [PEEP]) may result in lung derecruitment and increased shunt.[140] Three clinical studies shed light on these mechanisms.

Feihl et al[45] provided a detailed assessment of pulmonary physiology associated with a large reduction in V_T (mean: from 10 to 6 mL/kg). Induction of permissive hypercapnia markedly increased intrapulmonary shunt, although there was no effect on dispersion of $\dot{V}_A/\dot{Q}$ (Fig. 14-12).[45] Permissive hypercapnia increased cardiac output and decreased Pa_{O_2} from 109 to 92 mm Hg apparently owing to a combined effect of reduced V_T, increased shunt fraction, and decreased alveolar ventilation.[45] Thorens et al[138] studied the rapid induction of hypercapnia in eleven patients with ARDS, where V_T was reduced such that Pa_{CO_2} rose from approximately 40 to 60 mm Hg, and pH correspondingly decreased from 7.4 to 7.26.[138] There were significant increases in venous mixture, cardiac index, and mean pulmonary artery pressure, prompting the authors to caution against rapid induction of permissive hypercapnia. Pfeiffer et al[141] studied the effect of permissive hypercapnia consequent to V_T reduction in twenty-two patients with ARDS categorized into septic (i.e., hyperdynamic) or nonseptic groups. Multiple inert gas uptake measurements revealed an increase in intrapulmonary shunt but maintained—or increased—Pa_{O_2}.[141]

Overall, these data suggest two opposing sets of effects on oxygenation: reduced V_T worsens atelectasis and increases intrapulmonary shunt, but these effects are countered by elevated cardiac output (and perhaps reduced O_2 consumption), which increases mixed venous O_2 content.[141] These concepts have been supported by mathematical models of oxygen kinetics in ARDS.[139]

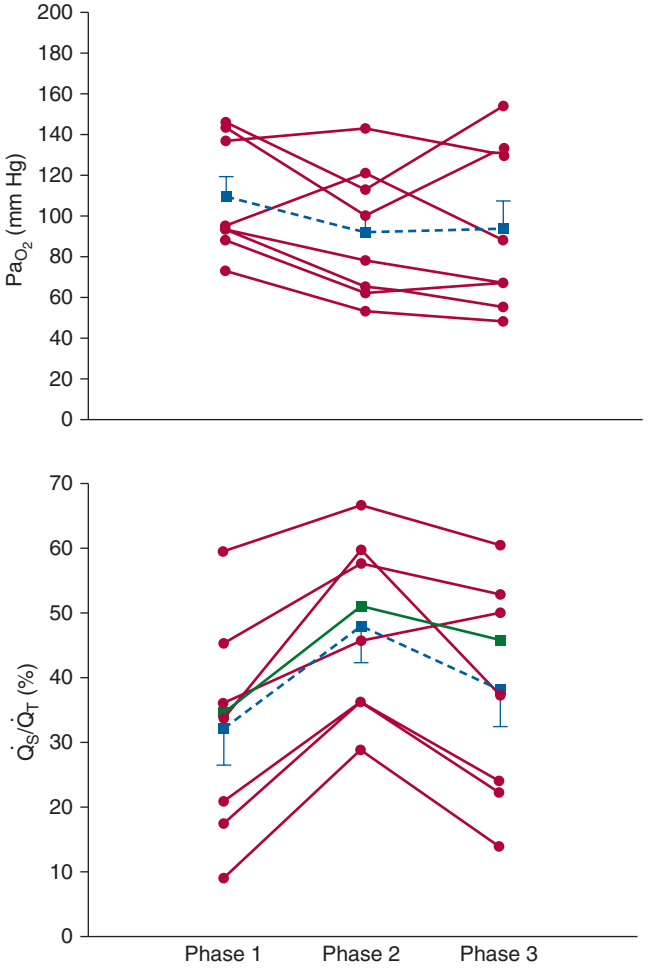

FIGURE 14-12 The effects of permissive hypercapnia and dobutamine on arterial oxygen tension (Pa_{O_2}) and venous admixture $\dot{Q}_S/\dot{Q}_T$. Phase 1 (high V_T, 10.3 mL/kg) represents baseline conditions. Phase 2 (low V_T, 6.5 mL/kg) represents a change to permissive hypercapnia, which was associated with a slight decrease in mean Pa_{O_2} and a large increase in $\dot{Q}_S/\dot{Q}_T$. Phase 3 represents resumption of baseline high V_T (10.3 mL/kg) plus infusion of dobutamine; it resulted in stabilization of Pa_{O_2} despite residual elevation of intrapulmonary shunt. (Reproduced, with permission, from Feihl F, Eckert P, Brimioulle S, et al. Permissive hypercapnia impairs pulmonary gas exchange in the acute respiratory distress syndrome. *Am J Respir Crit Care Med.* 2000;162:209–215.)

Hypercapnia and the Injured Brain

INSIGHTS FROM LABORATORY DATA

Several studies have demonstrated protective effects of hypercapnia in brain injury. Hypercapnic acidosis attenuates hypoxic-ischemic brain injury in the immature rat. Vannucci et al[142,143] developed a model of hypoxic-ischemic injury in the immature rat consisting of unilateral common carotid artery ligation, exposure to hypoxia (FI_{O_2} of 0.8%), and thereafter exposure to varying concentrations of inspired CO_2 (0%, 3%, 6%, or 9%) for 2 hours.[142,143] Neuropathologic assessment at 30 days of age demonstrated that hypocapnia was harmful and that elevated CO_2 was protective.[143] The experimental model caused hyperventilation. Without supplemental CO_2, the animals were frankly hypocapnic, which caused harm. Therefore, exposure to supplemental CO_2 may have provided protection by preventing hypocapnia rather than by producing hypercapnia. The investigators subsequently demonstrated that cerebral blood flow was better preserved during hypercapnia, and the higher oxygen delivery promoted cerebral glucose utilization and oxidative metabolism for optimal maintenance of tissue high-energy phosphate reserves.[142] Cerebrospinal fluid glutamate levels were also lowest with hypercapnia, and it is possible that inhibition of excitatory amino acid neuro-transmitter secretion may contribute to neural protection.[142] Additional mechanisms of neural protection may involve inhibition of free radicals[93,144] or attenuation of neuronal apoptosis.[145]

INSIGHTS FROM CLINICAL DATA

Hypercapnia greatly increases cerebral blood flow and, if critical, may raise intracranial pressure, resulting in

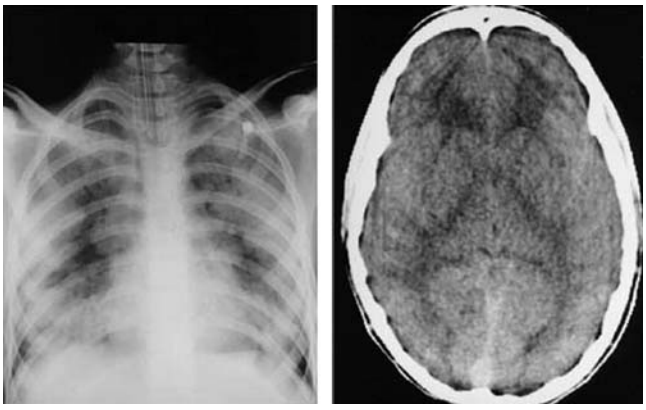

FIGURE 14-13 A chest radiograph and brain computed tomographic scan of a child with both ARDS and cerebral edema illustrating the trade-off that occurs when permissive hypercapnia is instituted to protect against ventilator-associated lung injury. (Reproduced, with permission, from Tasker RC, Peters MJ. Combined lung injury, meningitis and cerebral edema: how permissive can hypercapnia be? *Intensive Care Med*. 1998;24:616–619.)

papilledema and headache. In the clinical setting, cerebral effects of hypercapnia often overlap with the effects of hypoxemia.[146] The resulting abnormalities include restlessness, tremor, slurred speech, and fluctuations of mood. Very high levels of Pa_{CO_2} cause narcosis.[146] Raised intracranial pressure, however, is not an absolute contraindication to permissive hypercapnia; in fact, with careful management it has been used successfully in a patient suffering from acute lung injury and meningoencephalitis with cerebral edema (Fig. 14-13).[147]

Hypercapnia and the Cardiovascular System

INSIGHTS FROM LABORATORY DATA

Effects on the Myocardium. Hypercapnic acidosis protects the heart against ischemia–reperfusion injury. This has been demonstrated in isolated perfused neonatal lamb hearts, where greater degrees of hypercapnic acidosis were associated with progressively greater protection,[148] as well as in myocardial cells.[149] Although hypercapnia directly reduces contractility, it may also provide preconditioning protection.[150] Exposure to comparable metabolic acidemia (pH 6.8), however, followed by buffering to normal pH with bicarbonate and tris-hydroxymethyl aminomethane (THAM), is not protective.[148] In contrast, metabolic acidosis (pH 6.6) prevented myocardial stunning following global ischemia.[151] The latter investigators have since demonstrated that both hypercapnic and metabolic acidosis were equally effective in reducing infarct size in an in vivo canine model of coronary artery ischemia–reperfusion.[152] Possible mechanisms for the protective effects of acidosis include reduction of calcium loading to the myocardium through H^+ inhibition of calcium uptake and, in the case of hypercapnic acidosis, induction of coronary vasodilation. Nomura et al[148] found that the greatest coronary artery flow occurred with maximal hypercapnia. In contrast, increases in regional coronary artery flow do not contribute to the protective effects of normocapnic acidosis.[153]

Effects on the Vascular System. Hypercapnic acidosis attenuates the development of septic shock following cecal ligation and puncture.[24,123,125] The hemodynamic effect of hypercapnia in an ovine model was comparable to that seen with dobutamine,[108] and appears to be an effect of hypercapnia and not acidosis.[125] Hypercapnic acidosis improves microcirculation in the anesthetized rabbit,[154] which corresponds to the improvement in tissue oxygenation observed during surgery.[155,156] The absence of improved oxygenation during cardiopulmonary bypass[157] may reflect fixed aortic flow and suggest that hypercapnia-induced increases in oxygenation are a function of modulation of flow—and not vascular tone—in the perioperative setting.

INSIGHTS FROM CLINICAL DATA

Critical Illness The potential for hypercapnia to exert detrimental effects on cardiac output[158] and the peripheral circulation[159] may be overstated, particularly when hypercapnia develops gradually. As discussed earlier, the net hemodynamic effect is probably beneficial.[45,63] Nevertheless, hypercapnic acidosis may exert adverse hemodynamic effects in critically ill patients, particularly where myocardial function is already depressed. In addition, acute hypercapnia may cause hypotension where endogenous catecholamine production has been maximized or where β-blocking drugs reduce the potential for sympathetic activation to overcome the direct depressive effects of hypercapnia. Even in critically ill patients requiring inotropic drug infusions, cardiac output increases almost invariably after an acute rise in Pa_{CO_2}, although the mean arterial pressure may fall because of direct hypercapnia-induced systemic vasodilation.[136]

In patients with ARDS, the rapid induction of hypercapnia to a target Pa_{CO_2} of 80 mm Hg for 2 hours resulted in decreased systemic vascular resistance and increased cardiac output.[160] In addition, myocardial contractility was decreased, and mean pulmonary artery pressure was increased.[160] In stable patients with ARDS, reduction of V_T (from 10 to 7.7 mL/kg) associated with an increase in Pa_{CO_2} (from 37.9 to 56.7 mm Hg) was not associated with changes in hemodynamics or measures of oxygen delivery or consumption.[161]

Renal, Hepatic, and Splanchnic Effects

In isolated hepatocytes exposed to anoxia[162] or chemical hypoxia,[163] acidosis delays the onset of cell death; correction of pH accelerated cell death. This phenomenon

may represent a protective adaptation against hypoxic and ischemic stress. Isolated renal cortical tubules exposed to anoxia have improved ATP levels on reoxygenation at a pH of 6.9 when compared with tubules incubated at pH 7.5.[162] Elevated CO_2 preserves tissue oxygenation of the gastrointestinal mucosa during hemorrhagic shock[164,165] and has been reported to reverse sepsis-induced reductions in gastrointestinal cellular ATP[166] (and the reciprocal rise in lactate) and can prevent increases in mucosal permeability[167] triggered by endotoxemia.

The marked sympathetic activation associated with hypercapnic acidosis, particularly when combined with arterial hypoxemia, can lead to intense renal vasoconstriction and tubular sodium reabsorption, causing depressed glomerular filtration and increased fluid retention.[168] In a clinical study of ARDS, hypercapnia resulted in no important alterations in splanchnic circulation, although in this case CO_2 was increased by increasing apparatus dead space (and not by reduction of V_T).[169]

Effects of Acidosis versus Hypercapnia

EFFECTS MEDIATED VIA pH CHANGES

The protective effects of hypercapnic acidosis in experimental lung and systemic organ injury appear to be primarily a function of the acidosis generated.[98,112] The effects of buffering may depend on the model and the pathogenesis of the injury. In the isolated lung hypercapnic acidosis attenuated ventilator-induced lung injury, whereas in cultured cells buffering reduced cell resealing[111] and pulmonary epithelial repair[106] following physical injury. In the isolated lung, the protective effect of hypercapnic acidosis in ischemia–reperfusion was greatly attenuated when the pH was buffered,[112] and although metabolic acidosis attenuated reperfusion injury, it was less effective than hypercapnic acidosis.[112] The myocardial protective effects of hypercapnic acidosis are also seen with metabolic acidosis in ex vivo[151] and in vivo[152,153] models. Metabolic acidosis exerts protective effects in other models of organ injury; it delays cell death following caused by anoxia[162] or chemical hypoxia,[163] and reoxygenation at acidotic (compared with alkalotic) pH is associated with better preservation of cellular ATP.[162] In contrast to the lung, the type of acidosis (i.e., hypercapnic versus metabolic) appears to be of importance in the renal tubule.

EFFECTS MEDIATED VIA CARBON DIOXIDE

Certain effects of hypercapnia, including the inhibitory effects of hypercapnia on pulmonary epithelial wound healing,[106] and the deleterious effects in prolonged pulmonary sepsis,[86,87]appear to be a function of CO_2 and not pH. The effects of hypercapnia on the NF-κB pathway may also relate to CO_2 rather than acidosis,[70,106] and the developmental effects of hypercapnia, at least in *Drosophila* and in *C. elegans*, appear to be mostly independent of the pH.[70,71]

USE IN SPECIFIC CLINICAL SETTINGS

Acute Severe Asthma

Although much current work on ventilator strategies involving permissive hypercapnia concentrates on lung injury, its use was first described in status asthmaticus by Darioli and Pettet.[170] Permissive hypercapnia decreases dynamic hyperinflation in ventilated patients with acute severe asthma by increasing expiratory time and decreasing V_T, and this reduces end-inspiratory lung volume and lessens auto-PEEP. Other investigators have confirmed that morbidity and mortality are reduced with the use of permissive hypercapnia in ventilated patients with acute severe asthma.[171] Modest levels of permissive hypercapnia (approximately 60 mm Hg) are employed widely in ventilated patients with acute severe asthma.[81]

Acute Respiratory Distress Syndrome

The potential for protective lung ventilation strategies with varying degrees of permissive hypercapnia to improve survival in patients with acute lung injury and ARDS was suggested initially by Hickling et al.[12,13] Two studies by this group, one retrospective[12] and one prospective,[13] strongly indicated that use of low V_T was beneficial. In the retrospective study, fifty patients with severe ARDS (lung injury score ≥2.5; mean Pa_{O_2}/FI_{O_2} = 94) were managed with limitation of peak airway pressure to less than 30 cm H_2O.[12] The mean maximum Pa_{CO_2} was 62 mm Hg, and the hospital mortality (16%) was less than predicted by Acute Physiology and Chronic Health Evaluation (APACHE) II score (39.6%). Importantly, the authors reported no differences between survivors and nonsurvivors in terms of lung injury score, ventilator score, Pa_{O_2}/FI_{O_2}, or maximum Pa_{CO_2}.[12] The prospective study[13] investigated comparable patients and also limited peak airway pressures to less than 30 cm H_2O, did not buffer hypercapnic acidosis, and commenced with a V_T of 7 mL/kg (as opposed to 12 mL/kg in the retrospective study). Again, hospital mortality rates were lower than predicted by APACHE II score (26.4% vs. 53.3%).[13]

The five prospective, randomized, controlled trials[10,11,172–174] that measured survival in ARDS are discussed in detail elsewhere (see Chapter 42). Two were positive (the ventilator strategy had an impact on mortality),[10,11] and three were not.[172–174] To some extent, permissive hypercapnia developed in all the trials, although there was much variability. Among the four major trials, the postrandomization Pa_{CO_2} values (mean ± standard deviation [SD]) in the control (higher V_T) trial groups were 35.8 ± 8.0 mm Hg,[10] 36.0 ± 1.5 mm Hg,[11] 41.0 ± 7.5 mm Hg,[172] and 46.0 ± 10 mm Hg.[174] The postrandomization Pa_{CO_2} values in the protective (lower V_T) trial groups were 40.0 ± 10,[10] 58.0 ± 3.0,[11] 59.5 ± 15,[172] and 54.5 ± 19[174] mm Hg. It is clear that ventilation strategy can have an impact on mortality (in the positive trials), yet there was no discernible relationship between levels

of hypercapnia and survival. Also, there was no controlled approach to the administration of buffers. Finally, one of the reports mentioned (without supportive analysis) that the permissive hypercapnia might have increased the incidence of renal failure.[174]

The database of the largest of these studies[10] was subsequently analyzed to determine whether, in addition to the effect of V_T, there might be an independent effect of hypercapnic acidosis.[175] Mortality was examined as a function of permissive hypercapnia on the day of enrollment using multivariate analysis and controlling for other comorbidities and severity of lung injury. It was found that permissive hypercapnia reduced mortality in patients randomized to the higher V_T but not in those receiving lower V_T.[175] If these data are confirmed, there may be a good case for testing hypercapnic acidosis as an adjunct to attenuate ventilator-associated lung injury.

Neonatal and Pediatric Practice

Use of permissive hypercapnia in neonatology has been recognized since the study by Wung et al in 1985.[14] They described lower than previous mortality and lower incidence of chronic lung disease in neonates suffering from persistent fetal circulation who were treated with low V_T entailing a high Pa_{CO_2}.[14]

NEONATAL RESPIRATORY DISTRESS SYNDROME

Infants with neonatal respiratory distress syndrome have been studied in a randomized, controlled trial.[176] Although not powered to detect differences in survival, the duration of mechanical ventilation was shorter in the permissive hypercapnia group; and, no obvious adverse effects were seen (Fig. 14-14). Although encouraging, such a small study would not detect a subtle increase in adverse effects. More recently, a prospective multicenter study of extremely premature neonates in Denmark (1994 to 1995) reported that a ventilator strategy incorporating permissive hypercapnia and early use of nasal continuous positive airway pressure and surfactant reduced the incidence of chronic lung disease significantly.[177]

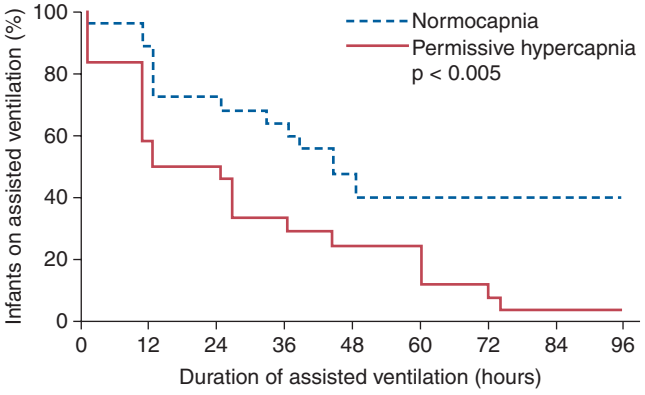

FIGURE 14-14 Duration of mechanical ventilation in neonates with respiratory failure randomized to conventional therapy or permissive hypercapnia. (Reproduced, with permission, from Mariani G, Cifuentes J, Carlo WA. Randomized trial of permissive hypercapnia in preterm infants. *Pediatrics*. 1999;104(5 Pt 1):1082–1088.)

CONGENITAL DIAPHRAGMATIC HERNIA

Permissive hypercapnia plays an increasing role in the ventilator management of infants with congenital diaphragmatic hernia.[178] This contrasts sharply with traditional management, which involved aggressive hyperventilation with the aim of producing systemic alkalinization. High levels of barotrauma, poor long-term respiratory outcomes, and poor survival rates, however, have prompted the recognition that the hypoplastic lung is the major pathophysiologic defect. Accordingly, avoidance of barotrauma has assumed increasing importance, and ventilator strategies involving permissive hypercapnia are used increasingly. A retrospective analysis of three treatment protocols in high-risk infants with congenital diaphragmatic hernia reported that permissive hypercapnia was associated with a substantial increase in survival, decreased barotrauma, and decreased morbidity at 6 months. In contrast, the earlier introduction of high-frequency oscillatory ventilation (which readily controls Pa_{CO_2}) had minimal impact. Despite limitations, the increased survival associated with the use of permissive hypercapnia is persuasive.[179]

CONGENITAL HEART DISEASE

Four studies of patients with congenital heart disease are relevant.[180–183] In the context of single-ventricle physiology, pulmonary vascular resistance can be controlled by inducing alveolar hypoxia or alveolar hypercapnia. Two studies documented that the addition of inspired CO_2 increased cerebral oxygenation and mean arterial pressure compared with reducing FI_{O_2} in hypoplastic left-heart syndrome[183] and following cavopulmonary connection.[182] Hypoventilation also improves systemic oxygenation after bidirectional superior cavopulmonary connection, potentially via a hypercarbia-induced decrease in cerebral vascular resistance, thus increasing cerebral, superior vena caval, and pulmonary blood flow.[180] Finally, a detailed recent study demonstrated that without altering V_T or mean airway pressure, the addition of CO_2 to inspired gas resulted in improved cerebral blood flow and systemic oxygenation following cavopulmonary connection.[181]

COMPLICATIONS

The complications of hypercapnia relate primarily to those caused by hypercapnic acidosis per se and those caused by the use of low V_T.

Complications Associated with Hypercapnic Acidosis

Although many physiologic effects are associated with hypercapnic acidosis, there are few complications. The most notable complications include intracranial and pulmonary hypertension. Complications are of most concern in patients with specific risk factors, especially where acidosis is acute, severe, or not buffered.

Complications Associated with Low Tidal Volumes

Reduced V_T may lead to increased intrapulmonary shunt, reducing Pa_{O_2}.[45] This is generally not a difficult problem and can be countered by a recruitment maneuver, elevation of PEEP or mean airway pressure, prone positioning, or other strategies. A more serious issue is whether small V_T values increase mortality, a source of significant controversy and a major issue in the meta-analysis by Eichacker et al.[184] They suggested that not only were very high V_T values dangerous, but so too were very small V_T values. This was the basis of a U-shaped curve depicting a relationship between V_T and mortality; the investigators suggested that the ARDS Network 6 mL/kg V_T protocol was potentially dangerous, should not be used, and should not be considered the standard of care.[184] Considerable controversy ensued. Another group published an abbreviated meta-analysis pooling the results of important clinical trials.[185] They countered the analysis of Eichacker et al and concluded that there was no statistical basis for the assertion that low V_T values are harmful.

LIMITATIONS AND CONTRAINDICATIONS

Limitations

A substantial body of literature emphasizes the potential for full recovery following exposure to extreme levels of hypercapnia, termed *supercarbia,* in both adults and children. Several children exposed to extremes of Pa_{CO_2} (155 to 269 mm Hg)[186] and one patient with asthma with a Pa_{CO_2} of 293 mm Hg (pH 6.77)[28] have been described, with excellent recovery and no long-term sequelae. In adults, in the early 1950s, the accidental development of severe respiratory acidosis was not uncommon in patients undergoing certain surgical procedures; Pa_{CO_2} as high as 200 mm Hg was reported during thoracotomy without apparent adverse effects.[187] More recently, reports exist of survival without sequelae following exposure to Pa_{CO_2} values of up to 375 mm Hg (pH 6.6).[188,189] Indeed, a case report indicates complete recovery following a pH of 6.46 secondary to ethylene glycol poisoning.[190] These numbers, impressive though they are, do not suggest that all patients—certainly not those who are already critically ill—would survive such exposure without incident or even survive at all. Nonetheless, they do indicate that severe hypercapnic acidosis per se is not *invariably* harmful.

Contraindications

As with almost any situation, there are few absolute contraindications and many relative contraindications. Some authorities suggest that intracranial hypertension is an absolute contraindication,[191] although this is disputed.[147] In any case, the risks and benefits of hypercapnia in the setting of intracranial hypertension must be weighed and monitored carefully. Additional relative contraindications include pulmonary hypertension, significant hypovolemia, or uncontrolled severe metabolic acidosis.[191]

ADJUNCTIVE THERAPIES

Buffering Hypercapnic Acidosis

Buffering of the acidosis induced by hypercapnia in patients with ARDS remains a common, albeit controversial, clinical practice.[192,193] The effects of buffering hypercapnic acidosis need to be considered because both hypercapnia—and acidosis—exert distinct biologic effects. As discussed above (Basic Principles), there is evidence that the protective effects of hypercapnic acidosis in ARDS are a function of the acidosis rather than the elevated CO_2 per se.[98,112] In contrast, some of the potentially harmful effects of hypercapnia, such as delayed wound healing[106] and worsening of lung injury as a result of prolonged pneumonia,[87] occur despite buffering.

SODIUM BICARBONATE

Buffering with sodium bicarbonate was permitted in the ARDS Network study.[10] Concerns with its use, however, have caused its removal from routine use in cardiac arrest algorithms.[194,195] The effectiveness of bicarbonate as a buffer depends on the ability to excrete CO_2, rendering it less effective in buffering hypercapnic acidosis. In fact, bicarbonate may further raise Pa_{CO_2} where alveolar ventilation is limited, as in ARDS.[196] Bicarbonate may correct arterial pH but worsen intracellular acidosis[197] because the CO_2 produced when bicarbonate reacts with metabolic acids diffuses readily across cell membranes, whereas bicarbonate cannot.[198]

In metabolic acidosis, the situation is also complex. Bicarbonate infusion can augment the production of lactic acid.[199–205] In ketoacidosis it can slow the clearance of ketoacids.[206] Of greater concern, bicarbonate administration is associated with a fourfold increase in risk of cerebral edema in children with diabetic ketoacidosis.[207] When compared with an equimolar dose of sodium chloride, bicarbonate administration does not improve the hemodynamic status of critically ill patients who have lactic acidosis.[208]

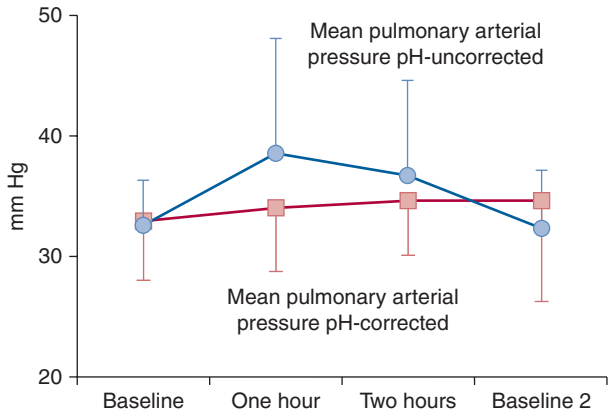

FIGURE 14-15 Pulmonary artery pressure is elevated by rapid institution (over 2 hours) of permissive hypercapnia (*blue line*) in patients with ARDS. Institution of a comparable degree of permissive hypercapnia buffered with tromethamine (THAM, *red line*) attenuated the effects. (Reproduced, with permission, from Weber T, Tschernich H, Sitzwohl C, Ullrich R, Germann P, Zimpfer M, Sladen RN, Huemer G. Tromethamine buffer modifies the depressant effect of permissive hypercapnia on myocardial contractility in patients with acute respiratory distress syndrome. *Am J Respir Crit Care Med.* 2000;162:1361–1365.)

TROMETHAMINE

There may be a role for the amino alcohol tromethamine (THAM) in hypercapnic acidosis. THAM penetrates cells easily and can buffer pH changes and simultaneously reduce P_{CO_2}.[209] Unlike bicarbonate, which requires an open system for CO_2 elimination in order to exert its buffering effect, THAM is effective in a closed or semiclosed system.[209] THAM rapidly restores pH and acid–base regulation in acidemia caused by CO_2 retention.[209] In a small but carefully performed clinical study of twelve patients with ARDS, rapid induction of a hypercapnic acidosis resulted in decreased systemic vascular resistance, increased cardiac output, decreased myocardial contractility, decreased mean arterial pressure, and increased mean pulmonary arterial pressure.[160] Buffering of the hypercapnic acidosis with THAM rapidly attenuated but did not fully reverse these changes (Fig. 14-15).[160] Thus, it could be argued that although permissive hypercapnia generally is well tolerated in patients with ARDS, buffering with THAM[160] might be a useful cotherapy where hemodynamic instability supervenes.

CARBICARB

Carbicarb is an equimolar mixture of sodium carbonate (Na_2CO_3 0.33 M) and sodium bicarbonate ($NaHCO_3$ 0.33 M) and may have advantages over the latter. Carbicarb has been studied in mixed respiratory and metabolic acidosis and has proved effective in raising arterial pH and preventing lactate elevation;[196] in contrast to sodium bicarbonate,[197] it corrects the systemic and intracellular acidosis seen with hypercapnia[210] without elevating Pa_{CO_2}. Carbicarb, however, did not appear to possess any advantages in terms of restoration of hemodynamic stability over isoosmolar amounts of hypertonic saline or sodium bicarbonate in a canine shock model.[201] The similar responses may relate to their identical sodium content, with no additional benefit attributable to correction of pH.[201]

In summary, although common clinical practice, no outcome data (e.g., survival or duration of hospital stay) support the buffering of hypercapnic acidosis in patients. In the absence of correcting the primary problem, buffering hypercapnic acidosis with bicarbonate is not likely to be of benefit. If the clinician elects to buffer a hypercapnic acidosis, the rationale should be clear (e.g., to ameliorate potentially deleterious hemodynamic consequences) and the responses measured. THAM and Carbicarb may have a role in these clinical situations.

Augmenting Carbon Dioxide Clearance

DEAD SPACE GAS REPLACEMENT

At the end of expiration, the ventilator circuit distal to the Y-piece and the anatomic dead space both contain alveolar gas. This CO_2-rich gas then constitutes the first part of the next breath delivered to the distal lung. The contribution of this dead space gas to ventilation increases with decreased V_T, given that dead space is relatively fixed. Techniques that aim to replace dead space gas with fresh gas have been advocated as an adjunct to protective ventilator strategies. These techniques may increase effective alveolar ventilation and facilitate further reductions in V_T, minimizing transpulmonary pressures.

Tracheal gas insufflation (TGI) delivers fresh gas into the central airways either continuously or in a phasic fashion during expiration (see Chapter 22). Experimental studies in animal models of ARDS and in lung models highlight the potential role of TGI in clinical practice.[211] Zhu et al[99] reported that TGI, either alone or in combination with partial liquid ventilation, attenuated the development of lung injury resulting from mechanical ventilation of surfactant-depleted lungs. Use of expiratory TGI can help clear CO_2 and facilitate V_T (and plateau pressure) reduction in patients with combined brain and lung injury, and it has also been demonstrated to augment CO_2 clearance when combined with high frequency oscillation. Despite extensive investigation, however, concerns persist with regard to the safety and monitoring of TGI that have impeded its introduction into clinical practice.[212]

Aspiration of dead space gas during expiration and controlled replacement with fresh gas is a related technique designed to minimize dead space. A feasibility study of eight patients with chronic obstructive pulmonary disease who were managed with permissive hypercapnia demonstrated that aspiration of dead space gas resulted in a similar decrease in Pa_{CO_2} but with less intrinsic PEEP compared to TGI.[213]

Coaxial double-lumen endotracheal tubes, which eliminate the contribution to dead space from the ventilator circuit distal to the Y-piece, may improve the efficiency of ventilation. No adverse hemodynamic effects or auto-PEEP

has been detected with use of the coaxial tube.[214] Reduction in Pa_{CO_2} is inversely proportional to V_T. Initial safety and efficacy evaluations of this promising adjunct in patients with ARDS are required.

ADDITIONAL TECHNIQUES

High-frequency oscillatory ventilation and extracorporeal CO_2 removal are discussed in Chapters 19 and 21, respectively.

ADJUSTMENTS AT THE BEDSIDE

Adjustments at the bedside are specific to the patient and the clinical context. The following principles may guide therapy, although in the end the physician must individualize the risks and benefits for each patient.

First, in a patient who is being mechanically ventilated, confirm correct placement of the endotracheal tube and the ventilation of both lungs. Consider and (where possible) correct reversible conditions that might have an impact on oxygenation or CO_2 removal (e.g., pleural effusion, atelectasis, and/or pneumothorax). Next, decide whether the patient is comfortable and whether there is patient–ventilator dyssynchrony. Then note the ventilator settings (i.e., plateau pressure, V_T, and rate) and the arterial blood-gas values, and consider whether these are appropriate. Concurrent with these considerations, evaluate the patient for causes of high Pa_{CO_2}, and reduce or eliminate any that are present. Such conditions include increased production of CO_2 (e.g., fever, sepsis, shivering, or more rarely, thyroid storm, malignant hyperthermia, or neuroleptic malignant syndrome) or decreased CO_2 elimination (e.g., increased dead-space-to-tidal-volume ratio [V_D/V_T]).

The next step involves arbitrary decisions made by the clinician at the bedside on the target tidal distension (V_T, or plateau pressure). It is important to recognize that optimal values are unknown, which is not to say that the values are unimportant; they are definitely important. Across populations, adverse effects are associated with very high V_T.[10,11] We do not advise on the ideal V_T or plateau pressure for any specific patient, recognizing that these issues can be both difficult and controversial. After clinicians select an appropriate V_T for the patient in question, they next consider the "maximal" allowable Pa_{CO_2} and the degree of acidosis that they believe the patient can tolerate. This is empirical. Although some authors suggest arbitrary limits, in the end, the decision is based on patient comfort, presence of contraindications, and clinician "comfort." When considering ventilator settings, consider the relative values of V_T, plateau pressure, and rate, and estimate the relative contributions of changes in each. For example, if the rate is inappropriately low, then increasing it will allow further reduction in V_T with less elevation in Pa_{CO_2}. Conversely, increasing the rate may induce a degree of hyperinflation (auto-PEEP),[215] which, although potentially protective, can complicate ventilator management and could induce elevation of the Pa_{CO_2}.

Finally, having decided on the desired ventilator settings and the permissible limits of toleration, decide on the trade-offs involved and the time scale. One trades the benefits of the approach—reduction of ventilator-associated lung injury—against the cost—conditions caused or exacerbated by permissive hypercapnia. Such trade-offs are inherent in the practice of medicine[216] but are seldom addressed by clinical trials. Finally, the clinician decides on the rate of introducing permissive hypercapnia. In some situations, there is little choice. For example, in acute severe asthma, hypercapnia occurs immediately, for otherwise, the patient would be subjected to incredibly high airway pressures. Having decided on the target V_T or plateau pressure, increase the rate and slowly decrease the V_T. There is no formula. Extremes of V_T or plateau pressure should be reduced immediately, and less extreme elevations should be reduced more gradually. For example, in ARDS, a V_T of 15 mL/kg could be reduced immediately to 10 mL/kg and further reduced over several hours with a concomitant increase in rate. Obviously, if ideal ventilator settings are tolerated by the patient and the Pa_{CO_2} and pH are normal, then the clinician would not do anything to elevate the Pa_{CO_2}.

TROUBLESHOOTING

To address problems that develop, it is key to understand the pathophysiology. This amounts to management of dyspnea, intracranial hypertension, pulmonary hypertension, and sometimes, hypoxemia. Troubleshooting follows logically the principles used in initiating permissive hypercapnia. In reality, it represents a work in progress, wherein the clinician considers risks versus benefits (real and potential) for each patient at the bedside.

Tidal Volume and Respiratory Rate

The first issue is to determine whether the V_T (or perhaps plateau pressure) is actually in the range desired by the clinician. If V_T is far lower than desired, increasing it will alleviate "unnecessary" hypercapnic acidosis. If the respiratory rate is too low, increasing it also will lower the Pa_{CO_2}.

Rate of Change

Was the permissive hypercapnia introduced too quickly? Overly rapid introduction of hypercapnia results in a greater degree of acidosis because the physiologic buffering systems are unable to cope. Most unfavorable effects of hypercapnic acidosis (e.g., dyspnea and intracranial hypertension) are more pronounced where acidosis is greater. More gradual introduction of permissive hypercapnia may prevent these problems.

Adjuvant Therapies: Control of Metabolic Acidosis

Buffering sometimes can be appropriate for modifying the adverse effects of significant acidosis. The clinician needs to identify conditions other than ventilator settings and Pa_{CO_2} per se that have an impact on acid–base status. Hyperchloremic acidosis may have developed consequent to high volumes of intravenous saline, total parental nutrition, or renal tubular acidosis, and can be buffered easily or possibly prevented. Renal impairment, which slows the generation of endogenous bicarbonate or excretion of hydrogen ion, or generates endogenous organic acids, can be alleviated by renal replacement therapy.

Adjuvant Therapies: Alternative Elimination of Carbon Dioxide

Adjuvant therapies can be directed at the elevated Pa_{CO_2}. Examples include high-frequency oscillation, TGI, and extracorporeal techniques.

Specific Evaluation of the Complication

In some circumstances, clinicians suspect a problem, such as pulmonary or intracranial hypertension, that leads them to completely avoid permissive hypercapnia. Such an approach may not be appropriate in the absence of clear proof of the feared condition because the patient may be at a far greater risk of ventilator-associated lung injury than of the feared condition or potential complication. In such a setting, the clinician should consider appropriate monitoring. For example, insertion of an intracranial pressure monitor or jugular oximetry catheter may provide evidence that allows the clinician to gradually introduce, titrate, or clearly avoid hypercapnia in a patient with head injury. Such an approach has been described when managing children suffering from meningococcal septicemia complicated by elevated intracranial pressure and severe acute lung injury (see Fig. 14-13).[147] Concerns about pulmonary hypertension can be addressed by measuring, and monitoring the degree of pulmonary hypertension or its sequelae (e.g., right-ventricular failure, tricuspid regurgitation, or right-to-left shunting). In this case, transthoracic echocardiography or pulmonary artery catheterization may be indicated. The clinician will recognize that adverse effects (e.g., epithelial fluid reabsorption) may exist, which may not be detected by conventional monitoring.

Specific Treatment of the Complication

Direct testing for a feared complication may enable early detection. It also permits the direct "independent" treatment if permissive hypercapnia is still deemed necessary to tolerate specific ventilator settings. Specific treatment might include inhaled nitric oxide for pulmonary hypertension[136] or sedation, osmotherapy, or hypothermia for intracranial hypertension. Of course, the most common complaint, dyspnea, can be treated directly with sedatives and opioids[217]; neuromuscular blockade, while paralyzing respiratory muscle contraction, of course, does not alter the perception of dyspnea.

IMPORTANT UNKNOWNS

Although much is known about hypercapnia, much remains unknown. The principles underlying the approach to permissive hypercapnia have been established.[25,31,33,191,218–220] Such principles are inherently limited by the state of our knowledge. The unknowns relating to permissive hypercapnia can be grouped as follows.

Hypercapnia versus Acidosis

Most of the acute physiologic effects of hypercapnic acidosis can be attributed to the effects of pH. CO_2 itself, however, has significant biochemical effects, especially on tissue nitration. In the context of endogenous or exogenous buffering, the effects of elevated CO_2 are not understood.

Therapeutic Hypercapnia

The role of the deliberate elevation of CO_2, as opposed to passive elevation of CO_2 resulting from reduced V_T, is experimentally exciting but essentially conjectural.[25] The state of knowledge is not sufficient to justify deliberating elevating CO_2 other than as a means of avoiding ventilator-associated lung injury; clearly, in the context of evolving understanding of the relevant mechanisms, clinical study with mortality as an outcome would not be justified.[135]

Mechanisms of Benefit (or Harm)

Although evolving studies are providing better understanding of the mechanisms of benefit and harm associated with hypercapnia and acidosis, clinical definitions of lung injury do not take into account the biologic processes that cause the injury. Although some mechanisms are understood, it is not yet possible for the clinician to extrapolate from mechanisms discovered in the laboratory to the care of a patient with lung injury.

Monitoring during Hypercapnia

There are no specific monitors for patients being ventilated with permissive hypercapnia. Regular arterial blood-gas analysis is a requirement, and clinicians will monitor

parameters that lead them to detect or prevent complications such as intracranial hypertension.

THE FUTURE

Future advances in the early diagnosis of acute respiratory failure and the development of specific therapies may reduce the need for ventilator strategies involving permissive hypercapnia. In the interim, ventilator strategies involving hypercapnia appear likely to play a central role in the management of these disease states. This highlights the need to improve our understanding of the biology of hypercapnia, which should lead us to a better understanding of the advantages, disadvantages, and contraindications pertaining to its use in the clinical context. If the requirement for adverse ventilator strategies lessens, the requirement for permissive hypercapnia will lessen in parallel, and concerns related to its use will become less relevant. Nonetheless, a fuller profile of biochemical and physiologic responses to elevated CO_2 will be needed for the clinician of the future to decide whether hypercapnia is dangerous—or potentially beneficial—in the management of a specific patient.

SUMMARY AND CONCLUSIONS

Permissive hypercapnia simply means reducing V_T in order to lessen the likelihood of ventilator-associated lung injury; in so doing, the clinician accepts the inevitable development of higher Pa_{CO_2}. Elevated P_{CO_2} is associated with a long list of physiologic alterations. Some of these effects are harmful, others may be neutral, and some may turn out to be beneficial. In any case, there is ample evidence that high tidal volumes harm patients. In avoiding such high tidal volumes, the clinician must decide for each patient what is the appropriate trade-off between the benefits of avoiding high V_T and the cost (and benefits) of the associated hypercapnia.

FEEDBACK ENHANCEMENTS ON CONVENTIONAL VENTILATOR BREATHS

Neil MacIntyre
Richard D. Branson

CONVENTIONAL POSITIVE-PRESSURE BREATH-DELIVERY STRATEGIES AND MODES

The first generation of positive-pressure mechanical ventilators were simple high-pressure gas regulators on which clinicians could set the circuit pressure and the breathing frequency. In the middle of the twentieth century, more sophisticated devices appeared that allowed direct clinician control of flow and volume along with breath timing and expiratory pressure. As ventilator design improved and microprocessors became available, feedback mechanisms appeared that could provide automatic adjustments in these set variables depending upon a variety of conditions.[1] A simple example was the use of a patient-effort sensor to adjust the number of mechanical breaths provided during assist-control modes or synchronized intermittent mandatory ventilation.[2–4] A variation on this breath rate feedback mechanism was mandatory (or minimum) minute ventilation, which used minute ventilation to adjust the number of positive-pressure breaths delivered.[5] At the same time, the development of flow control valves that could be adjusted based on a clinician-selected airway-pressure target appeared.[6–9] This gave clinicians the choice of using either set flow-volume-targeted modes (volume assist-control ventilation; volume-targeted synchronized intermittent mandatory ventilation [volume SIMV]) or pressure-targeted modes (pressure-targeted assist-control ventilation [PACV]; pressure support; pressure SIMV). Taken together, these flow-targeted, volume-targeted, and pressure-targeted strategies comprise what is commonly referred to today as "conventional" mechanical ventilation.

In the late twentieth and early twenty-first century, increasingly complex and clever feedback mechanisms for these conventional breaths have been introduced. The behavior of these features is made more understandable if one considers that all positive-pressure breaths can be described by three variables: the trigger variable (what initiates a breath—usually an effort sensor or a machine timer); the target variable (what governs gas delivery—usually either a set flow or a set pressure target); and the cycle variable (what terminates the breath—usually a set time, flow, or volume).[6,8] These newer feedback systems are designed to adjust one or more of these breath-delivery variables based on prescribed algorithms to provide more physiologically targeted and patient

interactive ventilatory support. In addition, there has also been the development of feedback mechanisms to adjust the fractional inspired oxygen concentration (FI_{O_2}) and positive end-expiratory pressure (PEEP). These feedback mechanisms are often considered "partial" closed-loop conventional mechanical ventilation. The clinician, however, cannot expect these features to provide safe and effective support automatically. Rather, the clinician must understand their rationale, design principles, lung-protective targets, and evidence-based outcomes to apply them properly. These are the focus of the remainder of this chapter.

FEEDBACK CONTROL OF COMBINATION PRESSURE-TARGETED AND FLOW-TARGETED BREATHS

The advantage of a flow-targeted, volume-cycled breath is that a guaranteed volume is delivered with every breath (even though applied airway pressures may change). The advantages of a pressure-targeted breath (either time- or flow-cycled) are that an airway pressure limit is guaranteed (even though volumes may change), that the rapid initial flow may enhance gas mixing, and that the variable-flow pattern may enhance patient–ventilator synchrony.[7,10,11]

Over the last two decades, a number of engineering innovations have attempted to combine these features by producing feedback algorithms that allow some control of volume with pressure targeting and some control of pressure with flow targeting. Collectively, these are often referred to as *hybrid breaths* or *dual-control breaths*.[12–15] On the current generation of mechanical ventilators, there are two basic approaches to providing these types of breaths: dual control within a breath (DCWB; intrabreath control) and dual control from breath to breath (DCBB; interbreath control). The former uses a measured flow input to switch from pressure targeting to flow targeting in the middle of the breath. The latter uses a measured volume input to manipulate the pressure level of subsequent pressure-targeted breaths.

Dual Control within a Breath

The currently available DCWB breath begins with either patient or machine triggering and is followed by a pressure-targeted flow-delivery algorithm.[16] There is thus a high initial flow to rapidly pressurize the airway and then subsequent flow adjustments according to respiratory system mechanics and patient effort to maintain the target pressure. As the lungs fill, flow decelerates until a flow-cycling mechanism terminates the breath. In these respects, this breath type is similar to the pressure support breath. Unlike pressure support, however, the clinician also must set a minimum tidal volume, flow, and backup rate with the DCWB breath. These backup settings take over control of the breath should the pressure-targeted flow drop below the minimum required to deliver the set tidal volume in the allotted inspiratory time. The breath thus begins like pressure support and can either flow cycle like pressure support (if the volume meets or exceeds the set minimum) or volume cycle like a flow-targeted breath (if necessary to deliver the set volume).[12–14,16]

The reasoning behind DCWB breaths is that the high initial flow provides better gas mixing and also reduces flow dyssynchrony during assisted breaths, whereas the volume guarantee ensures a constant tidal volume (V_T).[10,17–21] DCWB breaths thus can be considered to be "more comfortable" flow-targeted, volume-cycled breaths. Alternatively, they could be considered pressure support with a V_T "safety net."[16]

DCWB breath algorithms exist on several ventilators, but their clinical role remains unclear because the few studies looking at this strategy have generally focused only on device performance.[16,22] Indeed, DCWB mode use is driven primarily by a clinician's belief in the underlying concept. In recent years, DCWB modes have gradually disappeared and have been replaced with the simpler to use DCBB approach described below.

Dual Control Breath to Breath

DCBB techniques use standard pressure-targeted breaths (either pressure support or PACV), but the ventilator has the ability to adjust the pressure target according to a clinician-set V_T and the delivered V_T of previous breaths.[13,14,23–26] When DCBB breaths are exclusively supplied with time cycling, the mode is commonly referred to as pressure-regulated volume control, although there are a number of proprietary names (e.g., Dräger's Autoflow, Covidien's VC+, Hamilton's Adaptive Pressure Ventilation). When DCBB breaths are supplied exclusively with flow cycling, the mode is commonly referred to as volume support. Some ventilators will switch between these two breath types depending on the number of patient efforts (e.g., Maquet's Automode). With all of these modes, instead of setting a target pressure, the clinician selects a V_T. The ventilator then delivers one or more "test breaths" with a small amount of inspiratory pressure. The V_T exiting the ventilator is measured, and total respiratory system compliance is calculated. Thereafter, each subsequent breath uses the previous calculation of system compliance to manipulate the ensuing pressure target to achieve the desired V_T (Fig. 15-1). The maximum pressure change from breath to breath on most systems generally is limited to a few centimeters of water (<3 cm H_2O) to prevent large swings in pressure and volume. The volume signal used for DCBB feedback control is not exhaled V_T but V_T exiting the ventilator. This prevents a runaway effect, which could occur if a leak in the circuit prevented accurate measurement of exhaled V_T.

In volume support, the flow-cycling criterion is either manufacturer-specific (e.g., 25% to 35% of peak flow) or, on many newer machines, clinician-adjustable. A secondary cycling mechanism may be present on some devices if inspiratory time exceeds a certain fraction (e.g., 80%) of a set total cycle time. Also, as with other pressure-targeted

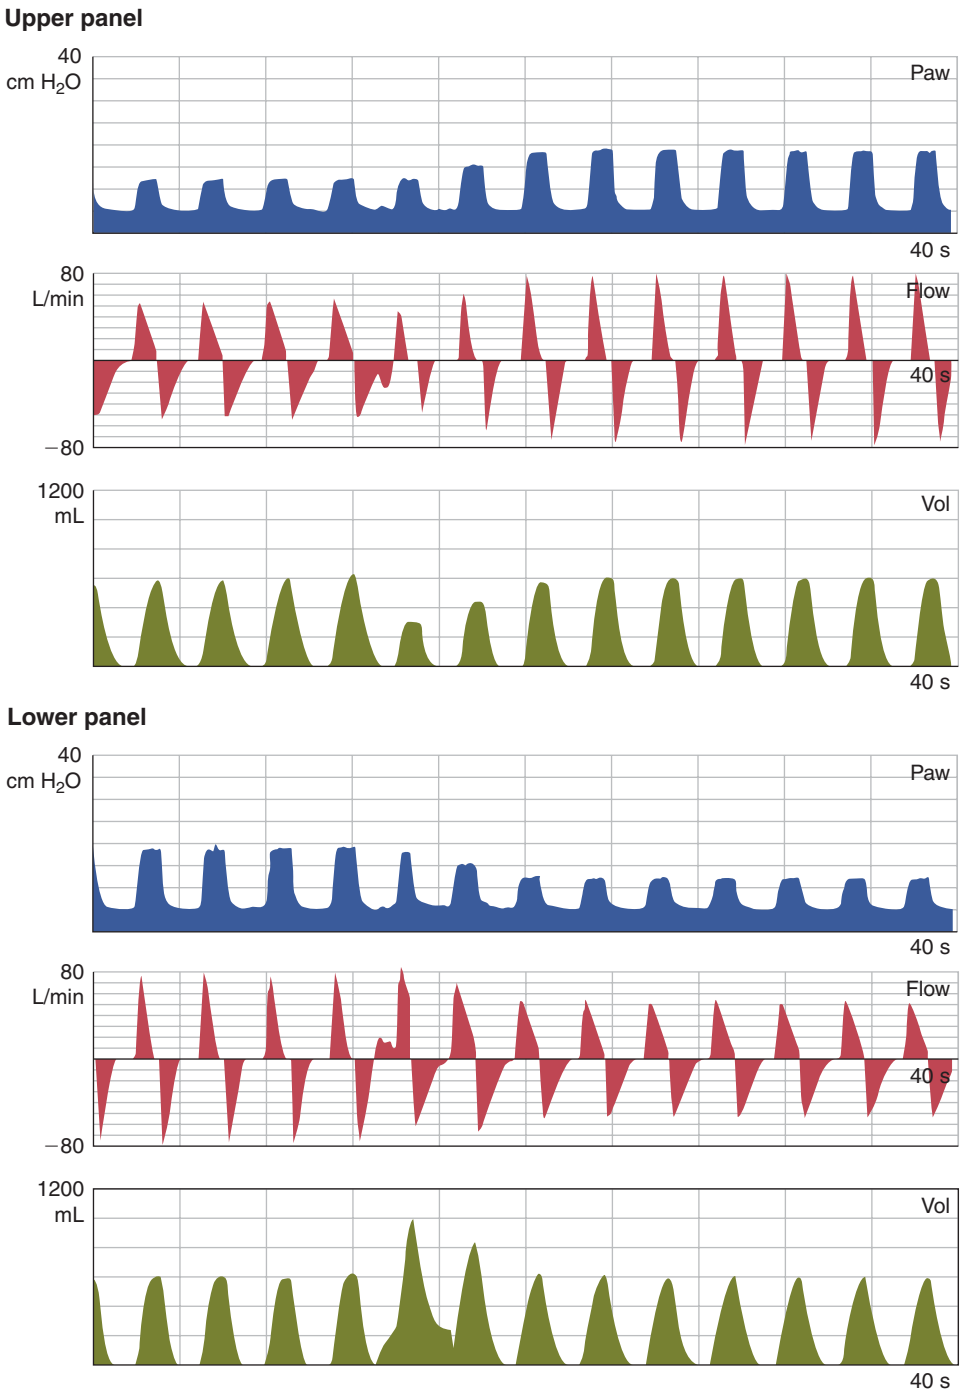

FIGURE 15-1 Behavior of DCBB breaths in a lung model simulation of changing lung compliance. In both the *top* and *bottom panels*, pressure (*Paw*), flow, and volume (*Vol*) are plotted over time. The target tidal volume in both panels is 600 mL. In the *top panel*, lung compliance decreases after the fourth breath. Initially, there is a drop in tidal volume, but then the DCBB algorithm gradually increases the target inspiratory pressure to restore the volume. In the *bottom panel*, lung compliance increases after the fourth breath. Initially, there is an increase in tidal volume, but then the DCBB algorithm gradually reduces the inspiratory pressure target to restore the volume. breaths, a rate-of-rise adjustment usually is available on DCBB breaths. When time-cycled DCBB breaths are interspersed with either spontaneous unsupported or pressure-supported breaths, or when flow-cycled DCBB breaths are interspersed with conventional PACV breaths, algorithms similar to SIMV or mandatory minute volume are often used to determine which breath type will be delivered.[27]

Both animal and human studies show that DCBB breaths function as designed using both flow-cycled and time-cycled approaches.[23–29] These studies emphasize that the DCBB

breath is similar to other pressure-targeted breaths with enhanced gas mixing and better patient–ventilator flow synchrony as compared with flow-targeted, volume-cycled breaths. They also confirm that DCBB breaths do provide a volume guarantee without untoward side effects. Not surprisingly, several of these studies showed lower peak pressures with DCBB breaths than with volume assist-control breaths.[23,24] This, however, is a finding consistent with the decelerating flow patterns of all pressure-targeted breaths (e.g., pressure support and PACV).

The role of DCBB modes in providing "lung-protective strategies" for patients with acute lung injury is unclear. Lung-protective strategies are based on data from numerous animal studies and clinical trials that low tidal volumes and low end-inspiratory lung-stretching pressures reduce ventilator-induced lung injury.[30] Setting a low tidal volume (e.g., 6 mL/kg ideal body weight) directly with flow-targeted volume-cycled breaths is the most reliable way to assure that a desired low tidal volume is delivered. Some researchers argue, however, that the set flow breath during low tidal ventilation may be particularly uncomfortable and that the variable flow feature of pressure-targeted breaths may synchronize better with patient efforts under these circumstances.[31,32] Assuring a guaranteed tidal volume with a pressure-targeted DCBB breath would seem an attractive way to combine these features. Kallet et al addressed this issue. Although they found that DCBB breaths did provide a more reliable small tidal volume ventilatory pattern than pure pressure assist control, in a minority of patients up to 14% of tidal volumes were above the desired target value.[33,34] Whether this variability is an acceptable trade-off for improved comfort during lung-protective ventilation needs further study.

DCBB breaths have also been evaluated during the ventilator-withdrawal process. Several evidence-based consensus groups have found that routine use of daily spontaneous breathing trials is critical in assessing ventilator discontinuation potential.[35] Less clear, however, is the role of gradually reducing ventilator support ("weaning"), either before or between spontaneous breathing trials. If weaning is desired, however, the DCBB modes have some conceptual appeal. Theoretically, the DCBB breath could be used to automatically reduce applied inspiratory pressure as the patient's ability to breathe improved. Conversely, inspiratory pressure would increase if patient effort diminished or respiratory system mechanics worsened. Flow-cycled DCBB breaths, either alone or in combination with time-cycled DCBB breaths or various SIMV and/or pressure-support modes, have been used in several weaning studies. In general, they have performed as well as (or sometimes better than) stand-alone SIMV or pressure-support protocols, especially in the rapidly recovering (e.g., postoperative) patient.[29,36–39] A common finding in these weaning studies is that the DCBB breath modes required fewer ventilator manipulations. One must be cautious, however, in interpreting these weaning studies. A number of clinical trials show that the SIMV or SIMV + pressure-support control strategies delay weaning inappropriately as compared with spontaneous breathing trials or stand-alone pressure-support strategies.[40,41] A more appropriate evaluation of DCBB breath-weaning strategies would be a comparison with spontaneous breathing trials delivered according to a protocol.[35,42,43]

Unfortunately, the simplicity of the DCBB modes for weaning may produce problems.[44] For instance, if the clinician-set volume is excessive for patient demand, a recovering patient may not attempt to take over the work of breathing for that volume and thus support reduction and weaning may not progress. In addition, if the pressure level increases in an attempt to maintain an inappropriately high set tidal volume in the patient with airflow obstruction, intrinsic PEEP may result. On the other hand, a patient may receive inadequate support if the clinician-set tidal volume is inadequate for patient demand. Under these conditions, a patient will perform excessive work to maintain a patient-desired tidal volume while the inspiratory pressure is being reduced because volume exceeds the clinician setting. Clinicians need to be aware of the behavior of DCBB breaths under a variety of circumstances to properly use this mode.

Tidal Volume Feedback Modes that Enhance the Dual Control Breath-to-Breath Principle

Airway occlusion pressure ($P_{0.1}$),[45] oxygen saturation (SpO_2),[37–39] and end-tidal CO_2 concentrations[46,47] have been incorporated into DCBB mode-control algorithms to adjust either the target V_T or the breath-delivery pattern. The one system that is commercially available uses end-tidal CO_2 and respiratory rate along with the tidal volume to adjust the applied inspiratory pressure.[47] Known by the proprietary trade name *SmartCare* (Dräger), the computerized feedback system attempts to find an inspiratory pressure support that maintains the respiratory rate and tidal volume in a clinician-set "comfort zone." The end-tidal CO_2 serves as a backup signal to assure adequate ventilation. The system is designed to wean the inspiratory pressure to as low a level as possible within these boundaries and then alert the clinician to perform a spontaneous breathing trial when this pressure reaches 9 cm H_2O.

A number of small observational trials have been done showing that the system did, indeed, keep patients in the clinician-selected "comfort zone" for 95% of the time.[46,47] In a larger randomized clinical trial, this approach appeared to remove ventilator support quicker than "physician-controlled" weaning.[48] Unfortunately, this control group did not have a protocolized spontaneous breathing trial approach, and thus may have had support removal delayed. Indeed, a subsequent trial noted that in the presence of an active protocol for discontinuing mechanical ventilation, automated withdrawal offered no advantage.[49] Even if it is not superior, however, an automated system that is "just as good" as clinicians could have applications in settings with rapidly recovering patients or low availability of clinicians to make frequent assessments.

FEEDBACK CONTROL OF VENTILATOR BREATH DELIVERY BASED ON RESPIRATORY SYSTEM MECHANICS

A novel approach to automated feedback control of ventilator support combines the DCBB principle with an integrated V_T, frequency and inspiratory-to-expiratory (I:E) ratio algorithm based on respiratory system mechanics. Known as *adaptive lung ventilation* or *adaptive-support ventilation* (ASV, Hamilton Medical),[50–55] the breath-control algorithm attempts to partition the frequency, tidal volume, and I:E ratio so as to minimize ventilator–patient inspiratory work and intrinsic PEEP. ASV does this by calculating respiratory system mechanics using several "test breaths." It then uses a "minimal work" calculation to set the frequency–tidal volume pattern that minimizes the combined resistance and compliance components of work. The clinician must input the patient's predicted body weight and the percent of desired minute ventilation. The predicted body weight frames the tidal volume range, avoiding volutrauma and hypoventilation. The predicted needed minute volume is 0.1 L/kg/min. As an example, a 70-kg patient set at 100% would receive a 7 L minute volume. If the percent minute volume was set to 125%, in the presence of increased physiologic dead space the minute ventilation would be 8.75 L. The ASV algorithm then uses a measurement of the expiratory time constants (RCe = resistance × compliance) to ensure an inspiratory time of at least one RCe and an expiratory time of at least three RCes. The actual formula is:

$$f = \frac{\sqrt{1 \quad 2aRC(\dot{V}_A/V_D) - 1}}{aRC} \qquad (1)$$

where *RC* is the respiratory time constant (the product of resistance *R* and compliance *C*), $\dot{V}_A$ and V_D are alveolar ventilation and dead space ventilation, respectively, and *a* is a constant that depends on the flow waveform.

Boundary rules exist to prevent excessive (runaway) settings (Table 15-1). Clinicians must set the desired minute ventilation and the proportion of that minute ventilation that the machine is to supply. Ideal body weight also can be used to calculate the desired minute ventilation based on metabolic demands and predicted dead space. Clinicians also must set the PEEP and FI_{O_2}.

ASV as a pure control mode has been evaluated in a number of ways. Initial lung-model testing[56] demonstrated that the ASV algorithm responded properly to abrupt changes in lung mechanics. Several early clinical studies have compared initial ASV settings with traditional clinician-selected settings and have found that ASV tends to select a lower tidal volume and faster rate (and thus lower inspiratory pressures) than do clinicians.[56–59] Two other early studies suggest that ASV also appropriately adapts to changes in patient position and the change from double- to single-lung ventilation during anesthesia.[55–61] One other study suggested that the I:E algorithm of ASV produced less air trapping in patients with chronic obstructive pulmonary disease.[62] Longer-duration clinical studies with ASV show that the algorithm provides adequate ventilator support in anesthetized patients,[56,59] as well as in patients with respiratory failure.[63]

More recent evaluations of ASV, however, have focused on its ability to provide appropriate lung-protective small tidal volumes. Indeed, when respiratory system compliance is poor, the ASV algorithm supplies a protective low tidal volume ventilator pattern similar to that recommended by the ARDS Network.[54] Problems arise, however, when respiratory system compliance is less deranged (e.g., patients with milder forms of acute lung injury). Under these conditions, the ASV algorithm tends to deliver tidal volumes often in excess of 10 mL/kg ideal body weight.[45,64] The clinical significance of this is unknown but the potential harm from this should be considered by clinicians wishing to use this mode.

ASV also might be considered an automatic weaning mode because the algorithm responds with lower pressures and fewer mandatory breaths as patient effort increases. When spontaneous efforts occur with ASV, the algorithm continues to try to conform to the minimal work tidal volume considerations above and in that sense resembles the feedback features of volume support noted above.[65] The ASV feedback control, however, is more complex than volume support in that the predicted body weight input as well

TABLE 15-1: BOUNDARY CONDITIONS FOR ADAPTIVE LUNG OR SUPPORT VENTILATION

Parameter	Minimum	Maximum
Inspiratory pressure (cm H_2O)	5 above baseline airway pressure (PEEP/CPAP)	10 below P_{max} alarm setting
Tidal volume (mL)	4.4 · IBW	15.4 · IBW or $\dot{V}_E$/5, whichever is lower (may be limited by P_{max} alarm)
Target respiratory rate (bpm)	5 bpm	22 bpm · % min vol/100 (if IBW > 15 kg) 45 bpm · % min vol/100 (if IBW < 15 kg)
Mandatory breath rate (bpm)	5 bpm	60 bpm
Inspiratory time (s)	0.5 s or 1 · RCe, whichever is longer	2 s
Expiratory time (s)	2 · RCe (possibly 3 · RCe)	12 s
I:E ratio range	1:4	1:1

% min vol, clinician-set proportion of predicted minute volume needed by the patient that will be supplied by the ventilator (the percent minute volume is based on predicted body weight, e.g., for an 80-kg patient, 100% of minute volume is a minute ventilation of 8 L/min); *bpm*, allowable breaths/min; *CPAP*, continuous positive airway pressure; *IBW*, ideal body weight; *I:E*, inspiratory-to-expiratory-time ratio; *PEEP*, positive end-expiratory pressure; *Pmax*, clinician-set maximal inspiratory pressure; *RCe*, resistance × compliance; $\dot{V}_E$, exhaled minute volume.

Note: These parameters set the limits on the various parameters used during ASV.

as respiratory system resistance, and compliance (and the resulting time constant) modulate the tidal volume target. A number of studies have evaluated ASV in patients being weaned from mechanical ventilation.[50,63,66–70] In general, these studies show that ASV safely provides adequate ventilator support and has similar (or faster) weaning times as compared with various SIMV and SIMV + pressure support protocols.[66,70] These studies also generally show fewer ventilator manipulations with ASV. As noted earlier for other DCBB approaches, a more appropriate evaluation of ASV weaning strategies would be a comparison with use of spontaneous breathing trials delivered by protocol,[35,42,43] not with SIMV or SIMV + pressure support.

Larger trials in patients with different forms of lung injury clearly are needed to establish the appropriateness of the ASV algorithms in various disease states and the effects of ASV on outcome.

AUTOMATIC ADJUSTMENTS IN PRESSURE AND FLOW BASED ON ARTIFICIAL AIRWAY GEOMETRY

The endotracheal tube (ETT) imposes a significant inspiratory resistance on a spontaneously breathing patient.[71,72] This imposed load can have an impact on flow synchrony during interactive assisted or supported breaths, and can make it difficult to assess potential for ventilator withdrawal during periods of unassisted or unsupported breathing (Fig. 15-2, *left panel*).

Low-level (e.g., 5 to 8 cm H_2O) pressure support has been proposed as a way of eliminating the ETT resistive load.[73–75] Unfortunately, the pressure-support algorithm supplies a constant inspiratory pressure, which, because of the high fixed resistance of the ETT, tends to undercompensate the load at the beginning of the breath (see Fig. 15-2, *middle panel*). Patient muscle unloading thus is uneven and may be suboptimal.

One way to address this is to use a pressure sensor at the distal end of the ETT to target the pressure support applied pressure. This approach would provide a more even pressure application to the contracting inspiratory muscles. Unfortunately, this approach is unreliable because intra-air-way sensors are subject to errors from positioning and mucus occlusion. An alternative is to have the ventilator calculate the ETT resistance properties and use those calculations to manipulate applied pressure in such a way as to compensate for the ETT effects (see Fig. 15-2, *right panel*).[76,77] To accomplish this, the clinician must input the tube geometry (length and diameter) and the percentage of compensation desired (10% to 100%). The ventilator then uses these data to calculate ETT resistance and incorporates this with measurements of instantaneous flow to apply pressure proportional to resistance throughout the total respiratory cycle.

The ETT compensation concept was first introduced in 1993 by Guttmann et al[76] and was applied during both inspiration and expiration. It was believed that the expiratory

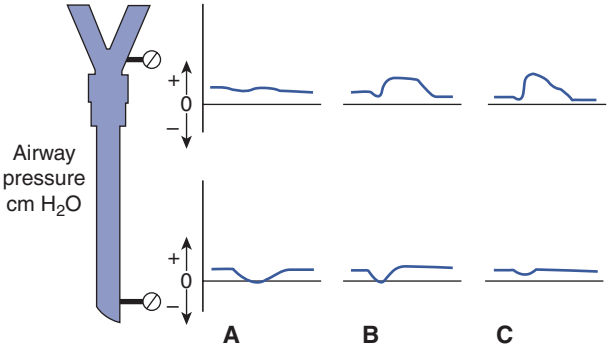

FIGURE 15-2 Effects of the endotracheal tube (ETT) resistance on the application of continuous positive airway pressure (CPAP), pressure support, and CPAP with ETT automatic tube compensation (CPAP-ATC) in a spontaneously breathing patient. Depicted are airway pressure profiles over time in the ventilator circuit (*upper panels*) and the distal trachea (*lower panels*). In the left breath, the CPAP tracing in the ventilator circuit is appropriately constant, whereas the tracheal pressure downswing reflects the patient work required to effect flow through the ETT. In the middle breath, pressure support is applied in the ventilator circuit. This reduces some of the patient work, but because the "square wave" pressure-support breath does not adequately pressurize the trachea rapidly enough, there still can be significant work required by the patient early in the breath. In the right breath, a similar pressure-support breath is applied, but the pressure profile is altered to provide a higher pressure early and the target pressure later (CPAP-ATC). This profile is machine determined, and knowledge of ETT geometry accounts more appropriately for the effects of ETT resistance. It thus creates a truer CPAP pattern in the trachea. Note that this ETT compensation feature also can be combined with pressure support on some ventilators. (Reproduced, with permission, from MacIntyre. *Respir Care.* 2005;50:275–286.)

effect (i.e., circuit pressure actually going below set baseline pressure or "subatmospheric" to "assist" expiratory flow) might further improve patient–ventilator interactions by reducing expiratory work and hyperinflation. In a series of ventilated patients, this approach was shown to improve subjective patient comfort substantially.[78]

Variations on this computational approach to manipulating applied pressure are now available as automatic tube compensation (Dräger, Covidien, and Maquet) and automatic airway compensation (CareFusion). Bench and clinical studies verify that the ETT compensation algorithms on these commercial systems generally perform as designed during both continuous positive airway pressure and pressure support.[79–81] Not all systems, however, have the expiratory feature, and the response characteristics of commercial systems may not be as robust as the Guttman design.[76]

It also must be recognized that the ETT compensation strategy is based on the input geometry of the artificial airway and cannot account for changes in tube characteristics induced by kinks or partial occlusions or the relationship of the tube opening against the tracheal wall. Thus, this strategy should not be considered a perfect surrogate for a tracheal pressure sensor, especially as the duration of intubation increases. Nevertheless, despite these limitations, and despite

the fact that ETT compensation has not been subjected to outcome studies, the simplicity of the concept and safety of the design would seem to warrant its application during pressure support and continuous positive airway pressure under most circumstances.

An interesting extension of the ETT compensation concept is to use a pleural pressure to target the positive-pressure breath.[82] This approach requires an esophageal balloon to measure esophageal pressure, a surrogate for pleural pressure. Conceptually, a pleural pressure target could be used to control the breath directly in such a way as to account for all the components of patient work, not just that caused by the ETT. At the present time, this approach has been explored only with prototype systems in experimental animals.

FEEDBACK SYSTEMS CONTROLLING POSITIVE END-EXPIRATORY PRESSURE AND CONCENTRATION OF FRACTIONAL INSPIRED OXYGEN

Maintenance of normal arterial oxygen saturation (SaO_2) is a key goal of mechanical ventilation. Hypoxemia has well-known consequences, including tissue injury, and if left uncorrected, can result in death. In modern intensive care units, hypoxemia is prevented through a variety of mechanisms including appropriate ventilator settings, sedation, analgesia, and maintenance of homeostasis. The current standard of care for detecting and ameliorating hypoxemia, however, has remained unchanged over the last 30 years. The clinician sets the low arterial oxyhemoglobin saturation (SpO_2) alarm setting and if the SpO_2 falls below this value (commonly 88%), an audible and visual alarm sounds. The alarm must be recognized by the clinician who must enter the room, elucidate the cause (e.g. ventilator disconnect, agitation, worsening pulmonary status), remedy the problem, and possibly increase the FI_{O_2}. This is an antiquated method that is analogous to trying to maintain the heat in your home by turning the furnace on or off based on falling below the "too cold" threshold.

Concentration of Fractional Inspired Oxygen Feedback Systems

The incidence of hypoxemia in ventilated adult intensive care unit patients is unknown. In neonatal intensive care units, hypoxemic events are frequent and life-threatening. Hyperoxemia also carries significant risk in this population. Recent data demonstrate that abdominal muscle contraction during crying and agitation is the most common cause of neonatal hypoxemia. The use of pressure-limited ventilation and uncuffed endotracheal tubes in infants, coupled with diaphragmatic contraction, profoundly limit oxygen delivery. [83] Both lung injury from oxygen toxicity and the retinopathy of prematurity are known complications of excessive oxygen exposure.

Closed-loop control of FI_{O_2} using either indwelling partial pressure of arterial oxygen (Pa_{O_2}) sensors, transcutaneous oxygen monitoring, and pulse oximetry has been attempted numerous times in the last 35 years.[84–91] Most of these investigations met with limited success owing to the sensor response and time required to alter delivered FI_{O_2}. Several of these studies used simple oxygen delivery to a head hood where both increases and decreases in FI_{O_2} occur slowly.
